Treatment of Morphea-Type Basal Cell Carcinomas With Radiation Therapy

Robert S. Bart, MD; Alfred W. Kopf, MD; Arthur H. Gladstein, MD

• Eight patients received superficial x-ray therapy for morphea-type basal cell carcinomas. Seven lesions did not recur. One recurrence adjacent to an irradiated field was observed; it was considered to be a geographic miss and has led us to include a wider field (10 mm) of normal-appearing skin beyond the clinical perimeter of the tumor when the lesion is ill-defined. The cosmetic results after treatment were poorer than anticipated for this schedule of radiation therapy, based on our extensive experience with other types of basal cell carcinomas.

To obtain the best long-term results we believe that, where technically feasible, Mohs surgery and conventional surgical excision with histologic verification of free margins are the treatments of choice for morphea-type basal cell carcinomas. However, our experience indicates that morphea-type basal-cell carcinomas can be cured with radiation therapy; therefore, x-rays have a place in the armamentarium of therapeutic modalities for this tumor if surgery is not feasible or if it is refused by the patient.

(*Arch Dermatol* 113:783-786, 1977)

Some textbooks[1,2] and articles[3,4] state that x-ray therapy is ineffective in achieving an adequate cure rate for morphea-type basal cell carcinoma. Furthermore, we have been unable to find a reference to the usefulness of x-radiation in treating a series of morphea-type basal cell carcinomas, although x-ray therapy has been reported as curative[5] and implantation of low-intensity radium needles advocated.[3] It is generally accepted by dermatologists that x-ray therapy is not useful for these tumors, and this very likely accounts for the fact that this treatment was rarely used at the Skin and Cancer Unit, New York University Medical Center. It could be postulated that x-ray therapy might be less effective because the dense stroma, which is characteristic of these lesions, renders the epithelial strands relatively anoxic and thus relatively radioresistant. Because of the fibrotic nature of their stroma (Fig 1), curettage-electrodesiccation is usually considered poor treatment for these lesions. Excisional and Mohs surgery are the modalities generally preferred at the Skin and Cancer Unit.

This report summarizes our experience with x-radiation of morphea-type basal cell carcinoma.

CLINICAL MATERIAL

Of the more than 4,000 histologically verified basal cell carcinomas coded in the Oncology Section of the Skin and Cancer Unit, only eight lesions with typical clinical and histologic features of the morphea type were treated with x-radiation. Sclerosing "field-fire" basal cell carcinomas are excluded from this report. The morphea-type lesions were treated by the "standardized" method of x-ray therapy described in detail elsewhere.[6] In brief, therapy consisted of five doses of 680R delivered during a period of 9 to 14 days for a total air dose of 3,400R. The half-dose depth (ie, the depth of tissue that reduces the dose by 50%) was 12 mm and the half-value layer of the beam was 0.9 mm of aluminum. A port cut in the 0.3- to 0.5-mm thick lead shielding included a 5 mm or greater border of normal-appearing skin.

Two tumors were in men, six were in women. Follow-up ranged from 1 year and 6 months to 13 years and 11 months, with an average of 9 years. Judgments concerning the cosmetic results were made according to the criteria previously published.[6] The Table summarizes the data concerning these eight patients.

REPORT OF CASES

CASE 1.—A 65-year-old white man was seen in 1957 for a lesion that had been present for ten years. It was a 15-mm, hard, smooth, telangiectatic whitish plaque located on his right cheek that was skin-colored with some mottled pigmentation. Histopathologic study showed a morphea-type basal cell carcinoma with fine epitheliomatous strands embedded in a sclerotic stroma. In October 1957 the lesion was treated in a ten-day period with 3,400R of superficial x-radiation, according to the standardized schedule as previously outlined. A brisk radioreaction ensued. Biopsy in December 1958 revealed no basal cell carcinoma. Three years after the x-ray therapy, the cosmetic result was considered only fair because of radiodermatitis. Another biopsy specimen taken 5½ years after the x-ray therapy was again negative for tumor. The patient's last visit was in December 1969. There had been no recurrence of the carcinoma, but the cosmetic result was poor, with atrophy and telangiectasia.

CASE 2.—A 49-year-old white woman was first seen in the Oncology Section in November 1961 for a 21 × 33-mm sclerotic, oval lesion on her left mandibular area (Fig 2). The lesion had a slightly depressed

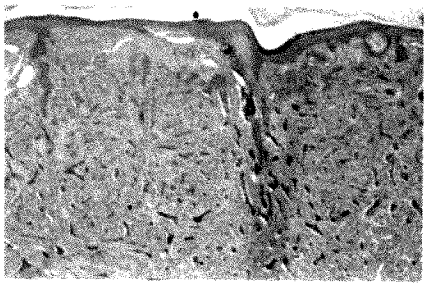

Fig 1.—Morphea-type basal cell carcinoma. Small islands and strands of basaloid carcinomatous cells are in dense, fibrotic stroma (hematoxylin-eosin, ×16).

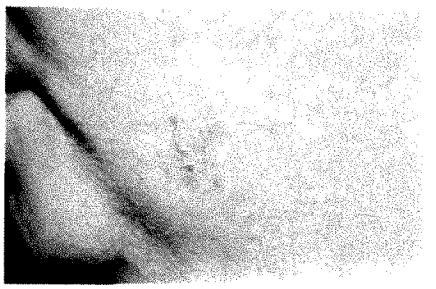

Fig 2.—Morphea-type basal-cell carcinoma (case 2). Note ill-defined sclerotic plaque overlaid with telangiectatic vessels.

Fig 3.—Brisk radioreaction following 3,400R x-radiation (case 2).

Fig 4.—Nine months following completion of radiation therapy (case 2). Good cosmetic result achieved but irregularly marginated, fibrotic area within irradiated field present.

Fig 5.—Fair cosmetic result after three years (case 2) because of hypopigmentation. Suture line is from biopsy.

Fig 6.—Morphea-type basal cell carcinoma (case 4). Scar-like lesion is eroded and crusted.

Fig 7.—Basal cell carcinoma 11 months later (case 4). Cosmetic result is fair, with depigmentation and telangiectasia.

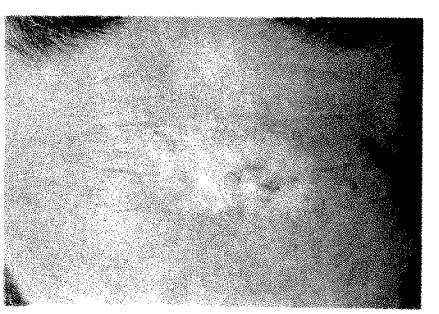

Fig 8.—Cosmetic result is fair to poor after treatment (case 4).

Fig 9.—Morphea-type basal-cell carcinoma (case 5). Tumor was irregularly shaped, hard, and telangiectatic.

Fig 10.—Basal cell carcinoma one month after radiation therapy with 3,400R (case 5). Within radiodermatitis, whitish, sclerotic areas were visible.

Fig 11.—Four months after completion of radiation therapy (case 5), radiodermatitis had subsided, but whitish fibrotic areas remained within treated site.

Fig 12.—Two years after completion of therapy (case 5), cosmetic result was considered poor. White sclerotic plaque remained.

Summary of Morphea-Type Basal Cell Carcinomas Treated With X-rays

Case No.	Sex	Age, yr	Duration	Location	Largest Diameter, mm	Recurrence	Cosmetic Results at Three Years	Follow-up	Cosmetic Results at Last Follow-up
1	M	65	10 yr	Cheek	15	None	Fair	12 yr, 2 mo	Poor
2	F	49	12 mo	Mandibular area	33	None	Fair	13 yr, 8 mo	Fair
3	F	48	14-18 mo	Upper lip	16	At 3 yr	Fair	5 y 9 mo	Fair
4	M	57	3 yr	Forehead	35	None	Fair to poor	13 yr 11 mo	Poor
5	F	74	47 yr	Forehead	35	None	Poor	9 yr	Poor
6	F	69	Unknown	Chin	25	None	Good	11 yr, 6 mo	Good
7	F	72	14-18 mo	Cheek	20	None	Fair	5 yr, 9 mo	Fair
8	F	63	2-4 mo	Forehead	16	None	...	1 yr, 6 mo	Good

center and barely raised borders overlaid by fine telangiectatic vessels. The patient stated the lesion had been present for one year. Results of an incisional biopsy verified the clinical impression of morphea-type basal cell carcinoma. The standardized x-ray treatment was given in a 13-day period between Dec 27, 1961 and Jan 8, 1962. A brisk radioresponse occurred (Fig 3). In September 1962 there was a good cosmetic result with only mild atrophy and no telangiectasia (Fig 4). However, in the center of the irradiated field was a macular, irregularly marginated, fibrotic whitish area that appeared to be scar tissue; this persisted until April 1963 at which time a biopsy was performed. The biopsy specimen did not contain neoplastic cells. There was no recurrence subsequently. The cosmetic result after three years (Fig 5) and again at the time of her last visit (August 1975) was considered fair.

CASE 3.—In 1961 a 48-year-old white woman was seen for a 16-mm, hard, skin-colored, eroded plaque on the left side of her upper lip. This had been present for many months and was adjacent to a site that had been treated elsewhere by curettage and electrodesiccation for a "skin cancer" approximately one year before. The histologic picture of the biopsy specimen was that of morphea-type basal cell carcinoma. In December 1961 the lesion was treated with 3,400R of x-radiation in a 14-day period, using the standardized schedule. A 5-mm margin of normal-appearing skin was included in the irradiated field. In September 1965 a histologically proved basal cell carcinoma was found adjacent to the irradiated field and excised. This was considered to be a peripheral recurrence. The patient remained free of recurrence and was last seen in the Skin and Cancer Unit in September 1967, at which time the cosmetic result was considered fair. She was last seen by her family physician in July 1972, at which time there was no clinical evidence of recurrence.

Comment.—Since the recurrence in this case was thought to be a geographic miss because of the ill-defined nature of the tumor, it was decided thereafter to include in the radiation port a 10-mm margin of normal-appearing skin around morphea-type basal cell carcinomas with ill-defined borders.

CASE 4.—A 57-year-old white man was first seen in the Oncology Section in January 1962 for a lesion of three years' duration on the center of his forehead. It measured 35 mm in its longest diameter and was oval, slightly depressed, skin-colored, telangiectatic, and "scar-like" (Fig 6). There was a 5-mm area of erosion and crusting. Results of a 3-mm punch biopsy confirmed the diagnosis of morphea basal cell carcinoma. From the 12th to the 22nd of January 1962 the patient was treated with 3,400R of x-radiation, employing the standard treatment schedule. Following this the patient developed a brisk erythematous response. In March of 1962 the patient had a sclerotic plaque surrounded by a zone of erythema. In December of 1962 the cosmetic result was considered fair with substantial depigmentation and some telangiectasis (Fig 7). By July 1963 the cosmetic result was considered poor because there was a circular depigmented, atrophic, telangiectatic area. The cosmetic result after three years was considered fair to poor (Fig 8). When the patient was last seen in December of 1975 the cosmetic result was considered poor. There had been no recurrence after 13 years and 11 months of follow-up.

CASE 5.—A 74-year-old white woman was first seen in the Skin and Cancer Unit in 1963 for a lesion on her forehead. She claimed the tumor had been present for 47 years. It measured 35 mm in its greatest diameter and was a hard, telangiectatic, irregularly shaped plaque (Fig 9). Histologic examination substantiated the diagnosis of morphea-type basal cell carcinoma. In March 1963 the lesion was treated with 3,400R in a period of 11 days. Subsequently, there was a severe radioreaction, which was still active one month later (Fig 10). By July 1963 the radiodermatitis had subsided and the cosmetic result was considered good, although a white fibrotic area remained in the center of the treated site (Fig 11). Two years after treatment the cosmetic result was considered poor and the white morpheaform plaque remained (Fig 12). This raised the question of whether the tumor was radioresistant or whether the epithelial component may have been destroyed, leaving behind its dense stroma. A biopsy was done and histologic examination of the specimen showed only dense fibrous tissue. The patient was followed up for nine years and no recurrence was seen.

CASE 6.—A 69-year-old white woman was seen in the Skin and Cancer Unit in September 1963 in follow-up for a basal cell carcinoma of the nose, which had been treated in 1957. A telangiectatic plaque, 25 mm in diameter, was found on the chin. Its duration was unknown. The histopathology of the biopsy showed morphea-type basal cell carcinoma. In November of 1963 the lesion was treated during a nine-day period with 3,400R of superficial x-radiation, using the standardized schedule. The expected acute radioreaction ensued. Some erythema and the sclerotic plaque per-

sisted for several months. In March 1965 a biopsy of the treated area was performed and showed fibrosis but no residual carcinoma. There was no recurrence during the 11½ years of follow-up. The cosmetic result after three years and at last follow-up at 11½ years was considered good.

CASE 7.—A 72-year-old white woman was first seen in the Skin and Cancer Unit in November 1963 concerning a lesion of about 18 months' duration on her left cheek. The tumor was a hard, telangiectatic plaque that measured 20 mm in its largest diameter. Study of a biopsy specimen confirmed the clinical diagnosis of morphea-type basal cell carcinoma. In December 1963, during an 11-day period, it was irradiated with 3,400R, using the standardized schedule. After 2½ years there was no evidence of recurrence and the cosmetic result was described as fair. The patient was followed up for five years and nine months after treatment; no evidence of recurrence of the lesion was noted. In 1969, when last seen, the cosmetic result was described as fair. Shortly after resolution of the radiodermatitis, and again two years later, biopsies of the treated area were performed and no tumor was found histologically.

CASE 8.—A 63-year-old white woman was seen in the Skin and Cancer Unit in April of 1974 because of a 16-mm, smooth, hard, skin-colored, telangiectatic plaque on the left side of her forehead. The tumor was said to have been of three months' duration. The histology was that of morphea-type basal cell carcinoma. It was irradiated with six doses of 680R each for a total dose of 4,080R in a 15-day period. The reason for the six treatments instead of the usual five was that after the initial treatment it was decided to enlarge the part to include an area not exposed in the first treatment. The factors used to treat this lesion were half-value layer of 0.85 mm of aluminum and a 10-mm tissue half-dose depth. When the patient was last seen in September of 1975, there was a good cosmetic result; however, there was alopecia on part of the left eyebrow, which had been in the irradiated field.

COMMENT

This series of eight morphea-type basal cell carcinomas, none larger than 35 mm in greatest diameter, which were treated with x-ray therapy, demonstrates that it is possible to use this modality to treat this type of tumor and achieve cure. The dosage schedule was the one generally used at the Skin and Cancer Unit for more ordinary basal cell carcinomas. This standardized schedule has been successful in achieving a five-year cumulative cure rate of 92% in 500 consecutive histologically proved basal cell carcinomas.[6] The width of normal-appearing skin that was irradiated averaged more than the usual 5 mm because of the frequent difficulty in accurately determining the borders of morphea-type basal cell carcinomas.

No clinical or histologic recurrences within the irradiated fields were found. Follow-up biopsies of irradiated sites were negative for tumor in the five patients so studied. A peripheral recurrence was assumed in case 3. This was thought to represent a geographic miss resulting from irradiating too narrow a margin of presumed uninvolved skin.

Mainly because of atrophy and telangiectasia, the cosmetic results were generally fair three years after treatment and fair or poor at follow-up examinations 5 to 14 years after treatment.

These cosmetic results were not as good as expected on the basis of our previous study of 500 basal cell carcinomas, not specified as to type, treated with x-rays. The reason for this is unclear. It may be related to the very dense stroma that characterizes this type of lesion, the vascular supply to the areas, the locations of these particular lesions, or the fact that this small number of patients might not be representative of a larger group.

There were no other significant complications or sequelae of the treatment other than alopecia.

Several features set apart morphea-type basal cell carcinomas from the more ordinary varieties. The morphea-type tends to be visually unobtrusive, with clinically very ill-defined irregular borders; therefore, it frequently is not diagnosed until it has become large. Because of the indistinct borders, dense stroma, and infiltrating nests and strands of tumor, morphea-type basal cell carcinomas are difficult to treat. The exception is for the Mohs surgeon who can trace out the extensions with microscopically controlled tissue removal.

The role of cryosurgery with liquid nitrogen spray remains unclear. Graham[7] claims that morphea-type basal cell carcinomas respond well to this modality whereas Zacarian[8] states that "sclerosing or morphea-like" lesions do not respond well; we await reports of long-term experience with this treatment.

Although for most morphea-type basal cell carcinomas we favor excision by Mohs surgery, or, if this is not available, conventional surgical excision with histologic verification of free margins, we were pleased to substantiate that cures can also be achieved with x-ray therapy. Thus, for selected patients who refuse or who are not candidates for surgery, this modality can be used to treat such lesions. Because this is a small series and because the cosmetic results were not as good as expected, we do not recommend x-radiation using our standardized schedule as a routine therapy for treating morphea-type basal cell carcinomas. However, it should be kept in mind that we have not reviewed the cure rates and cosmetic results for a series of morphea-type basal cell carcinomas treated by excision or Mohs surgery. Perhaps other schedules employing increased protraction and fractionation of x-radiation will result in a good cure rate and better cosmetic results than we have encountered with our standardized schedule.

Cutaneous Neural Proliferation in Highly Pruritic Lesions of Chronic Prurigo

Uee Runne, Constantin E. Orfanos

• Nodular lesions of chronic prurigo correspond to highly sensitive pruritic areas of neural proliferation. This has been shown by light and electron microscopic studies in four patients. Axons and Schwann cells were participating in this process. Their ultrastructure appeared mostly normal; however, some disorganization, axonal swelling, and dystrophy were also observed. At places, newly formed nervous tissue imitated neuromas, surrounded by mononuclear cells and a peculiar cell type which we called "spider cell." The noninvolved skin near the nodules showed no alterations. Occlusion with elastic bandages for four weeks betters the clinical and histological picture. According to these findings, it seems that the neural proliferation in prurigo is a secondary phenomenon due to chronic traumatization by scratching. We also feel that the extreme pruritus in chronic lesions is related to the increased number of dermal nerves.

(*Arch Dermatol* 113:787-791, 1977)

Chronic pruritic nodular lesions are a clinical entity called prurigo nodularis described by Hyde in 1909.[1] This is a rare condition with severe pruritus and considerable discomfort for the patients. It does not respond to therapy, even to systemic corticosteroids.

The pathogenesis of prurigo nodularis and the extreme pruritus are still completely unknown. In earlier investigations, some information has been given on the morphological substrate of the lesions. By light microscopy, the nodules revealed nonspecific dermal and epidermal changes. However, some authors, particularly Pautrier (1934),[2] Perez and Maruri (1949),[3] Thies (1955),[4] Kantner et al (1963),[5] and Cowan (1964),[6] described an increase of neural tissue in the dermis. Moreover, Cowan (1964) found that numerous nerve fibers were swollen, and Kantner et al (1963) believed that some of them entered the epidermis.

The present investigation was scheduled in order to clarify the presence and the significance of neural proliferation in this highly pruritic condition. In the meantime, Feuerman and Sandbank (1975)[7] published an electron microscopic study; they also reported an increase of dermal nerves in one patient with prurigo nodularis. In this article, we present our data on four cases and will show that in chronic prurigo, a *cutaneous neural proliferation* exists, which seems to be the result of chronic irritation of the nodules.

PATIENTS AND METHODS

All investigated patients had a typical prurigo for 12 years or more. Three of the patients showed classical nodules (Fig 1, top and center), the fourth patient had

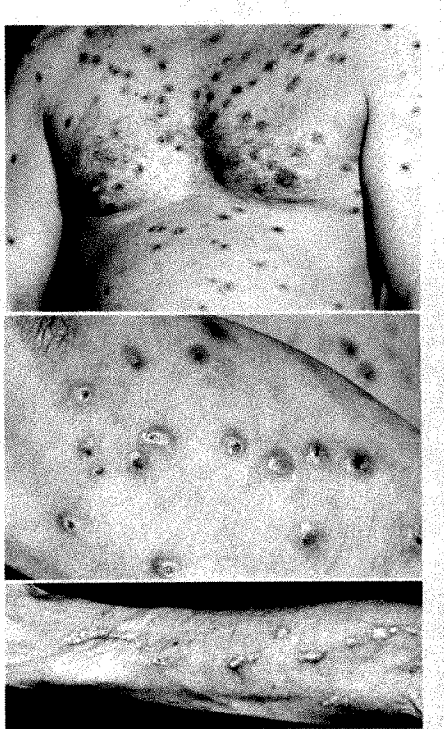

Fig 1.—Top, Multiple, widespread lesions of prurigo nodularis (48-year-old man). Center, Central part of most nodules is scratched and slightly ulcerated. Bottom, Highly pruritic linear skin lesions, persisting for more than 30 years (59-year-old woman).

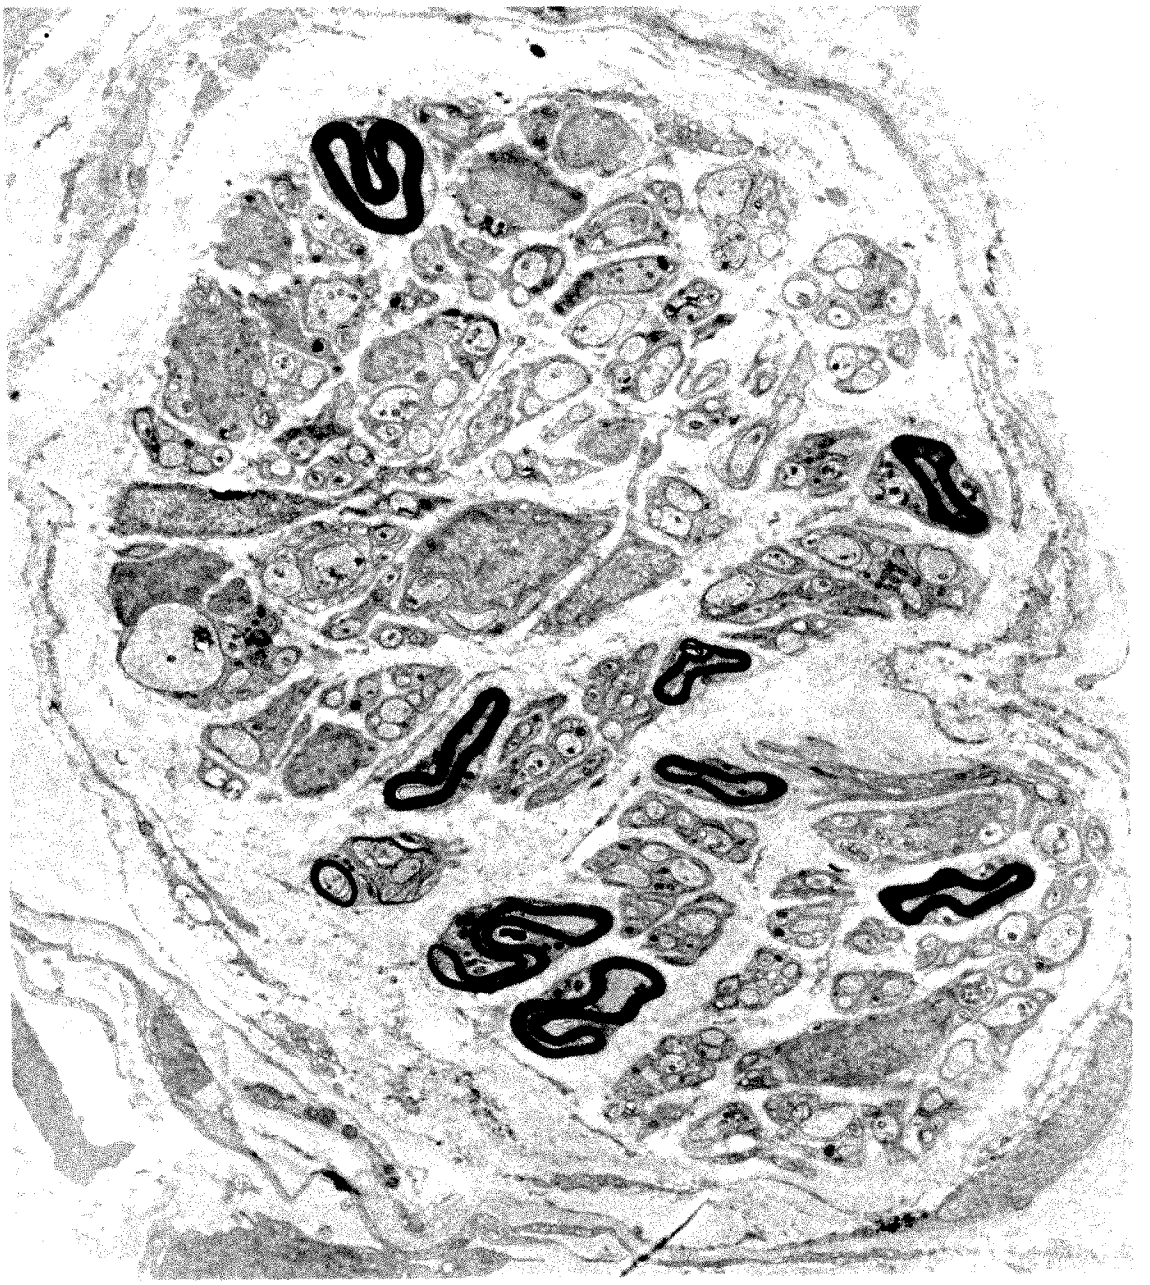

Fig 2.—Thick nerve from middle dermis (ø30 μm). Nerve is well-structured and contains normal myelinated and nonmyelinated axons (original magnification ×5,200).

Fig 3.—Inflammatory cells (IC) surround nerve but do not enter endoneural space (En). Perineural sheath (Pe) and most of axons seem intact. Asterisk indicates axonal dystrophy (original magnification ×6,500).

linear lesions all over the body (Fig 1, bottom). In previous clinical trials, no systemic or topical therapy has been proven effective in any of these patients. Antipruritic drugs, such as phenothiazines in high doses, had been given orally. Two, 4-mm punch biopsy specimens from typical prurigo lesions were taken from each patient under local anesthesia with 1% mepivacaine hydrochloride (Scandicain) (upper arm, forearm, and upper leg). All selected nodules had persisted for more than one year. Additional biopsy specimens were taken from the noninvolved skin near a typical nodule, and from a nodule on a leg that had been covered by elastic bandages for a period of four weeks to avoid scratching. After this period, the nodules in this area were still visible but they were significantly flattened, and the dermal infiltration seemed diminished. Another clinical experiment using intrafocal injections of cytarabine (cytosine arabinoside) (20 mg three times daily within four weeks) was not fully successful.

For conventional microscopic study, the skin specimens were fixed in 5% formaldehyde solution, embedded in paraffin, and stained with hematoxylin-eosin (H-E), Giemsa, PAS, and Palmgren stains. For the electron microscopic study, the specimens were fixed in ice-cold glutaraldehyde-paraformaldehyde solution (2.5:4.0%, buffered in cacodylate buffer, pH 7.2) for 18 hours and in 1% osmic acid solution for 1 hour and were embedded in an epoxy resin. Ultrathin sections were stained with uranyl acetate and lead nitrate.

RESULTS

Using a *light microscope*, we found an hyperproliferative epidermal reaction, partly with pseudocarcinomatous hyperplasia in two patients. Acanthosis, hyperkeratosis, some parakeratosis, elongation and interdigitation of the rete ridges, and some papillomatosis were present. In all dermal layers a patchy cellular infiltrate was seen, composed of lymphocytes, histiocytes, few mast cells, eosinophils, and fibroblasts. In old lesions, numerous collagen fibers were homogenized and seemed swollen; sometimes they were orientated in parallel as in scar tissue. Between the collagen fibers, several neural profiles were recognized, even in H-E stains. Moreover, neuroid structures similar to neurilemmoma were seen in some places surrounded by dense cellular infiltrate. Few dermal vessels showed swelling of their endothelial walls and deposits of eosinophilic fibrinoid material.

After a four-week period of wearing elastic bandages, the cutaneous infiltrate was markedly reduced, and no striking neural elements were seen, neither enlarged nerves nor neurolemmoma-like structures. Some epidermal changes were still present.

Histologic examination of the noninvolved skin near the nodules did not show any evidence of tissue alterations, especially no increase of nervous tissue was seen.

Under the *electron microscope*, it was obvious that cutaneous nerves were markedly increased in all dermal layers. Numerous profiles of normal nerves in all sizes and types were observed, alone or surrounded by cellular infiltrate. Some of them were surprisingly thick and contained myelinated and nonmyelinated axons (Fig 2 and 3). Most of the dermal nerves were well structured; the sheaths of Schwann cells, endoneural, perineural and epineural tissues were all normal. In some specimens, axonal

disorientation was seen; we called such profiles "*axonal seas*" because of their abundance and their peculiar appearance (Fig 4). We also had the impression that Schwann cell nuclei were present more often than usual and draw the conclusion that the peripheral neural proliferation involved axons and Schwann cells. Rarely, degenerative changes of individual axons and of proliferating Schwann cells were observed. At places, some axons and Schwann cells were enlarged and seemed swollen; also some bands of Büngner occurred, which is a rather rare phenomenon in normal human skin. We now examined thoroughly the epidermis, and in contrast to previous light microscopic studies we did not find any evidence for the occurrence of intraepidermal nerves.

The cellular infiltrate was mainly composed of mononuclear cells, which seemed somehow stimulated showing dense nuclear chromatin, abundant cytoplasm, and an increased amount of cytoplasmic organelles (Fig 5, top). Dermal Langerhans cells were found in one case and "wormlike" structures, characteristic of stimulated histiocytes, in another.

In some specimens, we repeatedly found an unusual cell type. This cell occurred in small numbers in the dermal infiltrate, had a small mostly excentric nucleus, and abundant cytoplasm. The cytomembranes were smooth and were organized in an extraordinary manner, similar to a labyrinth of wide, hollow spaces. For this reason, we called this cell type *spider cells* (Fig 5, bottom). They were coated by floccular material, resembling a basal lamina in some places, which distinguished them from plasma cells. There was no evidence of any physical connection between these cells and the neural tissue or the vascular walls.

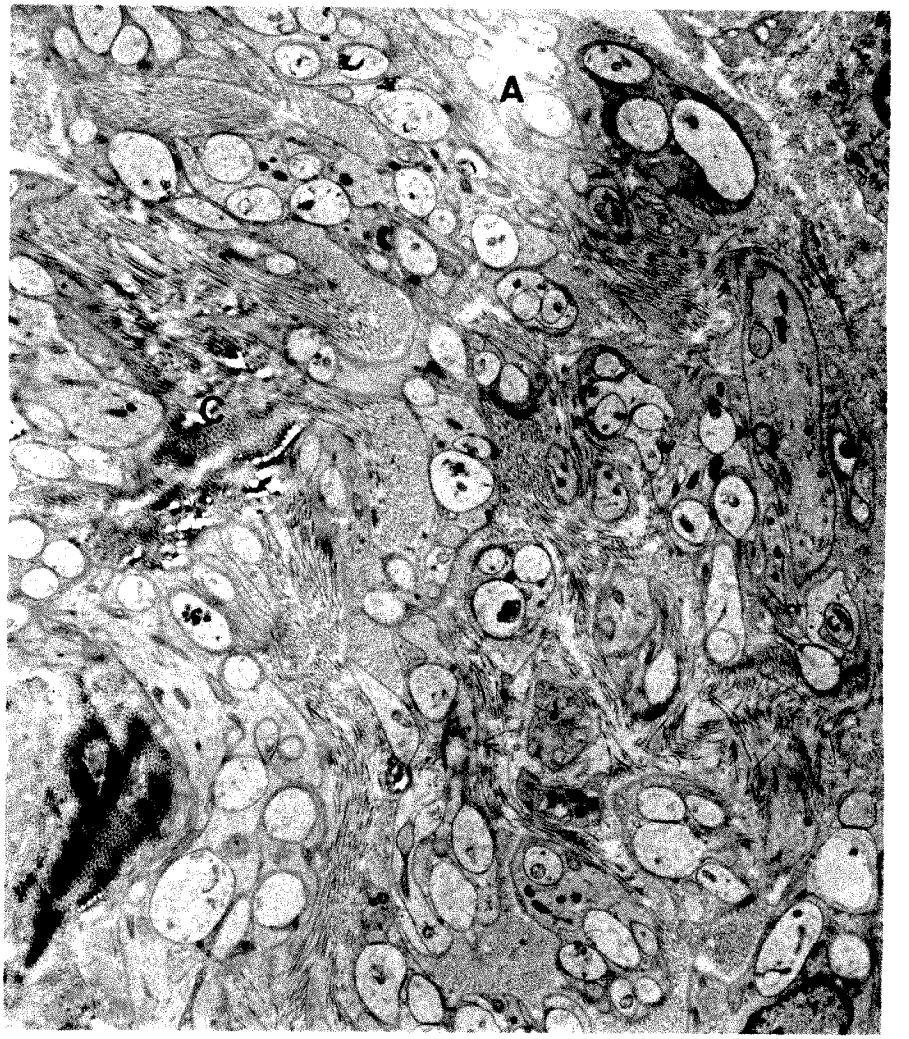

Fig 4.—Some dermal regions are crowded by axons (A) and their Schwann cells, irregularly distributed between collagen fibers (C); a perineural sheath is lacking (original magnification ×5,800).

COMMENT

The data presented in this study revealed that the cutaneous neural proliferation represents the most characteristic tissue change in prurigo nodularis and other types of chronic prurigo, since it has never been described in another comparable skin condition. This neural proliferation of the preterminal fibers is accompanied by hypertrophy of the larger cutaneous nerves. In noninvolved skin near the nodules, there was no increase in the number or size of cutaneous nerves.

Interestingly enough, the neural proliferation involves axons and Schwann cells simultaneously. The neurilemmoma-like formation that was observed light microscopically corresponds closely to fully developed nerve tissue. No true neurilemmoma was found in prurigo during this study, comparable to the ultrastructural data reported by Waggener (1966).[8] The ultrastructural findings suggest that some observed neural elements are newly formed nerve fibers with normal appearance, although some disorganization, axonal swelling, and axonal dystrophy, and bands of Büngner may occur. Thus, our observations confirm those described by Feuerman and Sandbank (1975), but we do not consider these findings to represent significant neural abnormalities. On the contrary, when we take into account the large amount of analgesic, sedative, and antipruritic drugs that all patients had to take, the ultrastructure of the nerves seemed nearly normal. As previously reported, drug abuse may cause marked alterations in cutaneous nerves though limited to a subclinical level (Runne and Orfanos 1975).[9]

In prurigo, the perineural sheaths,

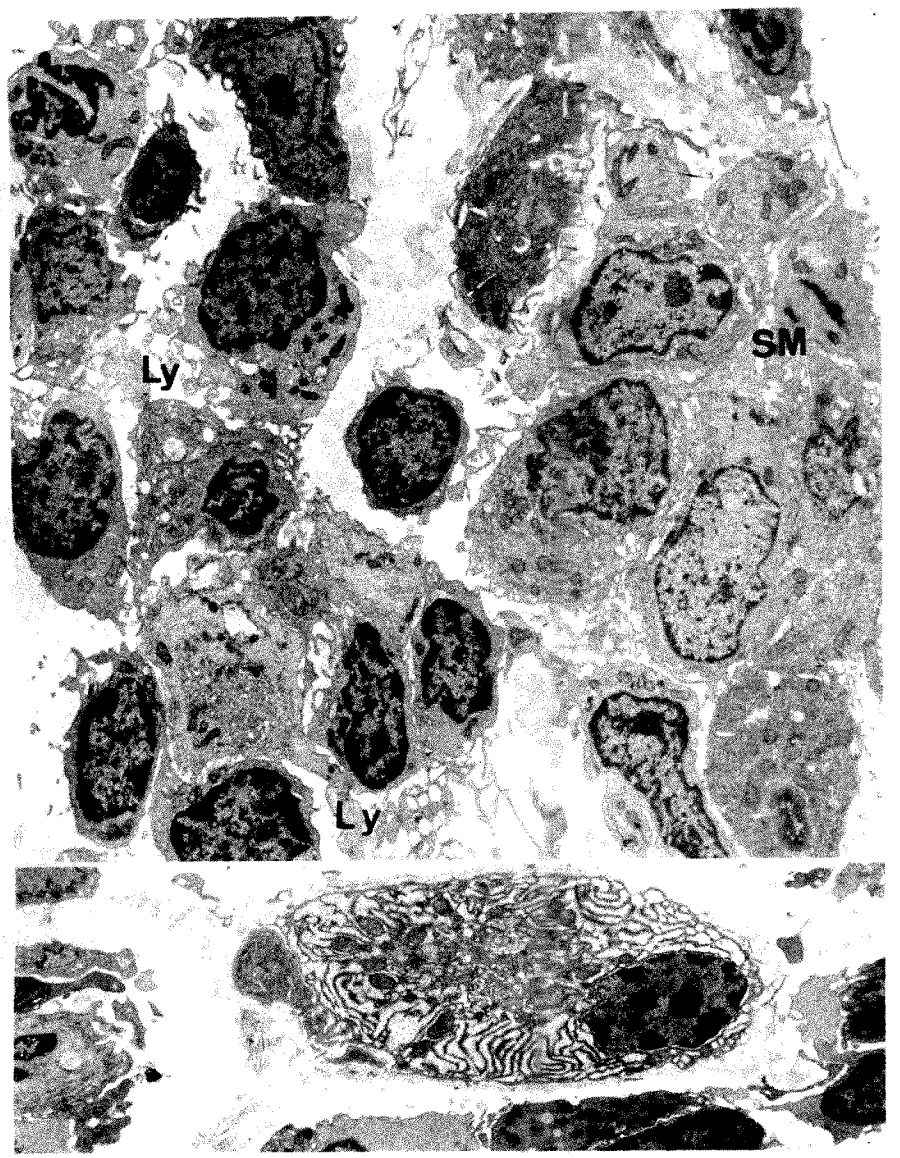

Fig 5.—Top, Dense cellular infiltrate mainly consisting of lymphocytes (Ly) and stimulated mononuclear cells with signs of cytoplasmic activity (SM) (original magnification, ×5,100). Bottom, Unusual cell with a large amount of cytoplasm and extreme organization of its cytomembranes; floccular material surrounds the cell surface resembling basal lamina (original magnification ×5,200).

if present, sufficiently protect the axons, especially against the dense cellular infiltrate. Therefore, the infiltrate does not seem responsible for the slight changes of the cutaneous nerves and their proliferation. On the other hand, no reasonable explanation can be given to the significance and the origin of the peculiar cell type that we called spider cells seen in some specimens. They are obviously highly active and seem to possess a secretory function.

In our view, in chronic prurigo a circulus vitiosus of pruritic lesions, scratching, and neural proliferation exists. It is obvious that scratching can damage preterminal nerve fibers and stimulate them to a reactive regeneration and new formation. Experimental data of O'Daly and Imaeda (1967)[10] and Dyck (1969)[11] suggest that mechanical trauma leads to degeneration and proliferative phenomena in peripheral nerves. Therefore, it seems likely that persistent scratching may cause neural proliferation in human skin and may intensify the pruritic sensations. From this point of view, the nodules of prurigo are highly sensitive "pruritic-islands" of neural origin. The flattening of the lesions and the decrease of cellular infiltrate and nervous elements after protection against scratching and after local pressure using elastic bandages shows that an interruption of this circulus vitiosus betters the clinical and histological findings.

Elisabeth Bodeux provided technical assistance.

Necrolytic Migratory Erythema

Distinctive Dermatosis of the Glucagonoma Syndrome

Ronald S. Kahan, MD; Maj Rafael A. Perez-Figaredo, MC, USAF; Lt Col Andris Neimanis, MC, USAF

• Glucagon-secreting tumors of the pancreatic islets (glucagonomas) produce a distinctive syndrome in which weight loss, diabetes mellitus, anemia, and prominent mucocutaneous findings occur. The cutaneous component—necrolytic migratory erythema—may be polymorphous, but most commonly manifests as erosions and crusts of the groin, perineum, buttocks, distal part of the extremities, and central area of the face. Alternatively, scaly papules and plaques may predominate in these areas. The eruption may resemble such dermatoses as pemphigus foliaceus, acrodermatitis enteropathica, chronic mucocutaneous candidiasis, psoriasis, and severe seborrheic dermatitis.

Two patients with chronic, previously undiagnosed dermatoses had necrolytic migratory erythemia, which led to the discovery of glucagonomas present in each. In one patient surgical resection of the tumor resulted in total clearing of the rash within 48 hours. Awareness of this distinctive entity may lead to early diagnosis and, possibly, cure.

(*Arch Dermatol* 113:792-797, 1977)

Changes in the skin can provide clues to the presence of internal malignant neoplasms. When cutaneous signs or symptoms antedate other manifestations of a malignancy, awareness of the relationship between dermatosis and neoplasm may lead to earlier diagnosis and possible cure. Such entities as acanthosis nigricans, dermatomyositis, acquired ichthyosis, and erythema gyratum repens have been associated with a variety of tumors. Rarely does a particular cutaneous disorder point directly to a particular type of internal malignancy.[1]

Accepted for publication Sept 24, 1976.

Reprints not available.

A distinctive eruption termed necrolytic migratory erythema has recently been described in association with glucagon-secreting islet-cell tumors of the pancreas (glucagonomas).[2-5] This dermatosis has a characteristic gross morphology and histopathology that appear to be diagnostic of this neoplasm. This report describes two patients in whom the presence of necrolytic migratory erythema led to the discovery of glucagonomas. These cases are presented to acquaint physicians with the cutaneous manifestations of this disease.

REPORT OF CASES

CASE 1.—A 40-year-old male school teacher was first admitted to the Massachusetts General Hospital on Nov 1, 1974, because of an extensive rash. Eighteen months prior to admission progressive weight loss began, and nine months before admission the patient first noted a scaling eruption involving the groin, buttocks, and web spaces of his feet. The dermatitis did not improve with use of tolnaftate, griseofulvin, and antibiotics. In August 1974 he was briefly hospitalized because his dermatitis had become erosive. Astringent compresses and topical corticosteroid therapy were not helpful and he was discharged. During the three months before admission the rash fluctuated in severity, but generally worsened. Because of increasing weakness the patient could no longer work. His weight loss now totaled 25 kg. There was no history of anorexia, diarrhea, jaundice, abdominal pain, fever, polydipsia, polyuria, drug ingestion, or previous skin disease. His family history was noncontributory.

On physical examination the patient appeared pale, thin, and chronically ill. His vital signs were normal; weight was 47 kg. An eruption consisting of multiple brown and red-brown crusts, a few intact pustules, and focal erosions, all on a background of mottled erythema, was localized to the central one third of the face (Color Fig 1). In addition, there were extensive erythematous erosions with peripheral scale involving the groin, perianal area, and genitalia (Color Fig 2). Similar but smaller and more discrete lesions were focally scattered on the medial part of the thighs and legs near the ankles. Many of the erosions exhibited arciform or circinate patterns. The feet were involved with tender erosions of the interdigital spaces and dry exfoliation of the soles. Occasional intact, flaccid bullae could be identified, especially on the thighs (Color Fig 3). These evolved rapidly into the erythematous erosions. Prominent macular hyperpigmentation surrounded or abutted the erosive areas, and it became clear that the hyperpigmentation resulted from the healing of active lesions. Scalp hair was sparse; nails were thin and friable, with longitudinal ridging. The tongue was large and beefy but not tender. The liver was palpable 6 cm below the right costal margin; neither splenomegaly nor abdominal masses were present.

Laboratory test results included the following: an hematocrit level of 28.5%, an erythrocyte sedimentation rate of 90 mm/hr, and a urinalysis trace positive for glucose. Gram stains of crusted areas showed a few Gram-positive cocci; potassium hydroxide preparations of crusted areas and pustules disclosed no hyphae; fungal cultures were negative. Determinations for alkaline phosphatase, SGOT, lactic dehydrogenase (LDH), prothrombin time, iron and iron-binding capacity, thyroxine, BUN, creatinine, stool fat, VDRL, antinuclear antibody, lupus erythematosus (LE) preparation, and complement studies as well as chest and gastrointestinal roentgenograms were normal. The initial glucose tolerance test showed the following values: fasting blood glucose, 117 mg/100 ml; one hour, 258 mg; two hours, 247 mg; and three hours, 239 mg. Skin tests for delayed hypersensitivity were positive with mumps and candida antigens, and were negative with intermediate strength purified protein derivative (PPD) and streptokinase-streptodornase.

Multiple skin biopsy specimens showed subcorneal and midepidermal clefts containing neutrophils, lymphocytes, nuclear debris, and a few cocci (Fig 1). The clefting occurred in the midst of psoriasiform hyperplasia with occasional spongiform

pustule formation. Of note was the presence of keratinocytes with fusiform shapes similar to those of parakeratotic cells, but lying free in the blister cavities. These cells had dot-like nuclei in the middle of strand-like, eosinophilic cytoplasm. In the dermis there was a loosely aggregated perivenular infiltrate of lymphocytes with some eosinophils and neutrophils. Direct immunofluorescent studies of involved and normal skin were negative for IgG, IgM, IgA, and complement.

A liver scan showed multiple filling defects consistent with a metastatic tumor. Results of a liver biopsy disclosed islands of small tumor cells with minimal mitotic activity. Special stains and immunochemical studies established the neoplasm as a glucagon-secreting alpha-cell tumor of the islets of Langerhans. A celiac angiogram confirmed the hepatic findings and showed a neoplasm in the body of the pancreas. A plasma glucagon level determined by radioimmunoassay and measured as total plasma glucagon immunoreactivity, using antiserum 30K,[7] was 2,200 pg/ml (normal, 106 ± 57 pg/ml). Plasma amino acid studies showed almost all amino acid levels to be below normal.

In view of the hepatic metastases and the patient's physical state, chemotherapy was instituted. He was treated first with streptozocin, later with vincristine sulfate, cyclophosphamide, and prednisone, and subsequently with additional streptozocin courses. During the 15 months of chemotherapy, the cutaneous findings improved, while his general physical state and laboratory measurements (including plasma glucagon) remained essentially unchanged.

Case 2.—A 39-year-old businessman was admitted to the Massachusetts General Hospital on Dec 10, 1974, because of a generalized skin eruption and two days of fever, chills, and tender erythema of the left side of the face. His health had been good until 4½ years prior to admission when he developed a scaling, red, nonpruritic scrotal rash, which during several weeks spread to involve the entire body. He also noticed intermittent scaling around the mouth and episodic "shedding of the lining of the mouth." He experienced burning and pain in areas of friction, and thus had been unable to wear shoes for

most of the 4½ years. His condition had been evaluated at several university centers and dermatologic society meetings. Past diagnoses included candidiasis, dermatophytosis, eczematous dermatitis, chronic erythema multiforme, pustular psoriasis, and generalized seborrheic dermatitis with exfoliation. Previous therapy included tar, ultraviolet light, topical corticosteroids, with and without occlusion, topical fungicides, griseofulvin, hydroxyurea, methotrexate, antibiotics, and systemic corticosteroids.

One year before admission the diagnosis of "erythema annulare centrifugum-like psoriasis" was made at another hospital. Subsequently, treatment with intramuscularly given triamcinolone, in high doses, partially controlled the eruption. Two days before admission he developed a redness and tenderness in his left ear and scalp with accompanying fever and chills. A review of systems disclosed an 11-kg weight loss; chemical diabetes and bilateral cataracts had been diagnosed nine months earlier.

Physical examination showed a thin, chronically ill-appearing man in moderate distress. His rectal temperature was 38.1 C. He had a mild "buffalo hump," and there was decreased muscle mass of his upper arms. The right inguinal and left cervical lymph nodes were enlarged and tender. The spleen and liver were not palpable.

A bright erythema with scaling involved much of the legs and feet. Several shallow, round erosions, from 1 to 5 cm in size, numerous large crusts, and scattered pustules were also present in these areas (Color Fig 4). The thighs, groin, trunk, and arms had areas of diffuse erythema with desquamation, as well as multiple guttate, scaly red papules, and tan-gray macules with peripheral scale (Color Fig 5 and 6). The scalp was moderately scaly; the hair and nails were normal. The buccal mucosa was clear but there was bilateral angular cheilitis. There was dusky erythema, induration, and pain on palpation involving the left ear, cheek, and frontotemporal scalp. The borders were discrete and slightly elevated.

Laboratory studies included an admission WBC of 14,200 cu mm with a normal differential and an erythrocyte sedimentation rate of 66 mm/hr. The following studies were normal: hematocrit, electrolytes, BUN, blood glucose, bilirubin, SGOT, LDH, alkaline phosphatase, amylase, prothrombin time, VDRL, antistreptolysin O titer, and chest roentgenogram. Blood cultures were negative, but skin cultures grew group A β-hemolytic streptococci. The urinalysis disclosed a glucose reaction of 2+ with moderate ketone. Fractional

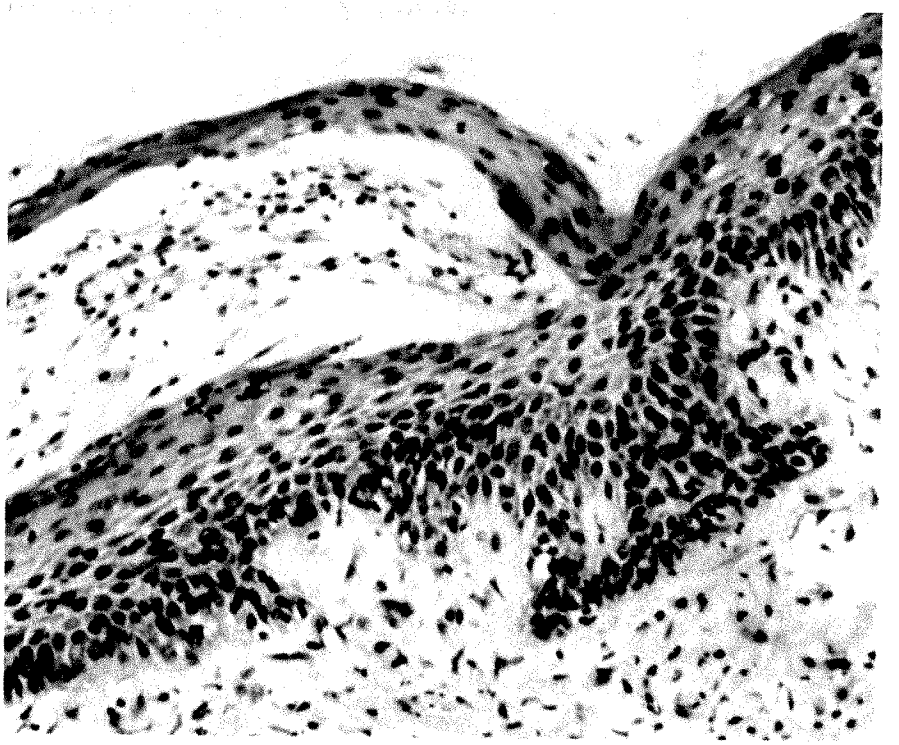

Fig 1.—Intraepidermal cleft, containing lymphocytes, neutrophils, and fusiform keratinocytes, some of which are dyskeratotic (patient 1) (hematoxylin-eosin, original magnifications ×300).

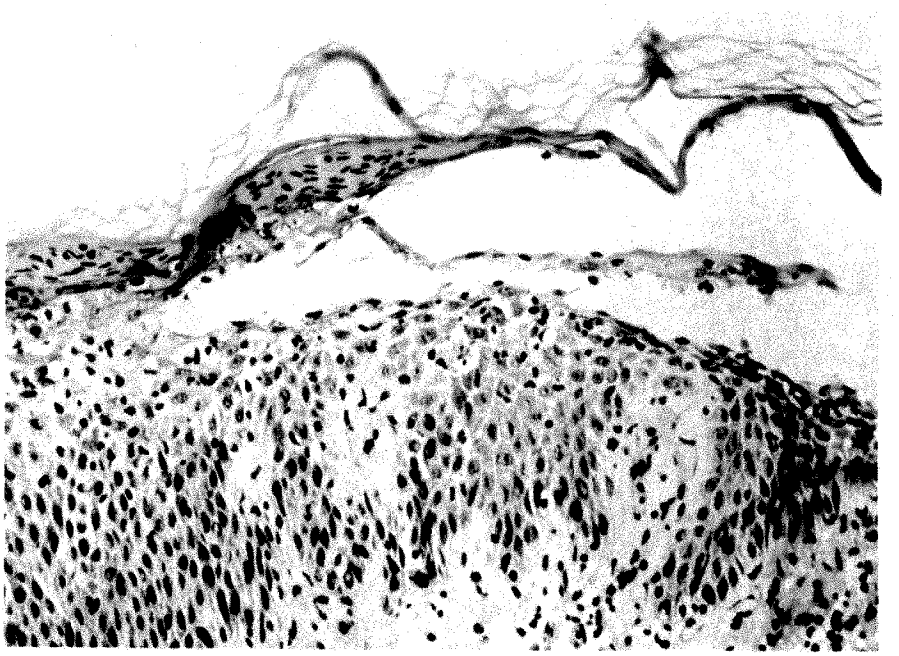
Fig 2.—Focal parakeratotic scale and stratum corneum form roof of blister containing tongue of dyskeratotic and fusiform cells. Underlying epidermis is hyperplastic, spongiotic, and infiltrated by neutrophils (patient 2) (hematoxylin-eosin, original magnification ×300).



urine reactions for glucose varied from 1+ to 4+. The fasting cortisol level was 0.7 μg/100 ml.

Skin biopsies exhibited psoriasiform hyperplasia with focal spongiosis and occasional clefts in the upper epidermis. Elongate cells similar to those seen in case 1 were noted, though less prominently so. These fusiform cells were aggregated, showed dot-like to elongated nuclei, and exhibited cytoplasmic staining varying from red to blue (Fig 2).

The admission diagnoses were erysipelas of the face and glucagonoma syndrome. Bilateral cataracts, proximal myopathy, and probably osteoporosis were thought to be secondary to long-term corticosteroid use. The patient was started on a regimen of intravenously given oxacillin and replacement corticosteroids; the erosive lesions of the extremities and groin were treated with Burow compresses. On the third hospital day he was afebrile and the facial inflammation had subsided. After six days his skin was generally clear except for his feet, groin, and buttocks. Scrapings from these areas disclosed hyphae, for which tolnaftate cream was given.

The patient's skin was virtually normal 13 days after admission and he was granted a leave of absence for Christmas, during which time he was to take prednisone, 25 mg, every other day. On readmission eight days later, the eruption had flared badly. The groin, legs, and feet were uniformly deep red-purple and oozed clear fluid. On the abdomen and thighs the lesions consisted of centrally depressed, erythematous, annular macules with paler elevated borders, resembling "target" lesions. Shallow erosions were noted around the beltline and on the dorsa of the feet. Subsequently, the eruption progressed to involve the scalp and face with erythema and scales resembling seborrheic dermatitis. The remaining lesions became more scaly, developed crusts around the periphery, and showed central clearing.

The result of the initial plasma glucagon level was 700 pg/ml (normal, 106 ± 57 pg/ml). An angiogram of the pancreas showed tumor vascularity of the body and tail, consistent with primary endocrine pancreatic neoplasm. Liver and bone scans were normal. As a result, the tumor was totally resected along with the distal part of the pancreas and the spleen. There was no evidence of metastases at the time of surgery. Histologically, the tumor was a pancreatic islet-cell carcinoma, and special stains showed it to contain glucagon. A random liver biopsy specimen obtained at surgery disclosed no tumor.

Twenty-four hours after surgery, there was a substantial decrease in erythema, the lesions appeared dry, and the face was almost normal; 48 hours after surgery, the skin was virtually clear. Superficial scaling could easily be brushed off, leaving normal-appearing skin. The patient was discharged on the eighth postoperative day; his plasma glucagon level was normal. For 12 months he remained free of skin lesions or evidence of tumor recurrence. On Jan 27, 1976, however, he was readmitted because of hematemesis and back pain. A massive hemorrhage necessitated a hemigastrectomy and repair of a perforated duodenal ulcer. At operation the liver was seen to be studded with tumor nodules, which histologically were identical to the initial pancreatic tumor. The plasma glucagon level was now 150 pg/ml (normal, 106 ± 57 pg/ml).

COMMENT

The earliest report of a case of this type was by Becker et al,[1] who in 1942 described a 45-year-old woman with a migratory erosive dermatosis. She had lost 7.7 kg of weight, had perlèche, smooth tongue, and normochromic anemia. Results of a glucose tolerance test were abnormal, and an islet-cell tumor was found at autopsy. Although glucagon-secreting tumors were not appreciated at that time, the authors' detailed clinical account makes it clear that their patient had a glucagonoma. McGavran et al,[6] in 1966, studied a clinically similar patient. An electron microscopy of the tumor cells disclosed granules characteristic of alpha-cells, and a radioimmunoassay for glucagon showed the resected tumor to contain large amounts of the hormone.

The term necrolytic migratory erythema was coined in 1973 by Wilkinson[2] to describe the appearance and five-year course of a 52-year-old woman with cyclic episodes of annular and gyrate erythema of the legs. This term incorporated the clinical and histologic features of both the figurate erythemas and toxic epidermal necrolysis, which Wilkinson felt were the predominant characteristics of this eruption. In 1975 Mallinson et al[3] collected nine cases from Great Britain (some briefly reported previously[2,7-9]). Their series established the glucagonoma syndrome as a distinct entity consisting of necrolytic migratory erythema, weight loss, anemia, and diabetes mellitus, in association with a pancreatic alpha-cell tumor and elevated plasma glucagon level.

Both of our patients had chronic cutaneous eruptions associated with weight loss and diabetes mellitus; both were ultimately shown to have glucagon-secreting alpha-cell tumors. In patient 2, surgical resection of the primary tumor resulted in a prompt resolution of all cutaneous findings. Patient 1 had metastatic involvement that rendered his tumor inoperable; he continued to have elevated glucagon levels and new skin lesions. These two patients illustrate both the extent and the variability of the glucagonoma syndrome.

Including our patients, a total of 15 well-documented cases have been reported.[2,3,5-11] The composite features of this syndrome, gleaned from these cases, are listed below.

- Systemic
  - *Weight loss, often profound
  - Weakness
- Mucocutaneous
  - Lesions
    - *Scaly erythematous macules and papules, often annular or arciform
    - Flaccid bullae
    - *Erosions with crusting
    - Hyperpigmentation on healing
    - *Glossitis, stomatitis, angular cheilitis
    - Thin, friable nail plates
  - Distribution
    - *Central one third of face
    - *Lower abdomen, groin, buttocks, thighs, perineum
    - Distal part of extremities
  - Course
    - Spontaneous exacerbations and remissions
    - Variable response to any therapy
  - Histopathology
    - Irregular acanthosis with spongiosis
    - *Subcorneal and midepidermal clefts
    - *Fusiform keratinocytes with pyknotic nuclei
    - Absence of acantholysis
    - Negative immunofluorescent findings
- Hematologic
  - Normochromic, normocytic anemia
  - Elevated erythrocyte sedimentation rate
- Gastrointestinal
- Diarrhea
- Endocrine
  - *Diabetes mellitus
  - *Elevated plasma glucagon level
  - *Alpha-cell tumor of pancreatic islets, with or without metastases
  - Hypoaminoacidemia

The major diagnostic criteria are marked with asterisks. The mean age of onset for the 15 patients was 50.5 years, with a range from 34 to 65 years. Eleven of them have been women.

The cutaneous component, necrolytic migratory erythema, appears most often as erythematous erosions and crusts involving the buttocks, groin, perineum, thighs, and distal part of the extremities. Individual lesions begin as small, often irregular macules that enlarge, blister, and ultimately break down to superficially eroded, sometimes oozing areas. These erosive lesions may assume linear, annular, or serpiginous configurations, either by extension of a single area or by confluence of several. Extensive denudation may result. At a given time, different lesions may be in varying stages of development, or lesions may progress in synchronous waves. Size and shape changes occur continually. Drier lesions may show a collarette of scale, or an entire erythematous plaque may be surmounted by scale, giving a psoriasiform appearance. Erosions, though healing without scarring, produce prominent postinflammatory hyperpigmentation.

Perioral and paranasal crusting, often with extension onto the central forehead and cheeks, is almost invariably present at some time. Thinning of nails with distal friability, a decrease in hair density, atrophic glossitis, stomatitis, and angular cheilitis are frequently associated findings.

Typically, the skin changes wax and wane, responding poorly to therapy of any type, yet regressing without apparent cause. Transient favorable responses to antibiotics, antifungal agents, diiodohydroxyquin, and systemic corticosteroids have been noted, but results have been inconsistent.

Substantial weight loss, often totalling 10 to 25 kg, has been present in every case. Anorexia and malaise are infrequent, but patients do complain of weakness. A normocytic anemia is characteristic, though our second patient was free of anemia for 4½ years. Bone marrow studies are nondiagnostic; iron stores are normal, as are serum iron levels. The erythrocyte sedimentation rate is always elevated, often to high levels. The main gastrointestinal symptom is diarrhea.

Derangements in glucose metabolism are prominent. Patients exhibit intermittent glycosuria, although ketonuria is uncommon. An abnormal glucose tolerance test result is generally demonstrated. Plasma glucagon levels are elevated, often substantially so. Our patients had initial glucagon levels of 2,200 pg/ml and 700 pg/ml (normal, 106 ± 57 pg/ml), and values cited for other cases have been similar. Although systemic corticosteroid therapy may produce increased plasma glucagon levels in normal patients, these increments have been of the order of twofold elevations over control levels.[12,13] This may serve as a useful differential point in a patient whose clinical picture has been clouded by previous corticosteroid use (as in case 2). Plasma amino acid values are significantly reduced. Determinations of the plasma "amino acid pattern" may be helpful in establishing the diagnosis.

The characteristic histologic feature of this disorder appears to involve a separation of cells in varying stages of keratinization in a subcorneal or midepidermal location. These cells, generally fusiform, exhibit pyknotic nuclei and cytoplasm varying from bright pink to blue in sections stained with hematoxylin and eosin. This change occurs in association with psoriasiform hyperplasia and spongiosis. Similar findings have been noted by Wilkinson[2]; he described the keratinocyte alteration as necrolytic. Sampling appears important, as the characteristic clefts may be only focally present. Acantholysis is notably absent. The dermis contains a loosely aggregated, perivenular inflammatory infiltrate. Direct immunofluorescent studies have been negative.

Diseases to be considered in the differential diagnosis of necrolytic migratory erythema are listed below.

Pemphigus foliaceus
Chronic mucocutaneous candidiasis
Seborrheic dermatitis
Psoriasis vulgaris
Pustular psoriasis
Subcorneal pustular dermatosis (Sneddon-Wilkinson disease)
Chronic benign familial pemphigus (Hailey and Hailey disease)
Acrodermatitis enteropathica
Erythema annulare centrifugum
Chronic erythema multiforme
Toxic epidermal necrolysis

The entity most suggested by the gross morphology is pemphigus foliaceus, which may exhibit small flaccid blisters, crusting, spreading erosions, and scaly erythema of the central part of the face. Its histology, however, with acantholysis and positive direct immunofluorescence, should identify it. Chronic benign familial pemphigus (Hailey and Hailey disease) is suggested by chronic intertriginious erosions and crusts. A positive family history and extensive acantholysis on biopsy ("dilapidated brick wall") help to distinguish it from necrolytic migratory erythema.

Acrodermatitis enteropathica must also be considered here, as patients with this disease exhibit periorificial and acral crusting. However, this condition begins early in infancy; the youngest age at which a glucagonoma became clinically significant was 34 years (our patient 2). Serum zinc levels in acrodermatitis are substantially low and appear to be normal in necrolytic migratory erythema; both our patients had normal zinc levels. Chronic mucocutaneous candidiasis may show a similar clinical picture, though *Candida albicans* can usually be identified in large numbers. Patients with necrolytic migratory erythema have not shown deficiencies in cell-mediated immunity.

The subsiding, scaling phase of subcorneal pustular dermatosis (Sneddon-Wilkinson disease) should also be considered, because older lesions in this disease often have irregularly shaped contours, exhibit crusting or scaling, and prefer intertriginious areas. Hyperpigmentation on healing, which may be the only finding during a quiescent phase, is characteristic of both diseases. However, the prominent pustules that initiate Sneddon-Wilkinson disease are not seen in necrolytic migratory erythema. Histologically, the subcorneal pustule of Sneddon-Wilkinson disease must be distinguished from the cleft seen in

necrolytic migratory erythema, which may contain polymorphonuclear leukocytes because of impetiginization; the fusiform keratinocytes of necrolytic migratory erythema may prove helpful to differentiate the two conditions. The annular or serpiginous character of necrolytic migratory erythema may at times resemble erythema annulare centrifugum. The nonexudative, raised, and well-made border of this condition should aid in differentiation. Chronic erythema multiforme with target lesions and bullae may mimic necrolytic migratory erythema. In the latter, however, there is little plantar or palmar involvement, mucous membrane changes are not severe, and hemorrhagic lesions are uncommon.

Psoriasis vulgaris, pustular psoriasis, and seborrheic dermatitis may be considered in cases where a bullous component is minor and scaly erythema predominates. Here, lack of response to conventional therapy and atypical morphology should alert the clinician. Histology may not be helpful, as a biopsy section of necrolytic migratory erythema often shows only nonspecific psoriasiform hyperplasia. Multiple biopsy specimens and careful selection of active borders for sampling are required.

The role of glucagon in producing the characteristic changes observed clinically and histologically is unknown. Glucagon is a polypeptide hormone that acts to elevate the blood glucose level by promoting glycogenolysis and gluconeogenesis in the liver. Little is known regarding its effects on the skin under normal or pathologic conditions. Mallinson et al[14] found that high plasma glucagon levels were associated with low plasma amino acid levels in their glucagonoma patients, and postulated that amino acid metabolism plays an "intermediary" role in producing the syndrome. Tasman-Jones and Kay[15] noted skin findings similar to necrolytic migratory erythema in patients with zinc deficiency from parenteral alimentation; however, the rash resolved promptly with zinc supplementation. This observation seems relevent to acrodermatitis enteropathica; zinc abnormalities have not been observed in glucagonoma patients. At present, the mechanism producing migratory necrolytic erythema remains speculative.

Patients with the glucagonoma syndrome are likely to consult initially with a dermatologist, as the rash is often the first symptom prompting medical attention. The clinical and histologic features of this condition are sufficiently distinctive that, when their presence is noted, a glucagon-secreting tumor must be ruled out. Plasma glucagon determinations may not be readily available; however, the presence of reduced plasma amino acid levels may be suggestive. Because early diagnosis might result in excision and cure of a malignancy, it is recommended that selective celiac angiography be performed when clinical, laboratory, and histologic findings suggest the presence of an islet-cell tumor.

Arcuate Dermal Erythema in a Carrier of Chronic Granulomatous Disease

Craig E. Nelson, MD; Mark V. Dahl, MD; Robert W. Goltz, MD

• A female carrier of chronic granulomatous disease developed arcuate, erythematous dermal plaques on her back and face. The lesions were clinically and histopathologically suggestive of Jessner benign lymphocytic infiltration of the skin. Some women with relatively fixed arcuate or annular, erythematous, dermal plaques may be carriers of chronic granulomatous disease.

(*Arch Dermatol* 113:798-800, 1977)

Discoid lupus erythematosus (LE) and Jessner benign lymphocytic infiltration of skin have been associated with the carrier state of chronic granulomatous disease.[1-6] We report a female carrier of chronic granulomatous disease who developed arcuate dermal erythematous plaques clinically resembling Jessner benign lymphocytic infiltration of skin.

REPORT OF A CASE

Our patient was defined as a carrier of chronic granulomatous disease in 1967, and her genetic pedigree has been published previously. The patient is the carrier mother of family S.[7] Mrs S is a 50-year-old woman first seen by us in March 1974, for evaluation of an indurated, erythematous, arcuate lesion over the midback, present for two months. It began as an erythematous plaque 1 to 2 cm in diameter and gradually enlarged peripherally with clearing of the center. It was mildly pruritic. Similar but smaller erythematous plaques were present on the bridge of the nose and on the malar eminences; these were asymptomatic and had been present for several years. At times they became more prominent; this could not be correlated with sunlight exposure. Mrs S had had no other skin disorders.

The patient's status as a carrier of chronic granulomatous disease was documented by leukocyte function studies. Her granulocytes showed roughly 50% of normal bacterial killing capacity by the method of Holmes et al.[8] Intermediate ability of the patient's granulocytes to increase the oxidation of the first carbon of glucose in response to phagocytosis by the method of Holmes et al[9] and an intermediate reduction of nitro-blue tetrazolium by the patient's cells were also shown using a modification of the method of Baehner and Nathan.[10]

One son and two nephews have chronic granulomatous disease. A second son died, probably from the same disease. A sister, daughter, and niece are carriers with abnormal leukocyte function.[7]

Examination showed areas of induration and telangiectasia of the skin on the bridge of the nose and both cheeks. There was no scaling, follicular plugging, atrophy, or scarring. Over the midback at the level of the scapula was a 9 to 10 cm, nontender, erythematous plaque with central clearing and a broken arcuate border (Fig 1). The border was readily palpable and blanched with pressure, but there was no evidence of scaling, follicular plugging, or vesiculation of the surface. Several telangiectatic vessels were noted, but atrophy was absent.

Mild tenderness was present in the left-upper quadrant and midepigastrium. Pin prick hypesthesia of the ophthalmic and maxillary branches of the left fifth cranial nerve extending into portions of the mandibular fifth cranial and second cervical dermatomes was found. There was an equivocally positive Babinski reflex on the right. The remainder of the neurologic and general physical examination was unremarkable.

The CBC was normal, as were values for

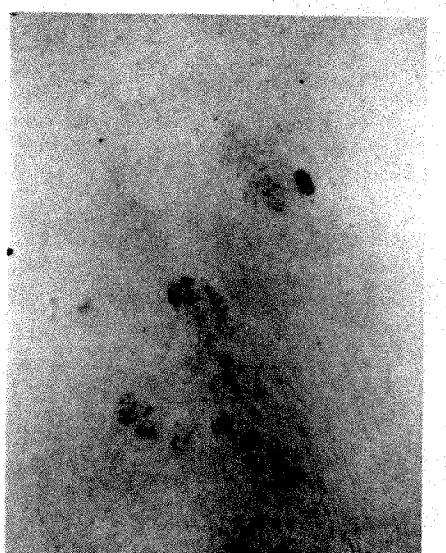

Fig 1.—A 9 to 10 cm, nontender, erythematous plaque with central clearing and a broken arcuate border was present over midback.

Accepted for publication March 9, 1976.

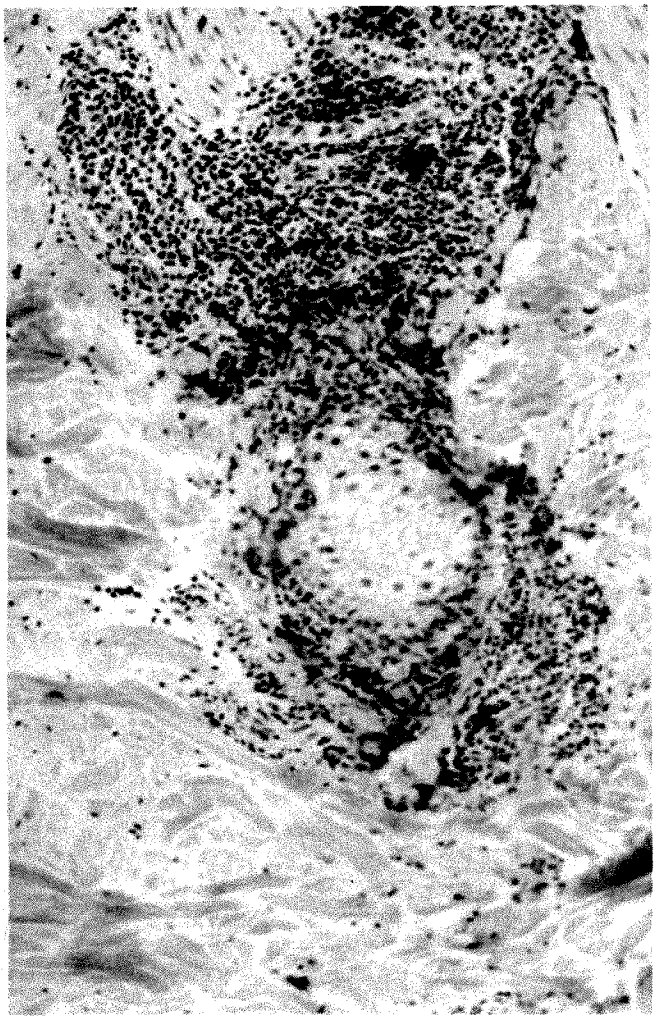

Fig 2.—A prominent infiltrate surrounds sebaceous glands and dermal blood vessels (hematoxylin-eosin, original magnification ×100).

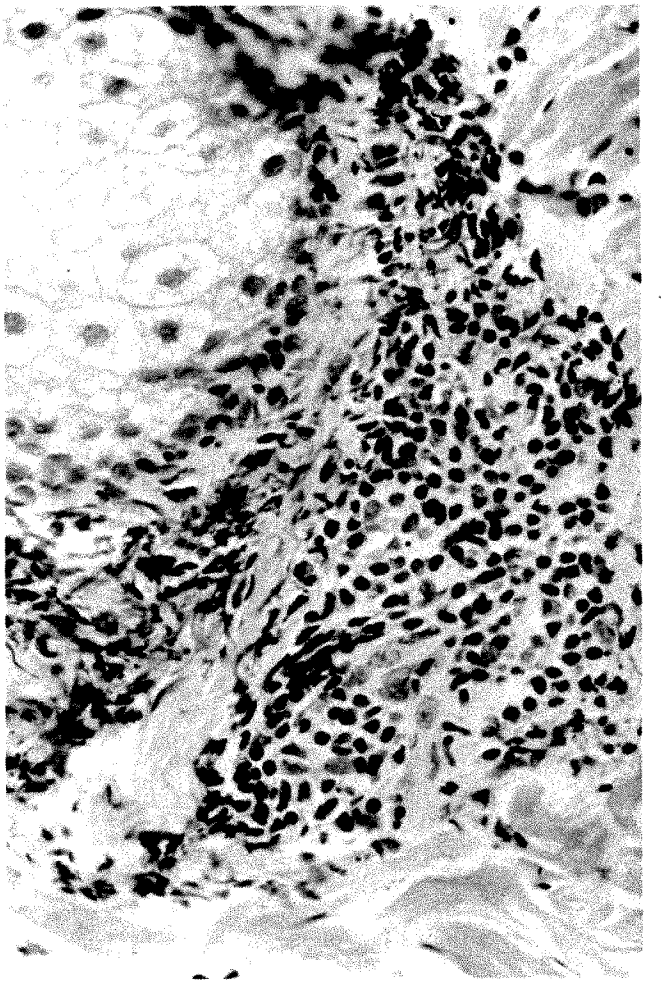

Fig 3.—Infiltrate is composed primarily of lymphocytes with some histiocytes (hematoxylin-eosin, original magnification ×160).

BUN, creatinine, fasting blood glucose, serum electrolytes, serum cholesterol and triglycerides, serum amylase, two-hour urinary amylase, SGOT, lactic dehydrogenase, alkaline phosphatase, prothombin time, partial thromboplastin time, thrombin time, urinalysis, ECG, proctoscopy, upper gastrointestinal series, barium enema, intravenous pyelogram, skull series, EEG, brain scan, intermediate purified protein derivative, bead defibrination tests for LE, and fluorescent antinuclear antibody tests. A mumps skin test showed 9 mm of erythema at 48 hours. An 8 to 13 mm nodule was present in the left-lower lobe. This was thought to be a calcified granuloma.

Histologically, the lesion on the back showed a somewhat flattened and thinned epidermis. In the middle and deep dermis, there were foci of dense, predominantly perivascular, round cell infiltration (Fig 2 and 3). Similar accumulations of lymphocytes were noted about pilosebaceous follicles and eccrine sweat glands in the deep dermis. Giant cells, neutrophil accumulations, necrosis, and lipid-laden histiocytes were not observed. A specimen from an indurated, telangiectatic area on the left cheek showed slightly thinned and flattened epidermis. There were basophilic degeneration of the connective tissue of the upper dermis and a moderate perivascular and perifollicular lymphocytic infiltrate in the mid and deep dermis. Aerobic and anaerobic bacterial cultures of tissue from the annular lesion on the back showed no growth.

Direct immunofluorescence was negative initially, but a second biopsy for direct immunofluorescence from the lesion on the back showed deposits of IgM and small amounts of C3 at the dermoepidermal junction in a diffuse, granular pattern. Deposits of IgG, IgA, and fibrinogen were not found.

COMMENT

Chronic granulomatous disease is a disorder in which granulocytes lack the ability to kill certain bacteria following phagocytosis.[11] The defect probably lies within the metabolic pathways normally triggered by the phagocytosis of bacteria. Intracellular hydrogen peroxide production is deficient in affected individuals,[12] and abnormalities in superoxide production[13] and the early phases of lysosomal degranulation[14] have also been demonstrated.

Chronic granulomatous disease is usually inherited as an x-linked recessive trait.[15] Occurrence in female subjects and in patients without carrier parents suggest an autosomal recessive form of the disease or spon-

taneous mutation.[16-18]

Affected individuals usually demonstrate superficial skin infection, eczematous dermatitis, and suppurative lymphadenitis in the first year of life.[19] Pulmonary infection and septicemia are frequent, and soft tissue abscesses, osteomyelitis, pyarthrosis, empyema, peritonitis, and meningitis may occur. Death before adolescence is common.

Female carriers show levels of granulocyte bacteriocidal and metabolic activity intermediate between the severely depressed levels of affected male subjects and normal controls.[20] Despite intermediate numbers of defective granulocytes, female carriers are usually phenotypically normal and show no tendency towards increased frequency of infection. However, there have been reports of discoid LE or discoid LE-like dermatoses[1-5] and one report of Jessner lymphocytic infiltration of the skin[6] in female carriers. These skin changes have, in individual cases, been accompanied by arthritis, pleuritis, fever, Raynaud phenomenon, photosensitivity, recurrent aphthous stomatitis, or hypergammaglobulinemia.[1] Serologic evidence of systemic LE is usually lacking in these patients, although one patient had a single positive clot test.

Skin lesions in our patient were most consistent with Jessner benign lymphocytic infiltration of skin. Relatively fixed erythematous plaques were present on the face, and a slowly enlarging, erythematous dermal plaque with central clearing was present on the back. In contrast to erythema annulare centrifugum which the back lesion superficially resembled, the lesion enlarged only very slowly over several months and lacked collarette scaling. Histopathological findings also favored Jessner infiltration since epidermal flattening and periappendageal inflammation were present in addition to a lymphocytic perivascular infiltrate.

The presence of deposits of IgM and C3 at the dermoepidermal junction of involved skin of the back supports other evidence that Jessner lymphocytic infiltration may at least sometimes be a form of chronic discoid LE, and further links previous reports of Jessner lymphocytic infiltrate and chronic discoid LE in other carriers of chronic granulomatous disease. Previous patients with Jessner lumphocytic infiltration of skin have lacked deposits of immunoglobulins in skin.[21,22]

Female patients with arcuate dermal plaques clinically resembling Jessner benign lymphocytic infiltration of skin, erythema annuare centrifugum, or discoid LE may sometimes be carriers of chronic granulomatous disease. Family history and impaired nitro-blue tetrazolium dye reduction should delineate the patients.

This investigation was supported by Public Health Service training grant 5T01 AM05560.

Atopic Dermatitis and Impaired Neutrophil Chemotaxis in Job's Syndrome

David Paslin, MD, Michael E. Norman, MD

• A 22-year-old white woman with Job's syndrome was found to have atopic dermatitis and impaired neutrophil chemotaxis in vitro. Major clinical features of Job's syndrome included large, "cold" and recurrent staphylococcal abscesses, and intermittent bacterial and yeast infections. Evidence for atopic disease included infantile eczema progressing to flexural dermatitis, a family history of atopy, positive immediate hypersensitivity skin tests, and hyperimmunoglobulinemia E. Defective erythema responses to histamine, methyl niacinate, and methacholine (Mecholyl) chloride may explain the lack of redness, heat, or pain signalling the development of abscesses (hence the term "cold"). Impaired chemotaxis was probably due to an intrinsic neutrophil defect since patient's serum generated normal amounts of chemotactic factors and did not contain an inhibitor of neutrophil chemotaxis. A delay in neutrophil exudation in vivo may explain the abscess formations and the atopic diathesis may explain the absence of clinical signs of inflammation that have been described in this and other patients with Job's syndrome.

(*Arch Dermatol* 113:801-805, 1977)

Job's syndrome is characterized by large cold staphylococcal abscesses, early childhood dermatitis, and intermittent bacterial and yeast infections. The large, deforming, cold (here meaning no redness, no heat, and no tenderness), chronic, and recurrent subcutaneous staphylococcal abscesses are the outstanding feature. The syndrome, originally observed in two unrelated children, was described by Davis et al in 1966.[1] At least three[2,3] and perhaps six[4,5] additional cases have since been described, and a defect in neutrophilic chemotaxis has been reported.[2,3] Seven of eight have been female patients, and all have had markedly elevated serum IgE values.

This patient is described not only to review the clinical and laboratory findings of Job's syndrome but also to elucidate mechanisms likely to explain these findings.

REPORT OF A CASE

The patient, a 22-year-old white woman, had recurrent cold subcutaneous staphylococcal abscesses. Eczematous dermatitis of the face and scalp was first noted at 3 weeks of age. At 5 years of age, a large "tender" submental abscess was noted, followed by similar and recurrent hot abscesses of the legs, back, neck, buttocks, shoulders, scalp, and face. From the age of 13 years, however, the abscesses were described as being very large, nontender, and cold, appearing on the shoulders, back, vulva, and buttocks. Some of the cold abscesses were sufficiently large to distort bodily contour. Incision and drainage of these abscesses produced as much as 1,000 ml of purulent material. Bronchitis, otitis externa, and frontal and maxillary sinusitis, requiring surgical drainage, occurred between ages 11 and 16 years. Chronic, recurrent oral moniliasis had been present for the past five to six years. There was a positive allergic history for dust, grasses, and animal dander, confirmed by immediate skin tests. There was no personal or family history of diabetes. The half-brother and half-sister are healthy. The maternal grandmother had hay fever. The health of the biological father is unknown. In recent years, the patient has done quite well while receiving nafcillin therapy followed most recently by cephalexin monohydrate (Keflex) taken daily. While receiving such therapy, new abscesses have not appeared.

Physical examination revealed a well-nourished woman with normal vital signs. The hair was chestnut brown, and the eyes were gray, similar to that of other family members. There was eczematous dermatitis of the scalp, a papular acneiform eruption of the face, coarse leonine facial features, flexural dermatitis of the antecubital fossae, the popliteal fossae and the neck, oral and vulvar moniliasis, scattered follicular pustules, surgical scars, and a 4 × 3.5 cm cold, nontender abscess over the left shoulder of which the patient was not aware. (At the time of this examination, she had not taken cephalexin monohydrate for one week.)

Routine laboratory studies included normal values for hemoglobin, hematocrit, urinalysis, urine culture, fasting blood sugar, and electrolytes. White blood cell count was elevated at the time of infection at 13,500/cu mm, with 83% mature neutrophils, 2% band forms, 2% eosinophils, 5% monocytes, and 8% lymphocytes. The serum protein electrophoresis revealed moderate elevation of α_2-globulin at 1.2 gm (normal 0.34 to 0.72) and of gamma globulin at 2.0 gm (normal 0.62 to 1.20). Numerous cultures of the large, recurrent abscesses grew *Staphylococcus aureus*. Morphologically, mature neutrophils which had ingested bacteria, were demonstrated on gram stain (phase microscopy). No free

bacteria were seen. Cultures of the anterior nares, pubis, anus, and random sites on glabrous skin also grew *S aureus*. *Candida albicans* grew from the oral cavity and vaginal vault.

MATERIALS AND METHODS

Assays of cutaneous erythema and inflammatory response included topical, intradermal or oral challenges to histamine, compound 48-80, croton oil, methyl niacinate, methacholine, and niacin. Histamine, 0.1 ml, was given intradermally (ID) in a concentration of 1:100,000.[6] Compound 48-80, in a concentration of 35 mg/ml and in 0.02 ml, was administered ID.[7] Croton oil as a 10% solution in mineral oil was applied in 0.05 ml to a 1 × 1-cm square of a fine cotton mesh bandage and placed on the forearm skin under an occlusive polyethylene tape for 48 hours.[8] Methyl niacinate, 0.1 ml, was applied topically as a 1% aqueous solution.[9] Methacholine chloride, 0.1 ml in a concentration of 1:500, was injected ID.[10] Niacin was taken by mouth first in a dose of 150 mg, and a week later in a dose of 500 mg.[11]

Tests of humoral and cell-mediated immunity were performed and included the following: quantitative immunoglobulins IgA, IgG, and IgM were measured on immunoplates, IgE was measured by a double-antibody radioimmunoassay procedure; isohemagglutinins, antistreptolysin (ASLO) titers, and typhoid H titers after three immunizations were measured by standard techniques; agglutination titers were measured against *C albicans* and the patient's own *S aureus;* C_3 and total hemolytic complement (CH50) were measured as previously described from this laboratory[12]; delayed hypersensitivity skin tests were performed in standard fashion using both commercially available antigens and the primary immunogen keyhole limpet hemocyanin (KLH) and dinitrochlorobenzene; in vitro cellular immunity was tested by measuring the proliferative responses of the patient's and control peripheral blood lymphocytes to phytohemagglutinin (PHA) and pokeweed mitogen (PWM). All cultures were performed in duplicate, with 1×10^6 cells/tube, cultured in 10% autologous plasma.[13]

Tests of host defense immunity included the following: in vitro phagocytosis of yeast[14] and bacteria,[15] intracellular bactericidal activity,[15] in vitro opsonic activity for yeast and bacteria,[14,15] and in vivo inflammatory activity as measured by the Rebuck skin window.[16] Chemotactic assays were performed by a previously described modification of the Boyden assay.[17] A washed suspension of either control or patient polymorphonuclear leukocytes (PMNs) at a final concentration of 5×10^6/ml was placed on one side of a 3 micropore size membrane. Materials with chemotactic activity were placed on the other side. These materials were generated from fresh control or patient plasma or serum by incubation with preformed antigen-antibody complexes or endotoxin. In previous studies, serum complement has been shown to contribute the major chemotactic activity in this assay, based on (*a*) loss of hemolytic activity in antigen-antibody complex treated serum, (*b*) activation of C_3 as demonstrated by immunoelectrophoresis, (*c*) failure to generate chemotactic activity in ethylenediaminetetracetic acid (EDTA)-treated serum, and (*d*) inhibition of chemotactic activity with antihuman C_3 antiserum. Following incubation for three hours at 37 C, the average number of PMNs per high-power field reaching the lower-most surface was determined (ten contiguous high-power fields were counted). All experiments were performed in duplicate, and most experiments were counted in "blind fashion" by a second observer. Preincubation of patient and normal cells in patient and normal serum (1%, 5%, and 10%) respectively, was carried out for 30 minutes at 37 C. The cells were then washed, resuspended in buffer, and placed in the chambers.

RESULTS

The patient's cutaneous erythema and inflammatory responses to some chemical challenges are listed in Table 1. She developed a 20 mm wheal at 20 minutes to compound 48-80. A positive reaction is the development of a wheal greater than 10 mm in diameter, 20 minutes after injection. Topical application of croton oil provoked redness, itching, and blistering throughout the test site at 48 hours. This constitutes a positive response. Her brisk reactions to compound 48-80 and to croton oil indicate an ability to form an inflammatory response. Yet, she had clear-cut atopic responses, for no flare occurred 15 minutes after intradermal histamine 1:100,000, and no redness was seen 15 minutes after topical methyl niacinate, 1% aqueous solution. Blanching was present on observation 15 minutes after intradermal methacholine, 1:500. There was no flush of any kind to oral niacin at 150 mg. She became markedly flushed over most of the body, but only slightly flushed on the face after an oral dose of niacin at 500 mg. This response lasted one hour, and is inverse to what is normally present, ie, facial but not body-wide flushing. One of the investigators (DP) developed a brisk facial flush lasting two hours after oral niacin at 100 mg.

Routine immunologic studies are presented in Table 2. Of significance is diffuse hypergammaglobulinemia with extraordinary hyperimmunoglobulinemia E, normal antibody production, and generally normal cell-mediated immune responses in vivo and in vitro. Note, however, the lack of development of sensitization to *Bacillus* Calmette-Guérin or DNCB.

Phagocytosis of yeast particles, the patient's own *Staphylococcus*, and a stock preparation of *Staphylococcus* by the patient's neutrophils, was normal. Intracellular killing of *Staphylococcus* was also normal, as was her neutrophil reduction of nitroblue tetrazolium. Similarly, the patient's serum produced normal opsonic function in these phagocytic assays when normal neutrophils were employed.

The patient's overall inflammatory response as measured by the in vivo skin window technique, was also normal as seen below.

Table 1.—Assays of Cutaneous Erythema and Inflammatory Response

Test	Patient	Normal
Histamine 1:100,000, 0.1 ml ID	No flare	Flare
Compound 48-80, 35 mg/ml, 0.02 ml ID	Large wheal	Large wheal
Croton oil 10% in mineral oil, topically	Redness, itch, and blistering	Redness, itch, and blistering
Methyl niacinate 1% aqueous, topically	Not red	Red
Methacholine 1:500, 0.1 ml ID	Delayed blanch	Flare
Niacin 150 mg, PO	No flush	Flush at 100 mg, lasting two hours
Niacin 500 mg, PO	Inverse flush lasting one hour (see text)	(Flush expected, but not attempted)

Host Defense Immunity

Neutrophil function in vitro:	
1. Yeast phagocytosis	Normal
2. Staphylococcal phagocytosis	Normal
3. Staphylococcal bactericidal activity	Normal
4. Random motility	Normal
Serum opsonic function in vitro:	
1. Yeast phagocytosis	Normal
2. Staphylococcal phagocytosis	Normal
3. Staphylococcal bactericidal activity	Normal
Inflammatory response in vivo:	
1. Rebuck skin window	Normal

In vitro tests of neutrophil movement included normal random motility but deficient chemotaxis. The results of the chemotactic experiments are shown in the Figure.

When comparing the chemotactic activity of the patient's serum or plasma as a percentage of the normal control plasma or serum for a particular experiment (eg, 100%), the mean value is 75 ± 25% ($P > .10$ Student t test). When comparing the chemotactic responsiveness of patient's PMNs to normal PMNs, using normal serum as a source of chemotactic activity, the mean response is 65 ± 17% ($P < .001$); the mean response is 61 ± 17% when these experiments employed patient's serum as the source of chemotactic activity ($P < .001$).

The deficient migration of patient's neutrophils could be due either to an intrinsic cellular defect or a cell-directed inhibitor in patient's serum. Consequently, additional chemotactic experiments examined the capacity of patient's serum to inhibit the chemotactic migration of normal neutrophils, by preincubating the cells in the serum (eg, 1%, 5%, and 10%). The controls included preincubation of normal neutrophils in both normal, autologous, and normal pooled (ten adult donors) sera. There was no difference in the migration of these neutrophils whether incubated in normal or patient sera. Migration of the preincubated normal neutrophils was not significantly different from that of neutrophils not preincubated.

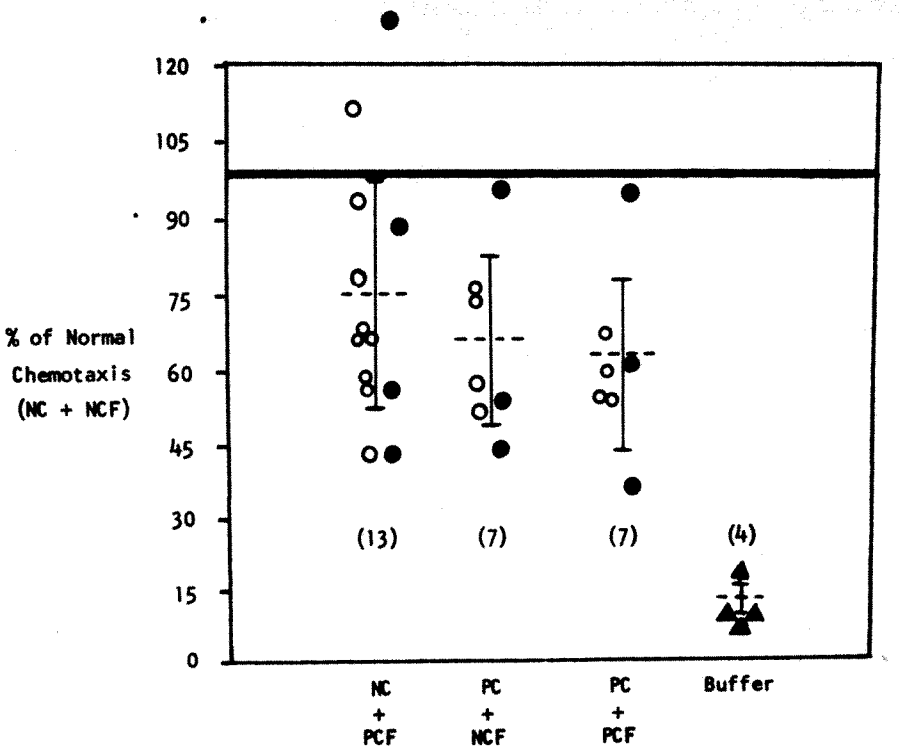
COMMENT

The outstanding and delineating feature of Job's syndrome is the occurrence of huge, cold, chronic, and recurrent staphylococcal abscesses that deform and distort bodily contour. Red hair and hyperextensible joints have been described in some patients.[1] Early childhood dermatitis and frequent bacterial and yeast infections complete the syndrome.

Hill et al[3] offered a perceptive explanation for the development of the large abscesses: patients with Job's syndrome, having defective chemotaxis of their neutrophils, do not develop a sufficiently early response to staphylococcal invasion through the skin. Multiplication of invading bacteria continue until finally checked by a massive tardive influx of neutrophils giving rise to abscess formation.

The explanation of Hill et al[3] may be extended. Once the mass of neutrophils arrive to form the abscess, they, being otherwise intact, perform the remaining tasks of leukocyte function. Hence, no free organisms are found on smear, and sepsis does not typically occur. It is therefore not surprising that these patients do not become septic in the face of huge abscesses, for when the Job's syndrome neutrophils are already present, as they are in the blood stream, they function normally.

Job's syndrome has been categorized as one of the disorders of leukocyte function.[18] With equal precision, it may also be categorized as one of the disorders of atopic dermatitis, in the sense that Wiskott-Aldrich is a disease of atopic dermatitis.[19] It is suggested that many of the composite features are the result of superimposing the chemotactic defect of



Results of chemotaxis experiments. Chemotactic response of normal neutrophils (NC) to chemotactic activity generated from normal serum or plasma (NCF) is set at 100% for each experiment. Chemotactic activity generated from patient serum (open circles) or plasma (closed circles) using either antigen-antibody complexes or endotoxin as activating agents (PCF) is compared to normal serum or plasma chemotactic activity (NC + NCF vs NC + PCF), for that experiment.

$$\% \text{ of normal chemotactic activity} = NC + PCF/NC + NCF \times 100$$

Number of experiments is shown in parentheses. Chemotactic migration of patient neutrophils (PC) is compared to that of normal neutrophils, when either normal serum or plasma was the source of chemotactic activity (PC + NCF vs NC + NCF), or patient serum or plasma was the source of chemotactic activity (PC + PCF vs NC + NCF). Group means ± 1 SD are indicated by the dotted horizontal and vertical lines, respectively.

Job's syndrome on the underlying vascular and inflammatory defects of atopic dermatitis. Patient's with Job's syndrome characteristically have an early childhood dermatitis. Our patient provides evidence that this early childhood dermatitis is atopic dermatitis and is an intrinsic part of Job's syndrome. She has a positive family history for atopic disease. She had infantile eczematous dermatitis and later developed chronic flexural dermatitis. She had a history of immediate type hypersensitivity to dust, grasses, and animals. She had negative delayed skin tests to purified protein derivative, histoplasmin, coccidioidin, SK/SD, KLH, and trichophytin. She could not be sensitized to DNCB. She developed no erythema after topical methyl niacinate 1% and developed a delayed blanch after intradermal methacholine, 1:500. Her IgE was highly elevated at 12,000 IU/ml. In sum, the evidence suggests that our patient had atopic dermatitis and has the atopic diathesis.

The general principle that persons with atopic dermatitis are prone to chronic bacterial[20] and fungal[21] infection is well established. Studies by Leyden et al[20] showed high counts of *S aureus* on the involved and uninvolved skin of patients with atopic dermatitis. Since the skin of patients with atopic dermatitis typically harbors large populations of *S aureus*, and since there is reason to believe that the skin of patients with Job's syndrome is atopic skin, it would be expected that Job's syndrome skin would also bear a large population of these organisms. Such was the case in our patient, who grew *S aureus* from both involved and uninvolved skin. One would expect, therefore, that abscesses in Job's syndrome would appear primarily on the skin rather than in some other organ. Yet, it has been observed that the large abscesses are often subcutaneous rather than dermal. The reason for this is not clear. It may be that an inoculum of bacteria in the subcutaneous tissue grows better than a comparable inoculum in the dermis. The differences may be related to the numbers of resident tissue mast cells and/or mononuclear cells and the richness of the blood supply.

Hill et al[3] could find no explanation for the lack of redness, heat, and pain in their patient's large cold abscesses. An explanation becomes apparent when it is realized that patients with Job's syndrome are atopic or at least have many of the stigmata of atopy. Study of our patient discloses defective erythema responses to a number of different stimuli. Lack of redness after intradermal methacholine has already been mentioned. This may simply represent an obfuscation of vasodilatation by edema formation, as seen in atopics and documented by Copeman et al,[22] Ramsey,[23] and Bystryn et al.[10] Yet our patient also shows lack of redness after topical methyl niacinate (as do other atopics—see Copeman et al[22]) and after oral niacin. The lack of normal erythema responses in our patient would suggest that impaired vasodilatation may be an additional characteristic of atopics with Job's syndrome. It is observed, however, that the large pus-filled abscesses not only lack redness, but they also lack heat and pain. Hence in Job's syndrome, there is leukocytic inflammation in the absence of these classic signs of clinical inflammation. Conversely, abundant clinical settings illustrate the presence of redness, heat, and/or pain in the absence of leukocytic inflammation. Examples include blushing, carcinoid flushing, horseradish ingestion, and erythromelalgia. Histamine, niacin, bradykinin, and serotonin are among the probable mediators of these vasodilator responses. In the above clinical settings, it is intense vasodilatation that gives rise to red-

ness, heat, and at times pain, not leukocytic infiltration. It is clear that leukocytic inflammation and the clinical signs of inflammation (redness, heat, and pain) can be independent phenomena.

The syndrome of defective neutrophil chemotaxis associated with recurrent bacterial infections and hyperimmunoglobulinemia E has recently been reviewed.[24] Several groups of patients have emerged and can be separated by the presence or absence of mucocutaneous candidiasis and the presence or absence of atopic features at the time of evaluation, in the face of a positive atopic history. In most of the patients reported, as well as our own, classical tests of humoral and cell-mediated immunity are normal. There is no evidence that IgE in the serum has a direct inhibitory effect on neutrophil chemotaxis; many patients with elevated IgE and/or atopic eczema have normal chemotaxis.[24] Thus, there is something uniquely different about the host defense response in these patients. The chemotactic abnormality in our patient's neutrophils was similar to that reported by others, and we were unable to detect inhibitory activity in her serum.

The dissociation of defective in vitro neutrophil chemotaxis from a normal in vivo inflammatory response has been observed in a number of patients with recurrent bacterial infections.[25] There is no well-established, in vivo assay of neutrophil chemotaxis in man; the Rebuck skin window measures the function of the overall inflammatory response, including both humoral and cellular mediators. Kinetic defects in early neutrophil responses are more easily detected in the current in vitro assays, as suggested by Hill et al.[3]

It cannot be excluded that the neutrophils in Job's syndrome are defective not only in their chemotactic response, but also in the manufacture and release of erythrogenic and pyrogenic polypeptides. Yet the atopic diathesis that is a part of this syndrome provides an alternative explanation for the absence of clinical inflammation in the face of leukocytic chemotaxis (albeit tardive) and phagocytosis. It is suggested that where there is no redness, there may be no heat and no pain. In like manner, the defective erythema responses of atopics with Job's syndrome may directly result in the lack of heat and pain—hence, no clinical inflammation. The cold abscesses of Job's syndrome vividly illustrate the dissociation of leukocytic function and the clinical signs of inflammation.

This investigation was supported in part by Public Health Service grant 5 M01-RR40 from the Department of Health, Education, and Welfare.

Richard K. Root, MD, performed the assays of staphylococcal phagocytosis and intracellular bactericidal activity.

Graft-vs-Host Reaction

Maj Thomas M. Grogan, MC, USA, MD; Lt Col Richard B. Odom, MC, USA, MD; John H. Burgess

• **Observations surrounding the clinical manifestations and pathological studies of a neonate who died at 9 weeks of age, indicate that distinctive cutaneous, histopathologic, and ultrastructural findings occur when graft-vs-host reaction (GVHR) complicates combined immune deficiency syndrome (CIDS). The prominence and specificity of the epidermal lesions, particularly a necrotic cell that occurs in association with satellite lymphocytes ("satellite cell necrosis" (SCN)), lead us to recommend that a cutaneous biopsy be performed to facilitate an early definitive diagnosis. Dermatologists can recognize GVHR at the bedside and establish the diagnosis with the pathological findings obtained from the skin biopsy.**

(*Arch Dermatol* 113:806-812, 1977)

Graft-vs-host reaction (GVHR) following introduction of allogeneic hematopoietic cells is a widely documented complication of transplantation. A recent paper by Slavin and Woodruff[1] emphasized the distinctive epidermal lesions in GVHR secondary to bone marrow transplantation. Several immunodeficient infants with GVHR secondary to allogeneic transplantation[2-7] and maternofetal cell transfer[8-10] have been described, but similar distinctive epidermal lesions have not been described in these circumstances.

We now have additional findings from our studies on a recently published case of GVHR in a neonate in whom combined immune deficiency syndrome (CIDS) occurred as a result of maternofetal cell transfer.[11] These observations indicated that distinctive epidermal lesions can occur in GVHR, complicating CIDS, as they do in adult allogeneic reactions. Furthermore, this entity may be readily recognized by the dermatologist at the bedside, and the diagnosis may be established by skin biopsy. We describe and illustrate the cutaneous lesions of GVHR, demonstrate the characteristic histopathologic features of GVHR, and for the first time, demonstrate that the specific diagnostic ultrastructural findings of GVHR seen in nonhuman primates (Woodruff et al),[12] do occur in man.

The distinctive epidermal lesion we describe has been referred to by Slavin and Santos[13] as an aggressor lymphocyte reaction, which causes single mummified epithelial cells with satellite lymphocytes. In earlier work we referred to this lesion as single cell necrobiosis with associated lymphocytes.[11] It has been described by Woodruff et al, in GVHR of primates as "satellite cell dyskeratosis."[12-14] As our ultrastructural findings demonstrate, it is a necrotic, not dyskeratotic, cell that occurs in association with satellite lymphocytes. Therefore, we now prefer the term "satellite cell necrosis" (SCN), as it is both descriptively accurate and concise.

REPORT OF A CASE

Cutaneous Manifestations

An erythematous, macular rash was apparent over the face and head of an infant girl when she was discharged from the hospital three days after delivery. A detailed description of the case was reported by Grogan and others in another work.[11] The rash progressed over her trunk and arms so that when she was readmitted to the hospital at 21 days of age for the treatment of interstitial pneumonia, the rash was diffuse, confluent, peeling, maculopapular, and erythematous. By 6 weeks of age, some areas of her skin appeared thin and parchment-like with a distinctive bronze hue. These areas enlarged, and at the age of 8 weeks (one week before death) the infant showed some persisting erythematous dermatitis, and large areas of skin appeared parchment-like and bronzed.

Center and Right, View of discrete epidermal space with degenerating epithelial cell and associated lymphocytes (SCN) (hematoxylin-eosin, ×950).

Histopathology of the Skin

Biopsy material for the microscopical studies was obtained from two sources: (1) the erythematous areas of the trunk (at 6 weeks and within one hour of death at 9 weeks), and (2) the bronzed, parchment-like regions of the trunk (within one hour of death at 9 weeks). Microscopical studies of the skin from regions of extensive erythematous rash demonstrated well-defined changes in the squamous epithelium (Fig 1). The papillary dermis had a diffuse infiltrate of small and large lymphocytes, with some associated histiocytes. The lymphocytes and histiocytes dissected the basal and spinous layers of the epidermis. In the regions with extensive lymphocytic invasion (eg, exocytosis), spongiosis and areas of discrete acantholysis were prominent findings (Fig 1). In the regions of extensive spongiosis, characteristic epidermal spaces were found. These spaces were distinctive because they were discrete (15 to 40 μ in diameter); they occurred largely in the stratum spongiosum of the epidermis; and they contained one or more large degenerating keratinocytes (Fig 2 left, center, and right). These discrete spaces have been referred to as "suprabasilar lacunae" by others.[1-13] The degenerated keratinocytes within these spaces had pyknotic, disrupted nuclei and eosinophilic, hyalinized cytoplasm. These necrotic cells were closely associated with one or more satellite lymphocytes. This distinctive lesion has now been identified by the term SCN.

Occasionally, hyalinized necrotic cells occurred without associated lymphocytes. Focal, vacuolar degeneration of the basal cell layer occurred at the sites of lymphocytic invasion. Frequently, a diffuse perivascular and periadnexal lymphocytic infiltrate was an associated finding. Occa-

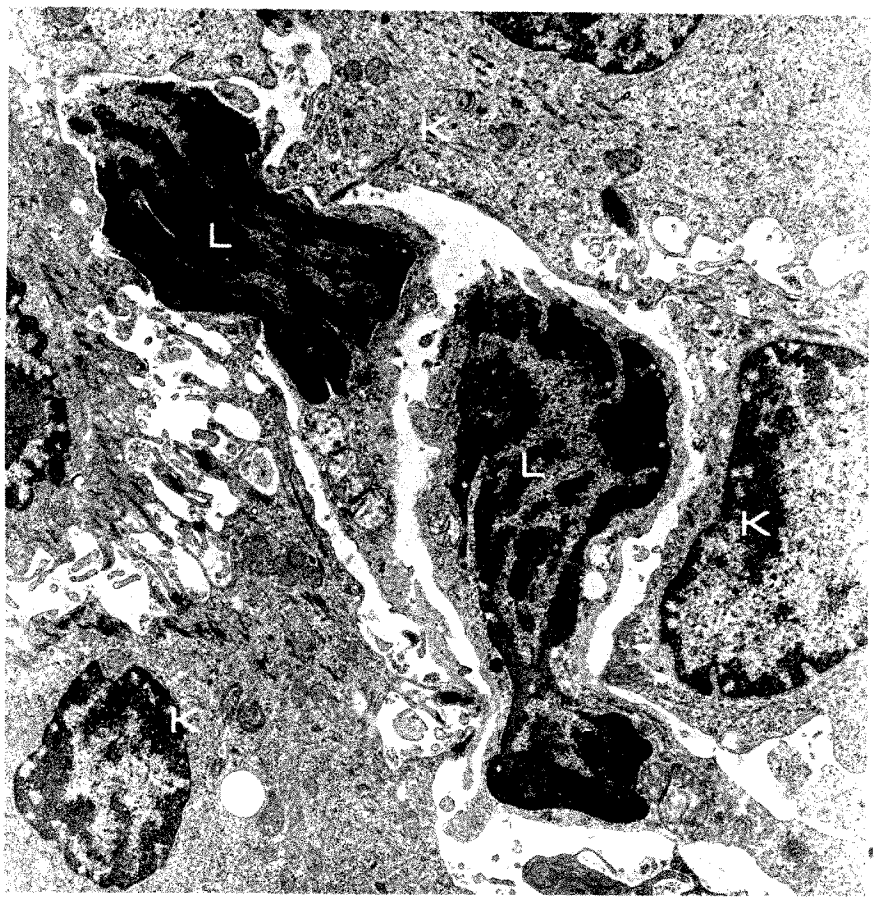

Fig 3.—Skin of abdomen showing two centrally located lymphocytes within stratum spongiosum demonstrating exocytosis. L indicates lymphocytes; K, keratinocyte (×4,000).

sionally, SCN was present within the pilosebaceous apparatus.

In the parchment-like and bronzed areas, focal, epidermal atrophy was observed. Many of these areas showed extensive parakeratosis and hyperkeratosis. Eosinophilic, hyalinized bodies were occasionally seen in these hyperkeratotic regions. There was some melanin pigment found in the papillary dermis in those atrophic regions.

Immunofluorescent and Ultrastructural Findings

Multiple biopsy specimens from the erythematous regions of the trunk were obtained when the neonate was 6 weeks old, and within one hour of her death at 9 weeks of age. The direct immunofluorescence studies were done on the skin tissue obtained at 6 weeks. The results of these studies demonstrated the absence of anti-human IgG, IgM, C, and fibrinogen in the tissue.

Portions of epidermis obtained within one hour of death were fixed in 4% glutaraldehyde, postfixed in 1% osmium tetroxide, embedded in a mixture of resins (Epon) and stained with 5% uranyl acetate and lead citrate. The results of ultrastructural examination revealed prominent migration of lymphocytes (exocytosis) within the stratum spongiosum (Fig 3). The lymphocytes were small or medium in size (most were 10 to 15 μ in diameter). The nuclei contained prominent nucleoli, and the cytoplasm showed an abundance of ribosomes and mitochondria. Many of the lymphocytes had elongated cytoplasm suggesting pseudopodia. Discrete lysis of desmosomes (ie, acantholysis) was apparent in the stratum spongiosum only in association with migrating lymphocytes (Fig 4).

Prominent epidermal spaces were present within the stratum spongiosum. These epidermal spaces showed a degenerating keratinocyte in close association with a lymphocyte (Fig 5). The epithelial nature of the degenerating cell was suggested by the presence of intracellular desmosomes and by many stacked tonofibrils within the

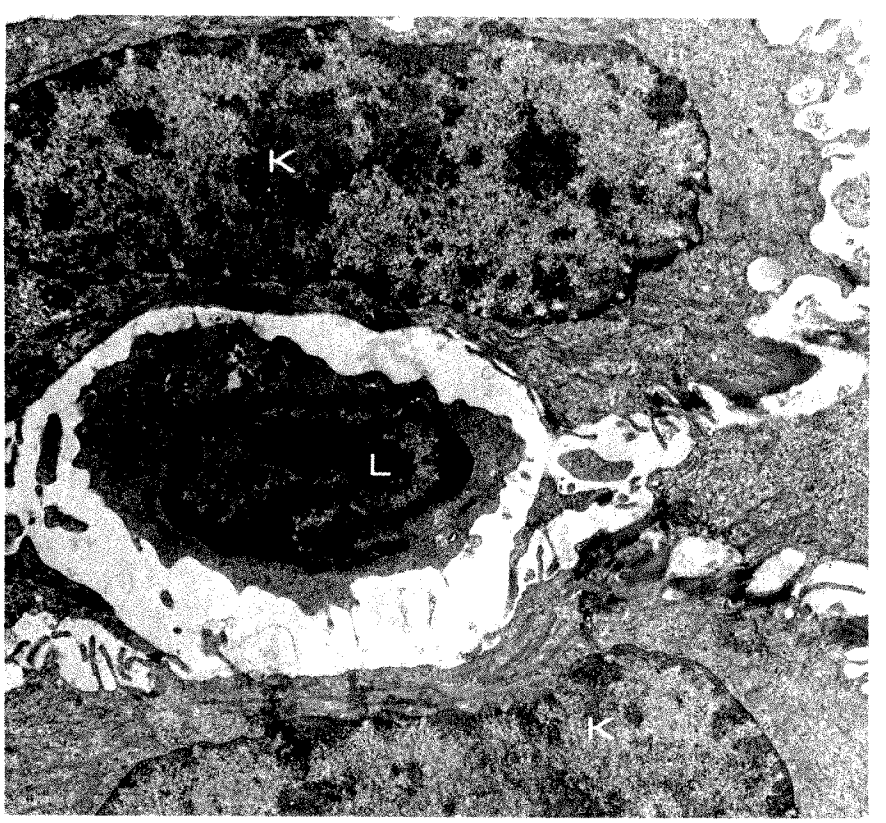

Fig 4.—Skin of abdomen showing lymphocyte within stratum spongiosum with associated focal lysis of desmosomes, ie, acantholysis. L indicates lymphocytes; K, keratinocyte (×4,000).

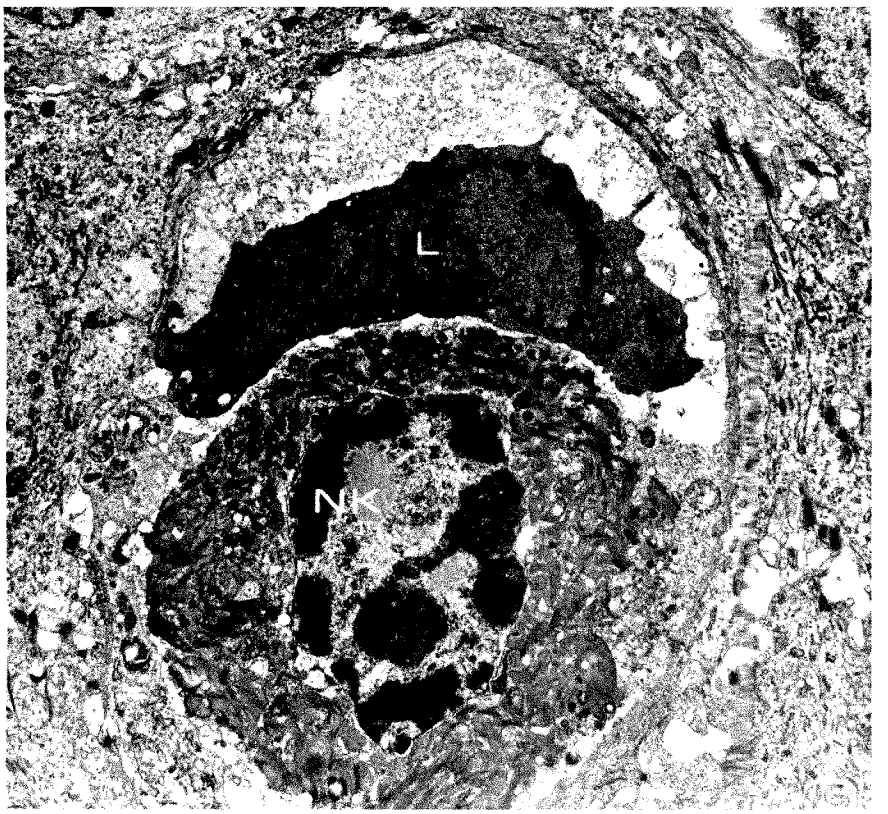

cytoplasm of the cell (Fig 6). The irregular, angular, disrupted, nuclear outline and the compacted, cytoplasmic tonofibrils suggested irreversible degeneration of the keratinocyte (Fig 6). The surrounding lymphocytes within the epidermal spaces contained abundant ribosomes and mitochondria. Some cytoplasmic projections were present, but intercytoplasmic bridges between lymphocyte and keratinocyte were not seen.

COMMENT
Acute vs Chronic GVHR

The cutaneous eruption of acute GVHR typically appears as an evanescent, erythematous, maculopapular rash that frequently begins on the face and head, and rapidly progresses

Fig 5.—Discrete epidermal space with necrotic keratinocyte in close association with lymphocyte (satellite cell necrosis). L indicates lymphocyte; S, epidermal space; NK, necrotic keratinocyte. Comparable to Fig 2, right (×4,000).

to the trunk and arms. As our case demonstrates, the eruption is initially so transient that careful observation is mandatory to document its existence. The morphologic features of the acute lesions usually are evident within a few days after the onset of clinical GVHR.[13]

While transient or abortive GVHR may follow the acute stage, typically the eruption becomes florid. It is characterized by a diffuse, confluent, erythematous, maculopapular dermatitis that is occasionally accompanied by bullae and alopecia. Frequently, the reaction then develops into a generalized, rather mild, exfoliative erythroderma. This represents the chronic state, which usually occurs within a few days or weeks after the onset of clinical GVHR.[13] Chronic GVHR may or may not be preceded by a clinically recognizable acute GVHR. The chronic GVHR may continue to evolve from exfoliative erythroderma to diffuse dermal sclerosis, epidermal atrophy, reticulate pigmentation, hyperkeratosis, and widespread ulceration that shows no tendency toward healing and resembles a poikilodermatous state.[15] The features of the florid stage predominated in our case when the 21-day-old infant was readmitted to the hospital.

After several weeks or months, the eruption enters a quiescent stage, and the skin appears thin and parchment-like, frequently with a bronze hue.

Differential Diagnosis

The cutaneous manifestations of GVHR usually present diagnostic problems to the clinician. The differential diagnosis of GVHR should include seborrheic dermatitis, Leiner disease, histiocytosis-X, drug eruption, exfoliative erythroderma, toxic epidermal necrolysis, lichen planus, and viral exanthem.

Seborrheic dermatitis may simulate the dermatological findings of GVHR, although the presence of systemic involvement in GVHR rules out this condition.[16] Leiner disease is characterized by generalized seborrheic dermatitis of the neonate; intractable, severe diarrhea; recurrent, local, and systemic infections, usually of Gram-negative origin; and marked wasting and dystrophy. Humoral and cellular immunity are normal although they did not occur in the case we report; hypergammaglobulinemia and leukocytosis are usually present. Demonstration of deficient opsonic activity of the patient's serum is diagnostic. This entity responds dramatically to administration of fresh plasma.[17]

The skin lesions in histiocytosis-X, particularly in the more severe form (Letterer-Siwe disease), are noteworthy for their constant appearance as individual, brown, scaling papules. These papules occur in crops on the scalp, face, neck, and trunk, and occasionally develop vesicles and pustules followed by erosions. The lesions frequently are purpuric, and often the surrounding region develops a petechial and hemorrhagic appearance.[18] Histiocytosis-X does not result in abnormalities of hair and nail growth, whereas bony defects and hormonal abnormalities not found in GVHR are characteristic of the histiocytic proliferative disorders.[16]

Drug reactions may provoke a variety of skin eruptions in different individuals, or even in the same individuals at different times.[19] Consequently, a drug eruption as a pathogenetic factor can only be ruled out by the knowledge of the absence of such an insult. In the past, exfoliative erythroderma was divided into distinct clinical entities, but recently this concept was abandoned. Exfoliative erythroderma is now considered a symptom complex that may be the result of many different causations.[20] It is now well established that the chronic stage of GVHR frequently demonstrates an exfoliative erythroderma.[1,3,9,21]

Toxic epidermal necrolysis (TEN) is a cutaneous reaction pattern of multiple causation that is characterized by desquamating sheets of epidermis. The eruption begins suddenly, spreads rapidly, and results in a painful, generalized erythema with flaccid bullae. Nikolsky sign is present. Peck et al[21] described TEN occurring in a patient with GVHR. The initial morbilliform eruption became intensely erythematous, and massive desquamation of large sheets of epidermis ensued. Early in the clinical course, cutaneous histopathologic studies revealed changes of GVHR. However, results of later biopsies were consistent with the diagnosis of TEN. Such results supported the concept of GVHR as a causal factor leading to TEN. A pattern resembling TEN has been observed in laboratory animals in which GVHR was experimentally induced.[22-25] Drug allergy, staphylococcal infection, viral infection, the association with underlying lymphoma,[26] and fumigant-induced reactions[27] are among the causal factors of TEN described. Since the patient of Peck et al[21] had received a bone marrow transplant for acute lymphocytic leukemia, and had received several immunosuppressive agents and antibiotics prior to the cutaneous eruption, the association of TEN with GVHR in man must await further elucidation.

Touraine et al[15] and Saurat et al[28] simultaneously reported GVHR and lichen planus-like eruptions in patients who received bone marrow transplants for posthepatitis aplastic anemia. Papular lesions typical of lichen planus developed in the skin; lesions of the erosive variety were noted in the buccal mucous membranes and nails of the patients described. In the case reported by Touraine et al,[15] severe, life-threatening, cutaneous sequelae developed in the absence of hematological, hepatic, or bowel disease, one year following the lichen planus-like eruption. Clinically, the patient had dermal sclerosis, epidermal atrophy, cicatricial alopecia, reticulate pigmentation, hyperkeratosis, and widespread ulceration showing no sign of healing. Histologically, the cutaneous lesions were characteristic of lichen planus. The lichen planus-like lesions, in both instances, occurred in the chronic stages (90 and 102 days) of GVHR.

The mild, acute GVHR is characterized by a subtle, transient, macular erythema that easily might be regarded as a viral exanthem. On both practical and theoretical bases, the possible role of a viral exanthem in these immunosuppressed patients must be considered in the diagnostic evaluation.

Light Microscopy and Ultrastructural Studies

The results of our microscopical studies confirmed that the basic changes of exocytosis, discrete acantholysis, and SCN do occur in GVHR-complicated CIDS. These are the same changes Slavin and Woodruff[1] described in allogeneic transplantation. Finding these three pathologic changes in combination with the appropriate clinical presentation should lead to a diagnosis of GVHR.

There are a number of skin diseases which show histologic features similar to GVHR. Mucha-Habermann, erythema multiforme, lupus erythematosus, lichen planus, actinic keratosis, and kerato-acanthoma may all show individual cell dyskeratosis. Darier disease and pemphigus vulgaris demonstrate the combination of acantholysis and dyskeratosis. Histopathologically, these entities can be excluded from consideration because the specific finding of SCN is not present. Clinically, they are excluded because they occur in settings unrelated to GVHR-complicated transplantation or CIDS. SCN has been reported in patients with squamous cell carcinoma and malignant melanoma,[12] but neither of these conditions present differential diagnostic problems.

The "mummified" body we identify in SCN may be similar to the colloid body in lichen planus. However, the specific change of satellite lymphocytes in epidermal spaces in association with mummified cells we described, is not described by Touraine et al[15] and Saurat et al[28] in lichen planus-like eruptions and GVHR. Therefore, we believe that while lichen planus and GVHR have some histologic features in common, they can be differentiated on strict clinical and histologic grounds. It may well be, as Slavin and Santos[13] have suggested, that lichen planus and the epidermal lesion of GVHR are similar pathogenetically.

There is a good correlation between histopathologic findings and the observed cutaneous manifestations. The areas of extensive erythematous, macular rash present in the infant in the florid stage of GVHR, correspond to the areas of acantholysis, exocytosis, and SCN on biopsy. The parchment-like areas with noticeable bronzing that are present in chronic GVHR, appear to correlate with the areas of hyperkeratosis, epidermal atrophy, and dermal melanin deposition.

Our electron microscopical studies of GVHR confirm exocytosis, discrete acantholysis, and SCN as prominent findings. Previously published works with reference to ultrastructural findings of GVHR in man were written by Kruger et al[29] and Dobbeleer et al.[30] Kruger et al[29] demonstrated acantholysis as the only significant finding in the epidermis. They made no specific mention of SCN or individual cell necrosis of keratinocytes. Dobbeleer et al,[30] in their ultrastructural studies of GVHR following leukocyte transfusion in man with lymphosarcoma, noted discrete dyskeratotic cells and acantholysis. However, exocytosis was sparse in the case they reported, and they found no intimate relationship between lymphocytes and dyskeratotic cells comparable to SCN.

Two ultrastructural studies[12,31] have come from experimental work on GVHR in animals. Weiner et al[31] emphasized the occurrence of mononuclear cell exocytosis in rabbits, but phenomena specifically related to SCN were not mentioned. The results of ultrastructural studies of GVHR in nonhuman primates by Woodruff et al[12] showed findings, including SCN, that are virtually identical to our findings in human GVHR. These observations suggest that the lesions of GVHR in man and in nonhuman primates are comparable, and that the pathogenesis of GVHR in man and nonhuman primates may be similar.

The mechanism of cell death (ie, rejection) in GVHR in man is unknown. Host cell death may be due to direct interaction between host cell and aggressor lymphocyte,[1] to the intermediate involvement of host leukocytes (aggressor lymphocytes/host lymphocytes/host cell)[22,33] or to cytotoxic humoral factors.[30,34] Dobbeleer et al[30] emphasized that epidermal cell damage appears to occur independent of direct aggressor lymphocytic interaction with host cells. They postulated that the dyskeratotic bodies were due to toxic damage to the epidermis caused by "immunologic phenomenon complicating GVHR."[30] They felt that this theory is corroborated by the work of Merritt et al[34] who found IgM antibody that is cytotoxic (in vitro) for epithelial cells in the serum of patients with GVHR.

Contrary to findings of Dobbeleer et al,[30] our electron photomicrographs indicate that direct interaction between host cell and aggressor lymphocyte is a definite factor in the pathogenesis of GVHR. Furthermore, on study by direct immunofluorescence, the absence of IgM, IgG, C, and fibrinogen on the surface of keratinocytes seems to discount any primary pathogenic effect of cytotoxic antibody. While cytotoxic antibodies may be a factor in the pathogenesis of GVHR, our findings support the speculation made by Slavin and Woodruff[1] that the basic lesion of GVHR probably represents direct epithelial (host cell) interaction with aggressor lymphocytes. This suggests that cellular, delayed hypersensitivity is a major component of graft rejection.

The prominence and specificity of GVHR lesions, particularly SCN, refute the concept that distinctive lesions are rare or absent in GVHR-complicated CIDS. While emphasis has previously been on the nonepidermal features as essential in the diagnosis of GVHR, we emphasize the specificity of the epidermal findings, and strongly recommend that a cutaneous biopsy be performed, and an evaluation of the histopathological findings be made to facilitate an early definitive diagnosis.

Immunofluorescence studies were done by Denny L. Tuffanelli, MD.

Photographic work was done by Harry J. Roberts.

Primary Cutaneous Phaeohyphomycosis Caused by *Drechslera spicifera*

Stephen A. Estes, MD; William G. Merz, PhD; Lynne G. Maxwell, MD

• A primary cutaneous lesion in a 5-year-old boy who had recently received chemotherapy for acute lymphocytic leukemia was found to be caused by a dematiaceous fungus, *Drechslera spicifera*. The lesion was an erythematous macule that rapidly developed necrotic ulcerations. The fungus, which is commonly found in soil and as a plant pathogen, was isolated from cultures of the lesion and from an excisional biopsy specimen. Hyphae and swollen hyphal cells resembling chlamydospores were observed in the biopsy specimen. Septate pigmented hyphae were found in the tissue, which is consistent with phaeohyphomycosis. Resolution of the infection occurred following excisional biopsy and systemic amphotericin B therapy. There was a concomitant recovery from neutropenia.

(*Arch Dermatol* 113:813-815, 1977)

Opportunistic fungus infections in the immunocompromised host present a challenge to accurate diagnosis and treatment. Numerous reports substantiate the significant morbidity and mortality of such infections, and new organisms have recently been recognized as opportunistic pathogens.[1-3] Cutaneous manifestations have been reported with *Cryptococcus*,[4] *Aspergillus*,[5,6] *Candida*,[7] and *Mucor*[8,9] infections.

Members of the genus *Drechslera* are common soil saprophyte and plant pathogens known to occasionally cause cutaneous and subcutaneous lesions in dogs, cats, and horses.[10-12] These infections have been called maduromycotic mycetomas because masses of septate hyphae and chlamydospores were present in drainage and tissue from infected sites. Whether such infections possess true granules and can be termed mycetomas is disputed.[10] More recently, Ajello et al[13] proposed the term "phaeohyphomycosis" for subcutaneous and systemic infections characterized by dematiaceous septate mycelial elements in the tissue. *Drechslera* was not known to cause human disease until 1973, when a fatal case of a fungal meningoencephalitis caused by *Drechslera hawaiiensis* was recognized at postmortem examination in a 31-year-old woman with an unsuspected lymphocytic lymphosarcoma.[14] This report describes a primary cutaneous infection caused by a member of the genus *Drechslera*, and the first human infection, to our knowledge, caused by *Drechslera spicifera*.

REPORT OF A CASE

The patient was a 5-year-old boy with acute lymphoblastic leukemia first diagnosed in December 1973. He was admitted to the Children's Medical and Surgical Center of Johns Hopkins Hospital in relapse for the second time in August 1975 for chemotherapy with asparaginase and daunorubicin.

On the fifth day of chemotherapy his absolute neutrophil count dropped below 500/cu mm. On day 11 he developed a fever that was unresponsive to broad-spectrum antibiotics, and bacterial cultures were negative. On day 16, an erythematous 12 × 15-mm macule on the extensor surface of the left forearm was noted in an area that had been abraded by adhesive tape securing an intravenous catheter. By the next day (day 17) there were three pinpoint necrotic ulcerations on the surface of the lesion. Swabs of this lesion were sent for bacterial and fungal culture. Over the next 24 hours these necrotic areas rapidly expanded to 4 mm in diameter. Two days after this lesion was noted, a complete excisional biopsy was done (Fig 1). Frozen-section and touch preparation of the biopsy specimen revealed septate hyphae with acute angle branching, believed to be morphologically consistent with members of the genus *Aspergillus*. Cultures of both the surface swab and biopsy specimens grew an organism identified as *Drechslera* sp. No bacteria or viruses were recovered from the swabs or biopsy specimens. Amphotericin B therapy was begun on day 18, at a dosage of 1 mg/kg every other day for eight days. The total dose of amphotericin B was 45.8 mg; 100 units of sodium heparin and 50 mg of hydrocortisone were added to each 500 ml of intravenous fluid that was administered over a six-hour period. The decision to stop the amphotericin B was made when the patient's neutrophil count had increased to 1,012/cu mm concomitant with a well-healed biopsy site and no evidence of dissemination. No other cutaneous lesions appeared during the entire hospitalization.

Histopathologic Findings

The biopsy specimen was fixed in 10% neutral formaldehyde. Sections of the tissue were stained with hematoxylin-eosin, PAS, and the Grocott modification of the Gomori methenamine silver nitrate stain. Microscopic examination of the hematoxylin-eosin-stained sections demonstrated focal ulceration of the epidermis and necrotic areas within the papillary and mid-dermis (Fig 2). A lymphocytic and histiocytic reaction surrounded numerous small groups of irregular septate hyphae and enlarged mycelial elements (Fig 3). These microabscesses were present in the papillary and reticular dermis. Occasional neutrophils and foreign-body giant cells were also present in the microabscesses. No invasion of blood vessels or subcutaneous

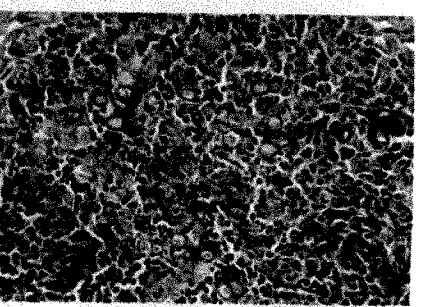

Fig 3.—Lymphocytic and histiocytic reaction surrounding fungal elements (hematoxylin-eosin, original magnification ×64).

tissue was noted.

PAS- and methenamine silver-stained sections showed septate hyphae (2.5 to 4.4 μ outside diameter) with acute branching and large swollen hyphal cells (5 to 31 μ outside diameter) resembling chlamydospores (Fig 4). One hyphal element was found within a foreign-body giant cell. An extensive review of unstained sections disclosed occasional golden-brown hyphae.

Mycological Findings

A pigmented organism grew out on Sabouraud dextrose agar after four days' incubation at 23 C from swabbings of the lesion taken on day 17. The fungus was identified as belonging to the *Helminthosporium-Drechslera* group and was considered a probable contaminant. Separate specimens of the skin biopsy were submitted to mycology, virology, and bacteriology laboratories. All three portions of the specimen also grew out a pigmented organism within five days. No other organisms were recovered from these specimens in any laboratory. During the time of the appearance of the cutaneous lesion, three blood specimens, an intravenous vascular catheter tip, and a bone marrow specimen were all negative for fungi.

The four isolates were studied further for a positive identification. Growth on Sabouraud dextrose agar at 23 C was rapid. The colony was approximately 6 cm in diameter after three days' incubation. The colony was fluffy, with a white border and dark gray center (Fig 5). On reverse, the colony was originally colorless and turned dark brown within seven days. Growth on brain-heart infusion agar at 37 C was slower than at 23 C; however, the colony morphology was similar in color but less fluffy than on Sabouraud dextrose agar at 23 C. No growth was noted on Sabouraud dextrose agar with chloramphenicol and cycloheximide at 23 C.

Examination of slide cultures prepared on corn meal-dextrose agar and incubated at 23 C for five days showed abundant production of pigmented, thick-walled conidia with four cells produced on unbranched pigmented conidiophores (Fig 6). The conidia measured an average of 25 μ in length and 9 μ in width. Up to four conidia were produced sympodially on each conidiophore. The conidiophores ranged from 13 to more than 100 μ in length, with an average outside diameter of 4.4 μ. These conidiophores gave the impression of producing a conidium, then growing around the spore, and producing another. The fungus was therefore identified as *Drechslera* sp, later specified as *Drechslera spicifera*, the imperfect state of the ascomycete *Cochliobolus spicifer*. Sensitivity testing determined that the organism was sensitive to flucytosine with a minimal inhibitory concentration of 0.78 μg/ml and a minimal fungicidal concentration of 6.2 μg/ml. Both inhibitory and fungicidal concentrations for amphotericin B were less than 0.05 μg/ml.

COMMENT

This case clearly illustrates the increasing variety of fungi that are capable of being opportunistic pathogens. Dematiaceous fungi have long been known to cause chronic subcutaneous infections. Ajello et al[13] have proposed that infections characterized by pigmented septate hyphae in tissue be designated as phaeohyphomycosis. In contrast, the fungi in mycotic mycetomas and chromomycosis are organized into discrete granules or sclerotic cells. *Drechslera spicifera* is a soil-, air-, and plant-borne organism known to cause subcutaneous phaeohyphomycosis in animals, presenting as chronic nodular granulomatous dermatitis.[10] However, this human case demonstrated a rapidly progressing necrotic cutaneous lesion with septate pigmented hyphae consistent with phaeohyphomycosis. Many other un-

suspecting fungi may be capable of producing similar infections in immunocompromised patients, and no fungi that are isolated may simply be ignored. Clinical and pathological investigations may be needed to resolve the clinical significance of any fungus isolated.

This case represents, to our knowledge, the first human cutaneous infection by *Drechslera spicifera* and the second time a member of this genus has been identified as a pathogen in humans. Fuste et al[14] reported a fatal case of meningoencephalitis caused by *Drechslera hawaiiensis* in a 31-year-old woman with an unsuspected lymphocytic lymphosarcoma. Similar histological findings have been reported in lung tissue taken from two patients without a detectable underlying neoplasm with bronchiectasis, chronic pneumonia, and, in one, multiple abscesses.[15] *Helminthosporium* was suggested as the pathogen in these cases, but definitive mycological identification was not done.

A number of factors probably contributed to this infection. The patient in the present case report was an immunocompromised host. He had a neoplastic process, was leukopenic, and had recently received cytotoxic therapy as well as broad-spectrum antibiotics. There was also a history of trauma from tape, which locally compromised his cutaneous barrier.

Opportunistic fungal infections such as in this case represent a real threat to the immunocompromised host. The morphology of the cutaneous lesion in this case was not distinctive. A rapidly spreading necrotic lesion in such hosts always raises the possibility of bacterial infection such as *Pseudomonas* as well as opportunistic fungal invaders such as *Aspergillus*. Indeed, we have recently observed cutaneous *Aspergillus* lesions in immunocompromised patients that looked remarkably similar to the lesion in this case.[16] These lesions provide the clinician a site in which an aggressive diagnostic approach can and must be initiated. Unlike fevers or pulmonary infiltrates in these patients, the cutaneous lesions allow rapid tissue diagnosis of a mycotic etiopathology. A biopsy of these lesions at their first appearance with frozen sections, touch preparation, and specimens for special mycological investigations is essential for diagnosis.

The diagnosis of phaeohyphomycosis rests on the observation of pigmented septate hyphae in tissue. The pigmented nature of the hyphae in this case was not obvious. An extensive review of unstained sections disclosed an occasional golden-brown hyphae. Muller et al[10] noted a similar sparsity of pigmented hyphae in their case of *Drechslera spicifera* in a cat.

No clinical, radiological, or cultural evidence of dissemination was found in this patient. During the time of the appearance of this cutaneous lesion, three blood specimens, an intravenous catheter tip, and a bone marrow specimen were all negative for fungi.

The successful resolution of this infection can probably be attributed to the early aggressive therapeutic approaches instituted. The initial excisional biopsy possibly removed all infected tissue. It was done with this intent and the entire lesion was excised. The amphotericin B therapy may have eradicated what organisms were left behind or had disseminated; it is speculative as to whether this was really of benefit or not. An alternative is that the patient's own immune status handled whatever organisms that remained, although it should be remembered that this lesion was growing rapidly prior to any therapy.

Cutaneous lesions caused by opportunistic fungi may be the primary site of infection that can lead to fatal disseminated disease rather than a secondary manifestation of disseminated infection. An aggressive diagnostic and therapeutic approach is strongly advocated in such instances.

M. B. Ellis, PhD, Commonwealth Mycological Institute, Kew, Surrey, England, identified the fungus as *Drechslera spicifera*. Smith Shadomy, PhD, Virginia Medical College, Richmond, did the sensitivity testing. George W. Hambrick, Jr, MD, and Patricia Charache, MD, critically reviewed this manuscript. Mary Zorn and June Lam gave secretarial assistance.

Westwood Pharmaceuticals, Inc, Buffalo, NY, financed the cost of the color reproductions.

Generalized Acute Mucocutaneous Herpes Simplex Type 2 With Fatal Outcome

Louis Lopyan, MD; Alexander W. Young, Jr, MD; Marilyn Menegus, PhD

• To our knowledge, we present the first culturally documented case of generalized acute mucocutaneous herpes simplex type 2 in an immunosuppressed adult who died during the course of the disease. The picture of the clinical spectrum of herpetic disease in immunosuppressed patients is detailed, and the need for typing the virus, particularly in the disseminated form, and for clarifying possible differences in epidemiology, clinical expression, and prognosis is emphasized.

(*Arch Dermatol* 113:816-818, 1977)

In 1974, Sutton et al[1] presented the first culturally documented and typed adult case of generalized acute mucocutaneous herpes simplex (HS) type 2 that occurred in a patient with thymic dysplasia. A review of the literature disclosed four other cases[2-5] that were proved culturally but were untyped, occurring in immunosuppressed adults without history of preexisting skin disease. The patient presented herein, who was receiving immunosuppressant drugs, is the first such culturally documented and typed case that, to our knowledge, has been reported.

REPORT OF A CASE

A 21-year-old woman with chronic glomerulonephritis was seen in the emergency room prior to hospitalization on April 9, 1973, complaining of fever, general malaise, and skin eruption of three weeks' duration. At this time, she appeared acutely ill and had a generalized, single and grouped, vesiculopustular, necrotic eruption of the glabrous skin and mucous membranes of the mouth, and an erosive, secondarily infected vulvitis and exudative vaginitis. Temperature was 39.1 C (Fig 1 through 3).

Medical history disclosed the first hospital admission to be in September 1971, when a diagnosis of stage 4 membranous glomerulonephritis on renal biopsy was made. Treatment with 10 mg of prednisone daily, 100 mg of azathioprine (Imuran) daily, and 400,000 units of penicillin three times a day was prescribed. On this regimen, the patient had remained well for two years, until the onset of her infection. The patient denied any past history of fever blisters or oral or vaginal lesions.

History of the illness indicated the onset of fever, shaking chills, myalgias, and skin disorder involving the vulva and buccal areas three weeks prior to admission. The eruption with fever (temperature rose on one occasion to 40.5 C) continued to develop and spread until the time of hospital admission. Dysuria and an erosive, necrotic vulvitis were prominent features throughout.

On hospital admission, results of urinalysis were the following: specific gravity, 1.009; protein, 2 +; WBC, 5 to 10/high-power field; RBC, 10 to 25/high-power field. Hemogram showed a hemoglobin level of 11.6 gm/100 ml, a hematocrit value of 34%, and a WBC count of 2,100/cu mm, with a normal differential cell count. Serum electrolyte determinations were normal, except for the following values: serum potassium, 5.5 mEq/liter; serum

glucose, 133 mg/100 ml; serum bilirubin, 136 mg/100 ml; serum creatinine, 13 mg/100 ml; serum calcium, 6.5 mg/100 ml; serum phosphorus, 6.8 mg/100 ml; serum cholesterol, 138 mg/100 ml; serum total protein, 4.5 gm/100 ml; serum albumin, 1.2 gm/100 ml; SGOT, 39 units lactic dehydrogenase, 570 units; serum alkaline phosphatase, 152 units. The chest roentgenogram and ECG were normal, except for sinus tachycardia.

Fig 3.—Edema and diffuse erosion of labia minora and multiple erosions extending to perianal region covered by prurulent exudate (from vulva).

A Tzank smear of a cutaneous lesion showed multinucleated giant cells with ballooning degeneration of the nuclei. A biopsy specimen of an intact vesicle showed intraepidermic acantholytic cells with ballooning degenerated and giant cells at the base and within the bulla cavity (Fig 4 and 5). Culture of fluid from an intact vesicle on the arm and the base of a vulvar erosion both grew HS virus, type 2.

Culture and typing of the virus was done in the following manner. Specimens for viral culture were obtained by vigorously rubbing a sterile cotton applicator over the lesion and then placing it in 2 ml of transport media (TM), minimum essential medium (MEM), with Earle salts containing 10 μg of amphotericin B, 100 μg of gentamicin sulfate, and 1,000 units of penicillin per milliliter (pH 7). Specimens were immediately transported to the laboratory where confluent monolayers of human embryonic kidney cells (HEK) and WI-38 cells in roller tubes were inoculated with 0.2 ml each of specimen. Before use, all cells were fluid changed to fresh maintenance medium consisting of MEM with Earle salts supplemented with 5% fetal calf serum and with 5 μg amphotericin B and 50 μg gentamicin sulfate added. All tubes were incubated at 2.2 C and were observed daily for evidence of viral cytopathic effect (CPE). Within 24 hours of inoculation, all HEK and WI-38 (human embryonic lung) cells inoculated with the vulvar lesion specimen showed focal CPE characteristic of HS virus type 2. Confirmation of viral type was performed by immunofluorescence study.

Initial therapy included cephalothin sodium (Keflin) (1 gm every six hours, intravenous), prednisone (10 mg daily), diphenhydramine hydrochloride (Benadryl) (25 mg four times daily), low potassium diet and potassium permanganate baths (1:9000

Fig 4.—Intact bulla taken from abdomen shows viral balloon giant cells admixed with inflammatory cells within bulla cavity (from abdomen) (hematoxylin-eosin, original magnification ×150).

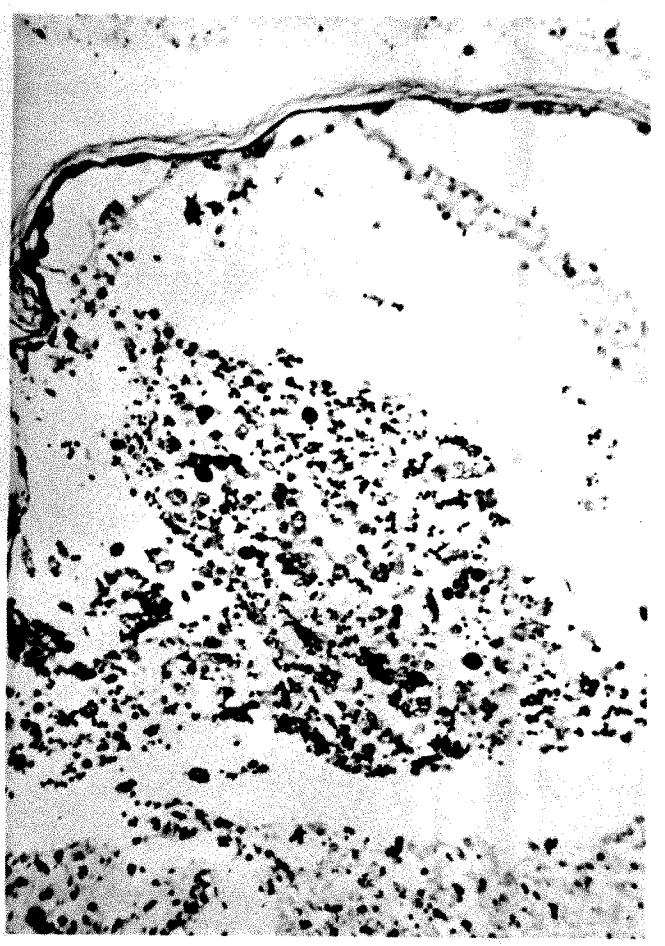

Fig 5.—High-power view of Fig 4 demonstrates multiple viral giant cells manifesting ballooning degeneration of nuclei (hematoxylin-eosin, original magnification ×450).

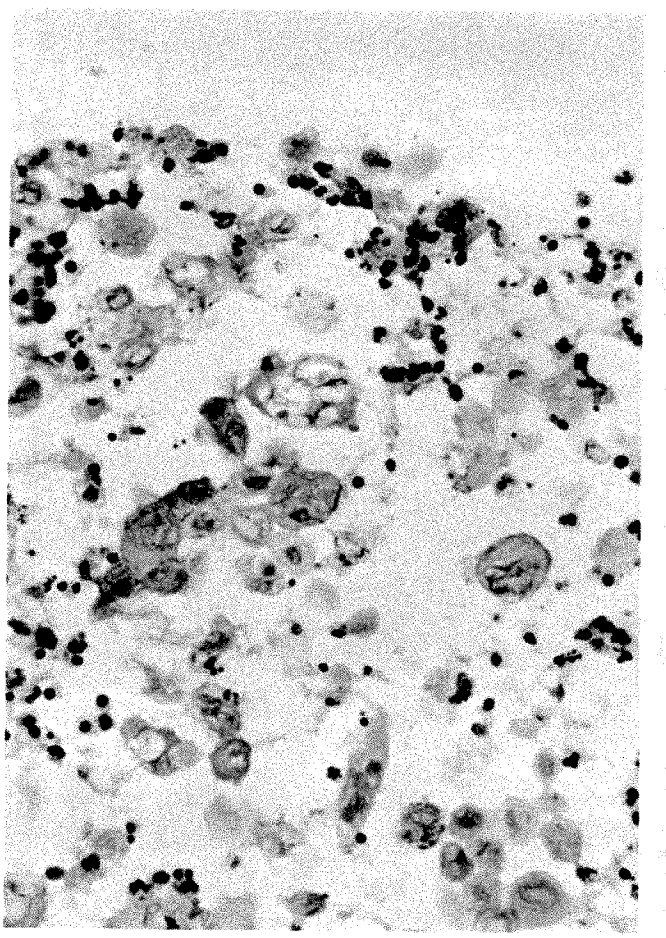

three times daily), and reverse isolation precautions.

The patient's condition remained stable until the third day of hospitalization, when she went into shock and sustained fatal cardiorespiratory arrest. Urine and blood cultures grew *Escherichia coli*.

Results of autopsy showed petechiae in the lungs, liver, adrenals, and kidneys; bilateral pleural effusions; a blood clot and hemorrhagic fluid in the peritoneal cavity; large, granular kidneys; and hemorrhages in the esophagus and stomach. Viral cultures of the lungs and kidneys were positive for cytomegalovirus (CMV); cultures of the spleen and adrenal gland were negative. Inclusion bodies consistent with CMV infection were seen in the lungs, kidneys, liver, pancreas, bone marrow, lymph nodes, and submucosal esophageal glands.

COMMENT

Certainly *E coli* sepsis as a preterminal event played a major role in the patient's death. The role of CMV in this patient is uncertain. Cytomegalovirus has been isolated from many immunosuppressed patients, but to our knowledge, its pathogenetic role has not been determined. Studies performed on patients undergoing renal transplants indicate that CMV may cause further immunosuppression[6] and may be a potential cause of injury to the lungs and liver.[7]

Nor has the exact pathogenetic role of HS virus been determined. However, review of the literature shows that more than 50% of the cases of generalized acute mucocutaneous HS virus have a fatal outcome. Whatever the exact pathogenetic role of the HS virus, this disease entity represents a grave prognostic sign.

The clinical disease and fatal outcome in this patient are remarkably similar to the case of thymic dysplasia presented by Sutton et al.[1] Both had an immunologic defect; both had generalized skin lesions including scalp and face and oral and vulvar disease caused by HS type 2 infection. In the latter, prednisone and azathioprine therapy for renal disease was associated with leukopenia (2,100/cu mm) predisposing to infection.

Cases of culturally documented but untyped disseminated HS have been reported. Those of Montgomerie et al (case 1)[2] and Lynfield et al[3] had a fatal termination; those of Rendtorf and Fowinkel[4] and Strom[5] were nonfatal. Although it is impossible to determine which type of HS was involved in these patients, those of Rendtorf and Fowinkel,[4] Lynfield et al,[3] and Strom,[5] which began in the genital area, clinically strongly suggest type 2 infection, whereas Montgomerie et al's case,[2] originating on the face, suggests type 1. Typing is recommended in future cases to identify possible differences in clinical expression and prognosis between HS, types 1 and 2.

The clinical spectrum of HS infection that develops in patients with immune deficiency varies. There have been numerous reports in the literature of localized ulcerations of the skin in immunosuppressed patients due to HS virus.[8-10] In 1971, Logan et al[9] described three cases of localized necrotizing herpetic ulcers in immunosuppressed patients, which he termed chronic cutaneous herpes.

At the other extreme is acute generalized mucocutaneous HS, as seen in our case and those of Montgomerie et al (case 1),[2] Lynfield et al,[3] Rendtorf and Fowinkel,[4] and Sutton et al.[1] These patients have a generalized skin and mucous membrane involvement that may extend to the viscera, an acute febrile course, and often, fatal outcome.

Within these limits is a clinical variety of HS infection that results from contiguous extension of the localized chronic cutaneous type. The lesions are usually long lasting and necrotic with regional spread. Montgomerie et al (cases 2 through 4)[2] and Muller et al(case 9)[10] have each presented examples of this picture. In the case herein, it is apparent that HS originated in the vulva and extended locally over a three-week period, prior to dissemination and fatal outcome. This course suggests that chronic cutaneous HS with regional spread has a potential to become generalized. For this clinical picture, the term regional chronic cutaneous HS is suggested.

This continuous spectrum of the clinical manifestation of HS infection in immunosuppressed patients is as follows: (1) localized form: ranging from localized recurrent HS with spontaneous healing (as seen in normal persons) to localized chronic cutaneous HS; (2) disseminated form: ranging from regional chronic cutaneous HS to generalized acute mucocutaneous HS (with or without visceral involvement).

Confirmation of viral type by immunofluorescence study was performed by Andre Nahmias, MD, at Emory University, Atlanta.

Erythema Elevatum Diutinum

Response to Dapsone

Lt Col Samuel L. Fort, MC, USA, Lt Col Orlando G. Rodman, MC, USA

• A patient with a 20-year history is presented as a classic example of erythema elevatum diutinum, with a dramatic response to dapsone therapy, and with interesting features of improvement during pregnancies and occurrence of giant cell tumors of soft tissue, neither of these latter features having been previously reported.

***(Arch Dermatol* 113:819-822, 1977)**

Erythema elevatum diutinum (EED) is a rare, chronic inflammatory dermatosis characterized clinically by the symmetrical occurrence of persistent red elevated lesions with a predilection for the skin over the extensor articular surfaces. Frequently, arthralgia and constitutional symptoms are present, but the patient's general health is unaffected. The etiology is unknown, but the dermatopathologic process is clearly a leukocytoclastic angiitis, with some of the older lesions appearing to undergo fibroproliferative transformation. Treatment with any number of modalities has been notably unsuccessful.[1-3]

REPORT OF A CASE

In January 1974, a 29-year-old white woman came to the Walter Reed Army Medical Center Dermatology Service with complaints of 19 years' duration. At the age of 10 years, the patient had a febrile illness with pain and swelling of the knee joints. Rheumatic fever was diagnosed, and she spent six to eight weeks in bed. Several months later, she was thought to have had a relapse, and it was approximately at this time that she began to develop lesions on her hands, fingers, and elbows. Since that time she has had episodic malaise, weakness, polyarthralgia, and the appearance of asymptomatic erythematous lesions over the extensor surfaces of the finger joints, elbows, knees, and to a lesser extent over the forearms, some of the lesions persisting indefinitely and others resolving spontaneously. Her main complaint has been with the joint pain and malaise, beside which the asymptomatic cutaneous lesions have been insignificant. Aspirin has given some minimal relief of the arthralgia but otherwise has had no effect on the condition. She has seen numerous physicians with no firm diagnosis and no effective treatment; however, she has noted dramatic relief of all symptoms during each of her three pregnancies. Her general health has been excellent. In 1969, she consulted an orthopedic surgeon because of an asymptomatic nodule on the right index finger. The nodule had grown slowly over the previous year. It was excised, and the tissue diagnosis was giant cell tumor. In 1971, an identical lesion appeared on the distal phalanx of the right fifth finger and continued to slowly enlarge.

On physical examination positive findings were confined to the skin. Red infiltrated papules, nodules, and plaques were prominent over the dorsa of the hands, particularly over the metacarpophalangeal and interphalangeal joints (Fig 1). These were also present over the extensor surfaces of the knees and elbows, and a few firm yellowish lesions were present on the volar surface of the right forearm. Some of the red lesions blanched with pressure, and others did not. There was a 1 × 1 cm firm, smooth, shiny nodule over the dorsolateral aspect of the right fifth distal interphalangeal joint (Fig 2).

Laboratory determinations were all normal with the exception of a slightly elevated sedimentation rate on one occasion. These determinations included CBC and differential cell count, automated blood chemical analysis, urinalysis, serum triglycerides, cholesterol, throat culture, urine culture, VDRL test for syphilis, rheumatoid factor, fluorescent antibody, lupus erythematosus preparation, serum protein electrophoresis, and quantitative immunoglobulin determination.

Four biopsies were done at our clinic and reviewed by the Skin and Gastrointestinal Branch of the Armed Forces Institute of Pathology, all showing essentially identical pictures (Fig 3 and 4): leukocytoclastic angiitis with marked dermal infiltration with neutrophils and their fragments. Lesser numbers of lymphocytes, histiocytes, plasma cells, and eosinophils were seen. Hemorrhage was not seen. A few vessels showed fibrinoid degeneration of their walls (Fig 4). The epidermis was not involved, and an upper dermal grenz zone of uninvolved dermis was present. Excision of the right fifth finger nodule revealed it to be a giant cell tumor of tendon sheath, showing an incompletely encapsulated tumor composed of closely packed round and polyhedral basophilic-staining cells with large pale oval nuclei, foamy histiocytes, and multinucleated giant cells. Dense bands of hyalinized stroma extended from the capsule throughout the tumor (Fig 5).

In May 1974, a regimen of dapsone, 100 mg three times daily, was begun. Within one week, the patient experienced dramatic relief of her arthritic and malaise symptoms and some of the cutaneous lesions cleared entirely. Over the ensuing months, the dapsone dosage was decreased stepwise to her present dosage of 50 mg daily. She has been virtually asymptomatic since dapsone therapy was begun, the skin lesions diminishing in substance and new ones seldom occurring. An attempt at discontinuation of the dapsone resulted in relapse symptoms of arthralgia and malaise within 24 hours.

COMMENT

In 1894, Radcliffe-Crocker and Williams[4] coined the name "Erythema Elevatum Diutinum" for a condition first described by Hutchinson in

1878,[5,6] and by Bury in 1889.[7] For a long time, there was confusion between EED and granuloma annulare, but by the late 1920s the precise histopathology of EED, as well as of granuloma annulare, had been established, and the two were clearly separate entities.[1,8,9] Confusion lingered as to a Hutchinson type and a Bury type of EED, but this distinction is no longer considered valid.[1,2,10] Another confusing issue was introduced in the 1930s with reports of a seemingly new entity called extracellular cholesterolosis.[11,12] This is now considered to be a variant of EED[2,13] not deserving of separate nosologic status.

Erythema elevatum diutinum is a chronic disease, waxing and waning in severity. It is thought to eventually involute spontaneously, usually after five to ten years.[1] Our patient has had EED for 20 years. The longest case recorded in the literature is 25 years.[14] Neither sex predominates.[1,15,16] Most cases begin in middle age but the age at onset may vary from 6 months[17] to 75 years.[3] There is no familial tendency, although one instance of occurrence in mother and daughter has been reported.[17] Almost all reported patients have been white, but two were oriental.[10,18] One poorly documented case in a black has been reported.[19]

General health and longevity are unaffected, with no known systemic component other than constitutional.[3,15,16] The major pathological events are presumed to be confined to the skin. However, constitutional symptomatology is common, can be severe, and indeed can be the patient's chief complaint as was the case with our patient. Arthralgia in particular is to be emphasized.[1,9,16,17] Fever might occur but usually does not. There is no particular association of EED with any other disease.[3,15]

The skin lesions are red (erythema), raised (elevatum), and persistent (diutinum). Most of them are of a red, purplish or brownish color but some are strikingly xanthochromic. They may occur as papules, nodules, or plaques up to 6 cm in width.[1] Coalescence of lesions may produce irregular, arcuate or gyrate forms.[1,16] Vesicular or bullous lesions may occur.[2,10,15] Early lesions are soft to firm but older lesions may be quite hard, reflecting a fibrosing tendency as lesions age.[15,20] Although the lesions are characteristically persistent, the life history of any lesion is variable and unpredictable. It might arise and persist indefinitely, it might resolve completely, never to return, or it might recur in the same location. Once a lesion has resolved, residual hyperpigmentation is common, and slight atrophy may occur.[1,3]

The acral distribution with almost invariable truncal sparing is highly characteristic. Classically, the lesions are symmetrically distributed over the extensor surfaces of the finger joints, elbows, and knees. Other commonly involved sites are the buttocks, lower legs, and pinnae of the ears.[1-3] Lesions of EED are usually asymptomatic, but pruritus or pain may occur in an occasional case.[1-3,15]

The pathological process observed is that of a strikingly prominent leukocytoclastic angiitis,[1-3,9,20] with neutrophils and their fragments present not only in the walls of the small vessels of the dermis and their immediate perivascular area, but also diffusely infiltrating the dermis, distant from as well as near to the vessels.[1-3] The infiltrate is polymorphous, with lymphocytes, histiocytes, plasma cells, and eosinophils, but the overwhelming majority are neutrophils.[3,9] In some but not all biopsy specimens of EED, an eosinophilic hyaline material is noted within and around the vessel walls.[1,3,9,20] The term "toxic hyaline" was used by Weidman and Besancon to denote this material when they definitively established the histopathological features of EED in 1929.[9] There is no justification for the continued use of this special appellation, however, as the picture is essentially identical to that of fibrinoid

degeneration. The epidermis is usually uninvolved, but secondary changes of acanthosis, spongiosis, and superficial necrosis are occasionally present.[1,2,21]

Giant cell tumor of soft tissue,[22-28] not to be confused with giant cell tumor of bone (osteoclastoma) or giant cell epulis of gingiva, connotes a distinctive histopathologic entity, which when forming a discrete nodule attached to a tendon is called giant cell tumor of tendon sheath, and when diffusely spread over a broad area such as a joint synovium is called villonodular synovitis. Giant cell tumor can occur in other soft tissues, so that "giant cell tumor of soft tissue" is an appropriate inclusive term. It is a fairly common condition, occurring more frequently in women, usually in the young to middle-aged, and occurring most commonly on a finger, usually as a solitary nodule 1 to 3 cm in size, of a yellowish color and a firm consistency. The lesion on our patient is a classical example both clinically and histopathologically (Fig 2 and 5). It is usually asymptomatic and slowly growing over months to years, but rapid acceleration of growth can occur. Giant cell tumor is benign histologically and in behavior, although mitotic figures are not uncommon and contiguous bone may be eroded by pressure of the tumor. Excision is usually curative but recurrences occasionally occur. The histopathological appearance is distinctive, being that of a fibrocellular tumor with histiocytic-appearing polyhedral cells, lipid-laden cells, hemosiderin-laden cells, and multinucleated giant cells. These latter give the entity its name, but they need not be a prominent component. There is a tendency for fibrous encapsulation and for hyalinization of the stroma.[27] Giant cell tumor is considered to be a variant of fibrous histiocytoma,[22,28] of which more familiar variants are dermatofibroma, sclerosing hemangioma, and dermatofibrosarcoma protuberans. As is the situation with dermatofibroma and other fibrous histiocytomas, it is unknown whether giant cell tumor is a "true neoplasm" or whether it is a reactive fibrocellular hyperplasia secondary to some inflammatory injury. One might speculate that the giant cell tumors in our patient represented a fibrohistiocytic proliferative response to repetitive inflammatory injury from the EED; there is, of course, no way of proving this. Intriguing in any case is the coexistence in the same patient of an inflammatory condition, EED, which can eventuate in a fibroproliferative response and a fibroproliferative lesion, giant cell tumor, which possibly originates from an inflammatory stimulus. The two conditions allude to each other in this patient.

The pathogenesis of EED is unknown. The occurrence of an Arthus-type of phenomenon is suggested by the histological findings of a leukocytoclastic angiitis.[1,29] No antinuclear antibodies have been found in the few cases tested. Elevated[3,19,29,30] as well as normal[31] levels of immunoglobulin have been reported. Our patient's immunoglobulin levels were normal in the midst of therapy, but pretreatment levels were not obtained. Examination for tissue deposits of immu-

noglobulin by the immunofluorescent technique has been done in at least one reported case, but the results were inconclusive.[29] Two cases have been reported in which intradermal injection of streptococcal antigen resulted in a delayed reaction whose histopathological finding was a leukocytoclastic angiitis identical to the clinical lesions.[29] Others have done this test with negative results.[31] There are no consistent laboratory abnormalities in EED.[3]

The striking response of our patient's EED to pregnancy is of particular interest, as it has not been reported before. With each of her three pregnancies, she noted a very definite improvement beginning within the first four to six weeks of pregnancy and continuing throughout the pregnancy, with relapse of the EED within two to three weeks after parturition. A reasonable speculation would be that some kind of hormonal influence was acting. In any case, she has taken norethindrone acetate-ethinyl estradiol as a contraceptive, with neither beneficial nor detrimental effect on the EED.

Erythema elevatum diutinum is notoriously resistant to treatment. Any number of agents and modalities, including systemic corticosteroids, have been attempted without consistent success.[2,3,16,29,30] Several instances of response to chloroquine have been quoted or reported,[16,17,32,33] but instances of failure with it and its hydroxy analog have been noted as well.[3,16,17,34] Since 1960, reports have come from Germany and England of a good response to sulfones. Including our patient, six cases of response to dapsone have been reported and in each instance the response has been dramatic.[19,29,30,35] Two cases of dapsone failure have been reported.[29,36] The mechanism of action of dapsone in EED is not known. Perhaps dapsone's action in EED is similar to its action in dermatitis herpetiformis: both are chronic diseases in which the neutrophil is conspicuous. It has been hypothesized that in dermatitis herpetiformis, dapsone might work by stabilizing the neutrophilic lysosomes[37] or by interfering with the deposition of complement (C3).[38] Whatever its mode of action in EED, dapsone is suppressive rather than curative. As in dermatitis herpetiformis, discontinuation of dapsone results in relapse.[19,29]

The clinical differential diagnosis of EED includes the multicentric syndromic form of reticulohistiocytoma, dermatomyositis, Sweet syndrome, granuloma annulare, hypertrophic lichen planus, xanthoma tuberosum, and cutaneous sarcoidosis. The histologic differential diagnosis would include granuloma faciale, Sweet syndrome, and leukocytoclastic angiitis of whatever etiology. Taken separately, either the clinical or the histologic features of EED are sufficiently characteristic as to suggest the diagnosis; taken together, there is hardly another condition to compete for the diagnosis, particularly after it has demonstrated its remarkable chronicity.

Supernumerary Areolae

Lt Comdr Stephen W. Shewmake, MC, USN, Capt Gene T. Izuno, MC, USN

• One of the more unusual forms of supernumerary breast tissue is characterized by the presence of areolar tissue only. The case presented describes a patient with three supernumerary areolae, including one located outside the embryonic milk line. There is a possibility that this finding represents an atavistic phenomenon.

(Arch Dermatol **113:823-825, 1977)**

Polythelia, polymastia, and other forms of supernumerary breast tissue are clinical entities that present an unusual and striking appearance. The reported incidence varies from 0.4% to 6%,[1-4] and the most common form is the isolated presence of an accessory nipple or nipples (polythelia).[1,5,6] One of the more unusual forms of aberrant breast tissue, characterized by the presence of areola only, is a condition known as polythelia areolaris.[3,6,7] The term "polythelia" is of Greek derivation meaning "many nipple."[3] Polythelia areolaris, when used to describe the isolated clinical presence of aberrant areolar tissue alone, is inaccurate and contradictory. It would be more aptly described as "supernumerary areolae."

This report discusses a case of supernumerary areolae as compared with other related types of supernumerary breast tissue. The patient in this report was also noted to have an aberrant areola located outside the milk line. The possibility that this finding may be an atavistic phenomenon is also considered.

REPORT OF A CASE

A 32-year-old woman of Italian descent was seen in the Dermatology Clinic at the Naval Regional Medical Center in San Diego in October 1974. She related a lifelong history of pigmented "wrinkled" lesions located on the right shoulder, right-upper abdomen, and right side of the pubic region (Fig 1). There was no history of previous injury or trauma to these areas. There was no history of tenderness or swelling associated with pregnancy or menses but, she stated, these lesions had become darker brown after each of her three pregnancies. She denied any family history of similar lesions. Physical examination revealed a 1.5 × 2.5 cm irregular atrophic pigmented lesion in the right shoulder region near the base of the neck. No nipple or hair was present. A 2.8 × 3.5 cm wrinkled, hyperpigmented depressed macular lesion was present on the right-upper abdomen, directly beneath the right breast (Fig 2). No erectile protuberance or nipple was noted and glandular tissue could not be palpated beneath the lesion. Surrounding the lesion was a collarette of dense dark hair. Examination of the pubic region revealed a 3.5 × 3.5 cm atrophic-appearing, hyperpigmented lesion located within the pubic hair of the right lateral aspect of the mons pubis (Fig 3). This lesion was nonhair-bearing and again, no nipple or glandular tissue was detected. Examination along the left milk line from the axilla to the groin revealed no similar lesions. Elliptical biopsies of all three lesions revealed similar histopathological findings.

All three tissue specimens demonstrated an irregular epidermal surface with tall connective tissue papillae and a small amount of hyperkeratosis and epidermal pigmentation. Vacuolar degeneration was abundant throughout all epidermal layers (Fig 4). Smooth muscle bundles were present in great numbers randomly interlacing in the mid and reticular portions of the dermis (Fig 5 and 6). This represents one of the most characteristic histopathological features of areolar tissue. Lactiferous ducts and the glands of Montgomery were not noted in any of the specimens.

The lack of lactiferous ducts and the accessory glands of Montgomery within the tissue specimens is explained by the fact that these ducts are found only at the tips of the nipples, and the glands of Montgomery are associated only with the palpable tubercles present on the areolar surfaces.[7] Since these clinical structures were not present in our patient's lesions,

Reprints not available.

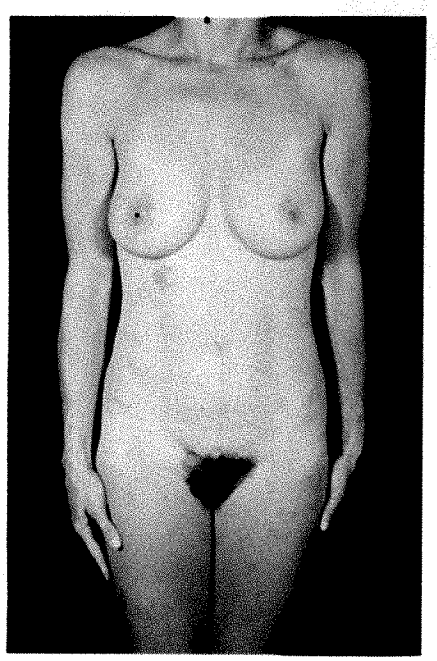

Fig 1.—Supernumerary areolae of right shoulder, right-upper abdomen, and the right pubic region.

Fig 2.—Supernumerary areola located at right margin of pubic region.

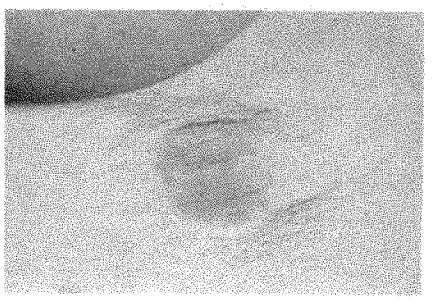

Fig 3.—Supernumerary areola of right-upper abdomen.

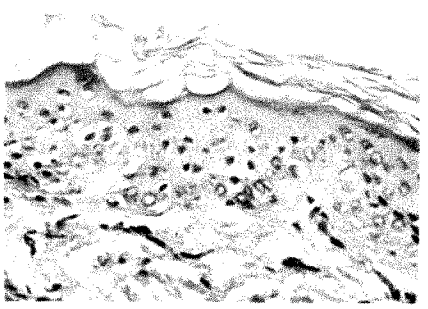

Fig 4.—Median power view of tissue from right shoulder showing slight hyperkeratosis and abundant vacuolar degeneration throughout the epidermis (hematoxylin-eosin, original magnification ×128).

Fig 5.—Scanning magnification of tissue from right abdomen showing irregular epidermal surface and numerous smooth muscle bundles interlacing in mid and lower dermis (hematoxylin-eosin, original magnification ×40).

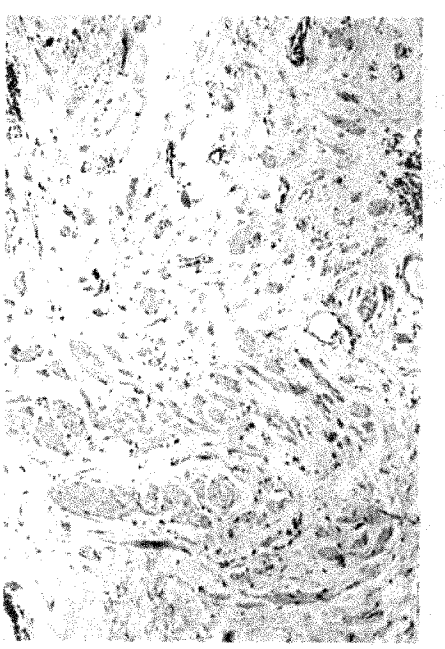

Fig 6.—Higher magnification of Fig 5 showing abundant smooth muscle bundles and scattered dilated capillaries within fine collagenous stroma (hematoxylin-eosin, original magnification ×102).

the absence of lactiferous ducts and the accessory glands of Montgomery in this case would not be inconsistent with the diagnosis of supernumerary areolae.

COMMENT

The presence of supernumerary breast tissue in humans has been well documented in the medical literature.[1-4] As most reports deal with only the subject of polythelia, the rare type of aberrant breast tissue reported here has seldom been mentioned. The classification of supernumerary breast tissue first described by Kajava in 1915 is still in use today and consists of the following categories[2,5,6]:

1. Complete breast with nipple, areola, and gland tissue.
2. Supernumerary breast without areola but with nipple and gland tissue.
3. Supernumerary breast without nipple but with areola and gland tissue.
4. Aberrant gland tissue only.
5. Nipple and areola with gland tissue replaced by fat–pseudomamma.
6. Nipples only–polythelia.
7. Areola only–polythelia areolaris.
8. Patch of hair only–polythelia pilosa.

In this classification, Kajava restricted the definition of the term "nipple" to mean only the protuberance in the center of the areola.[5] Unfortunately, most reports of polythelia or supernumerary nipples define this term in a very broad sense as follows: a papilla or protuberance, which may or may not be associated with areola, follicles, and/or hair.

Supernumerary breast tissue usually occurs only along the milk line that extends from the axillary area to the groin.[2-4] Polythelia and pseudomamma represent the most common forms of aberrant breast tissue.[5] Complete supernumerary breasts are exceptional but, when present, they can secrete milk during lactation and undergo cyclic as well as potentially malignant changes as does the normal breast.[2-4] Aberrant glandular tissue, alone, is observed infrequently and is almost exclusively limited to the axillary areas.[6] These lesions are commonly bilateral, usually becoming apparent at or after puberty and especially during pregnancy. This aberrant glandular tissue is also capable of developing the same pathophysiologic changes as normal breast tissue. Since there is no outward visible lesion, this condition is often misdiagnosed as lipoma, lymphoma, lymphadenitis, or hidradenitis suppurativa.[7]

The various types of supernumerary breast tissue develop most often in the embryonic milk lines, but they can also occur at atypical locations on the torso or extremities at sites that are normal in certain other mammals.[2] One theory as to why lesions occur outside the embryonic milk lines is based on the premise that misplaced embryonic anlage represents reversion to more primitive or ancestral characteristics.[2,3] This is known as the Geffroy-Saint-Hilaire-Darwin theory of atavism.[2,3] The lesion on our patient's right posterior shoulder may represent such an atavistic phenomenon since breasts are normally found in the same anatomical location of animals such as the nutria and the gentle lemur.[2] De Cholnoky reviewed 64 patients with supernumerary breasts in atypical locations and found that they occur at many unusual sites. He included three cases of lesions occurring in the shoulder region.[1,2] Other authors,[2,5] however, have regarded the presence of supernumerary breast tissue, regardless of its location, to be accidents of development having no phylogenic significance.

The presence of supernumerary breast tissue can also be an indicator of systemic disease. A number of authors have drawn attention to the association of aberrant breast tissue and peptic ulcer disease, neurosis, cardiovascular disease, and renal and gonadal hypoplasia.[3,6-8,9] Evans,[3] in a detailed study, found the incidence of polythelia much higher in patients with systemic hypertension who had either enlarged left ventricles, pulmonary hypertension with right ventricular hypertrophy, or cardiomyopathy. Ash-Upmark[10] found an association between inverted nipples and migraine headaches. Fleisher[11] noted that nipples that were lateral to the midclavicular line (wide set) were associated with an increased incidence of renal hypoplasia and gonadal dysplasia. The more unusual varieties of supernumerary breast tissue such as supernumerary areolae have not been reported as being associated with systemic disease.

Surgical treatment of supernumerary breast tissue, especially of supernumerary areolae, is usually performed for cosmetic reasons. If glandular tissue is present, carcinomatous change can occur, but does so only very rarely.[2,4,12]

This investigation was supported in part by Bureau of Medicine and Surgery Clinical Investigation Program.

Westwood Pharmaceuticals, Inc, supplied a grant for the publication of the color photographs.

For Skin Without Water

Neutrogena® Dry Skin products are specially formulated to supplement surface fats and aid in the retention of moisture.

- Neutrogena® Dry-Skin Soap contains humectants, lubricants, and emollients to soften and moisturize, and is nonirritating to sensitive skin.
- Neutrogena® Rainbath® Dry Skin Bath Gel is lipid-free, cleanses with a rich lather without the drying effect of ordinary soap, and leaves skin soft and smooth. Available both scented and unscented.
- Neutrogena® Hand Cream is a heavy-duty formula containing a special blend of naturally occurring oils and glycerin, and is a useful adjunct in steroid-responsive hand dermatoses.[1]

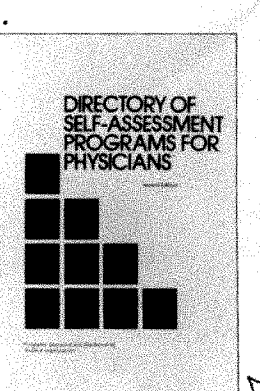
Los Angeles, California 90045

Now available! The latest information on self-assessment programs.

The new edition of the AMA's DIRECTORY OF SELF-ASSESSMENT PROGRAMS FOR PHYSICIANS is now available. It lists programs sponsored by all major specialty societies, on 21 topics.

Each program is listed by topic and sponsor and includes sites and times of tests, content, format, time required, method of scoring, aids to learning, fees and whom to write.

To order your copy of the Directory, ($1 ea.) write: Order Dept. OP-414, American Medical Association, 535 N. Dearborn St., Chicago, Ill. 60610.



For Skin Plagued by Acne

Neutrogena® Acne products aid in drying while they clean and degrease acne-plagued skin.

- Neutrogena® Acne-Cleansing Soap gently cleanses and degreases the skin, and does not interfere with topical or systemic acne treatment.
- Neutrogena® Acne-Drying Gel combines antisepsis with astringency, contains 47% active drying agents, is perfume-free, can be applied under or over makeup, and is imperceptible on the skin.

Neutrogena®
Dedicated to Sensitive Skin Care

Neutrogena Corp.

Perma Tweez®

ELECTROLYSIS FOR PERMANENT HAIR REMOVAL

Clinical study (copy on request) proves safety and efficacy of laity self-use electrolysis. Study shows chin and even axilla can be self-treated effectively through use of mirror. This permanent hair remover features the only patented self-correcting needle in existence. Battery operated instrument sterilizes itself when current flows. No-puncture safety feature also helps prevent infection.

Thousands of units sold to physicians for such varied application as removal of inverted eyelashes to cosmetic use.

Review Article

Lupus Band Test

Eugene W. Monroe, MD

• **The lupus band test (LBT) is a direct immunofluorescent technique for demonstrating a band of localized immunoglobulins at the dermal-epidermal junction in the skin of patients with lupus erythematosus (LE). Studies have shown immunoglobulins and complement at the dermal-epidermal junction in systemic (involved and uninvolved skin) and in discoid (involved skin only) LE. It is essential that the appropriate skin site be selected for biopsy; ie, involved or uninvolved skin, light-exposed or light-protected skin. The proper location of the biopsy site is determined by whether the LBT is intended for diagnostic or prognostic purposes. From a diagnostic standpoint, the LBT is a very sensitive and specific test for LE. In addition, this procedure has considerable value as a prognostic test for a patient with an established diagnosis of LE.**

(*Arch Dermatol* 113:830-834, 1977)

In 1963 Burnham et al,[1] using direct immunofluorescent techniques, demonstrated a band of localized immunoglobulins at the dermal-epidermal junction in the skin of patients with discoid (involved skin only) and systemic (involved and uninvolved skin) lupus erythematosus (LE). This immunofluorescent technique has become known as the lupus band test (LBT). In 1964 Cormane[2] demonstrated that certain patients with systemic LE had a band of immunoglobulins at the dermal-epidermal junction of visibly normal skin. Subsequently, several other studies[3-16] have shown immunoglobulins and complement at the dermal-epidermal junction in systemic and in discoid LE.

Three patterns of immunoglobulin deposition at the dermal-epidermal junction have been observed by various investigators.[9,13] A homogeneous or solid band of well-demarcated, bright fluorescence is seen mostly in chronic atrophic or hyperkeratotic skin lesions. A pattern of multiple, short, closely set, bright threads or fibrils is seen in more acute erythematous, edematous lesions, and occasionally, in clinically normal skin. A stippled band consisting of multiple small round points of fluorescence is the type most commonly seen in the clinically normal skin of systemic LE patients.

The frequency of the various immunoglobulin classes present in the subepidermal deposits varies with reports from different investigators. Several studies have shown that IgG represents the predominant immunoglobulin in the bands.[3,4,9] Other studies have shown IgM to be predominant.[17,18] In a recent study, Gilliam[19] found that approximately 80% of the patients with subepidermal staining had IgG at the dermal-epidermal junction and an equal number had IgM. The most frequent combination was IgG and IgM. Occasionally, IgA was found but always in combination with IgG. The importance of these data is that in performing the LBT, antiserum directed against both IgG and IgM must be used or a large number of false-negative test results will occur.

Other immunopathologic investigations have shown dermal-epidermal deposition of complement (C3 and C4) in involved and uninvolved systemic LE skin, suggesting involvement of the classical complement cascade.[8-10,17,18] More recent investigations have also demonstrated deposition of properdin or C3 proactivator, or both, in involved and uninvolved systemic LE skin, suggesting activation of the alternative complement pathway.[17,18,20,21] To what extent the classical and alternative pathways of complement activation are involved in the production of these skin lesions must still be resolved.

Some studies[22-25] have been performed to clarify the nature of the immunoglobulin deposits present at the dermal-epidermal junction in patients with LE. Acid buffer eluates from the skin of LE patients have disclosed both antinuclear and antibasement membrane properties of the deposited antibodies. However, circulating basement membrane antibodies have not been demonstrated in patients with LE.

The LBT is a very useful tool for the physician. This procedure has value as both a diagnostic and a prognostic test. The purpose for which the LBT is

intended, for example, diagnosis or prognosis, will dictate the proper location of the biopsy site. It should be stressed that when one refers to the LBT, he must specify the exact site of the biopsy—whether it is involved or uninvolved or light-exposed or light-protected skin. This is critical as results will vary in the same person depending on the site selected for the biopsy.

DIAGNOSTIC VALUE OF LBT

The value of the LBT as a diagnostic tool is well established. Its primary use is in diagnosing LE in patients with cutaneous lesions. Approximately 90% to 95% of the patients with systemic or discoid LE have a positive LBT in involved skin.[26,27] Thus, the test in involved skin is a very sensitive indicator of LE; ie, there are few false-negative test reactions.

The specificity of the LBT is also very high in differentiating LE from other cutaneous disorders that are clinically similar; ie, there are few false-positive test findings. Dermal-epidermal fluorescence is almost always negative in the following conditions: polymorphic light eruption,[7,10,14,15,28] benign lymphocytic infiltrates of Jessner,[10,26,29,30] lymphocytoma cutis,[15,26] lichen planus,[14,15,26,31] seborrheic dermatitis,[14,15,26] contact dermatitis,[14,15,26] drug eruptions,[26] psoriasis,[14,15,26] sarcoid,[14,26] pseudopelade,[26] morphea,[26] vitiligo,[26] idiopathic vasculitis,[14,15,31] and purpura.[31]

Some of the diseases that have had isolated reports of positive dermal-epidermal immunofluorescence reactions are indicated in the following tabulation.

Bullous pemphigoid[26,32]
Cutaneous porphyria[8,26,33]
Dermatitis herpetiformis[26,34]
Cicatricial pemphigoid[37]
Pemphigus erythematosus[26,38]
Hypocomplementemic vasculitis[26]
Anaphylactoid purpura[39]
Facial telangiectasia[26,35,36]
Rosacea[26,35,36]
Polymorphous light eruption[26,40]
Benign lymphocytic infiltrates[9]
Lepromatous leprosy[26,41,42]
Amyloidosis[26]
Primary biliary cirrhosis with amyloidosis[19]
Autoimmune thyroiditis[43]
Cold agglutinin syndrome[43]
Chronic biological false-positive reactions for syphilis reactions[43]
Phenobarbital-induced bullae[31]
Drug-induced LE[31,44,45]
Scleroderma[7,36]
Dermatomyositis[20,16,46]
Rheumatoid arthritis[19]
Mixed connective tissue disease[47]

Two of these diseases, bullous pemphigoid and cutaneous porphyria, usually have positive immunofluorescence.[26] However, other clinical and laboratory data should easily distinguish them from LE. In bullous pemphigoid the homogeneous band is often tubular in appearance with a dark center and brighter, sharply demarcated margins. In contrast, the band in LE tends to be wider and more solidly homogeneous.[14] In addition, bullous pemphigoid usually has circulating antibodies directed against the epithelial basement membrane and a negative antinuclear antibody (ANA).[32] In cutaneous porphyrias, fluorescence of the dermal-epidermal junction is usually much less intense than that found in the dermal blood vessels—exactly the reverse of the usual situation in LE. In addition, complement is rarely found in the band.[8,26,33] In dermatitis herpetiformis, the diagnostic immunofluorescent finding is the deposition of IgA at the dermal-epidermal junction, predominantly at the tips of the dermal papillae.[26,34] Studies have shown the frequent presence of dermal-epidermal junction fluorescence in the lesions of patients with rosacea and patients with facial telangiectasia, either essential in origin or those accompanying systemic scleroderma.[26,35,36] In lesions of lepromatous leprosy, dermal-epidermal fluorescence, predominantly of an IgM type, is often present.[26,41,42] Similar deposits were also found in clinically normal but histologically abnormal lepromatous leprosy skin.[42]

Two conditions that may be confused with lupus clinically, polymorphous light eruption and Jessner benign lymphocytic infiltrates, have had a few rare reports of dermal-epidermal fluorescence.[9,26,40] However, most large studies have shown consistently negative LBT findings in patients with polymorphous light eruptions[7,10,14,15,28] and Jessner lymphocytic infiltrates.[10,26,29,30] The immunofluorescent findings in drug-induced LE, scleroderma, dermatomyositis, rheumatoid arthritis, and mixed connective tissue disease will be discussed under the subject of other ANA-positive diseases. We believe, from reviewing all available data, direct immunofluorescence of involved skin is, in general, more sensitive and specific in differentiating LE from most conditions than is a routine histopathologic study of a biopsy specimen.[26]

The second diagnostic value of the LBT is in the differential diagnosis of systemic from discoid LE. Whereas both usually have positive direct immunofluorescence in involved skin, only systemic LE has positive immunofluorescence in clinically normal

light-protected skin (Table 1). Approximately 50% of systemic LE patients have positive LBTs in uninvolved light-protected skin.[19,26] No cases of positive LBT reactions have been reported in the normal skin of patients with discoid LE.[19,26,27]

The third diagnostic value of the LBT occurs in making a diagnosis of systemic LE in patients without cutaneous lesions. When cutaneous lesions are absent, most authors suggest that biopsies be made of sun-exposed skin, such as the dorsal forearm. The incidence of positive LBT results in uninvolved, sun-exposed skin of systemic LE patients is somewhere between 50% (the incidence in normal light-protected skin) and 95% (the incidence in involved skin). In the experience of Jablonska and Chorzelski[10] about 80% of these patients have positive LBTs in normal skin from the dorsal forearm.

The differentiation of systemic LE from other connective tissue diseases is sometimes quite difficult because their clinical and serologic pictures often overlap. A fourth diagnostic value of the LBT occurs in the diagnosis of SLE from these other antinuclear-antibody (ANA) positive diseases. As Table 2 shows, the specificity of the LBT in this group of diseases is quite high. Dermal-epidermal complexes are rarely found in patients with procainamide hydrochloride- or hydralazine hydrochloride-induced LE.[31,44,45] In scleroderma[7,36] and dermatomyositis[10,16,46] only rare cases of positive immunofluorescence have been reported, and these have been basically confined to areas of vascular lesions of the telangiectatic type. For example, in one study[36] where four patients with scleroderma had positive immunofluorescent reactions in facial telangiectatic lesions, all had negative immunofluorescence in indurated lesions without telangiectasia. A recent report indicated that three of six patients with the mixed connective tissue disease syndrome had positive immunofluorescence in clinically normal light-exposed skin.[47] This study casts some doubt on the validity of using sun-exposed, clinically normal skin to confirm a diagnosis of LE. Until a large study is completed, which analyzes the results of LBTs in clinically normal, light-exposed skin of other connective tissue diseases, it might be prudent to perform a biopsy on light-protected as well as light-exposed normal skin for diagnostic purposes.[48] An interesting immunofluorescent finding in patients with the mixed connective tissue disease is the frequent presence of a thready, intraepidermal nuclear-staining pattern, which appears to be associated with high titers of antibody to extractable nuclear antigen.[19] This pattern may prove to be of diagnostic value for the mixed connective tissue disease syndrome.

Table 3.—Lupus Band Test and Renal Disease

Study	Biopsy Site (Uninvolved Skin)	Results
Burnham & Fine (1971)[15]	Light protected	LBT result positive: renal disease increased three times
Caperton et al (1972)[50]	Light exposed	No relationship
Grossman et al (1974)[51]	Light protected	No relationship
Gilliam et al (1974-1975)[19,55]	Light protected	LBT result positive: 84% severe; 23% mild
Dantzig et al (1975)[49]	Light protected	LBT result positive: 83% severe; 19% mild
Gilliam & Pennebaker (1976) (oral communication)	Light protected	Poorer prognosis with IgG than IgM alone

PROGNOSTIC VALUE OF LBT

Although the diagnostic value of the LBT is well accepted, its prognostic significance is more controversial. The first critical point is that all biopsy specimens taken for prognostic purposes must come from clinically normal, light-protected skin such as the medial flexor forearm, medial upper arm, or buttocks. Several studies have clearly shown that direct immunofluorescence from uninvolved, light-protected skin correlates with laboratory measurements that have been associated with disease activity and poorer prognosis—hypocomplementemia,[15,19,31,49] elevated titers of antinative-DNA antibodies,[19] and peripheral pattern ANA.[15,19] The presence of leukopenia[49] and LE cells[15,49] also appears to be increased in patients with LBT-positive reactions. The frequency of positive ANA reactions does not correlate with cutaneous immunofluorescence.[19,49]

The correlation of a positive LBT finding in uninvolved skin with general clinical disease activity in systemic LE has been shown in several studies.[15,19,31] In addition, a recent study by Schrager and Rothfield[18] has attempted to correlate general clinical disease activity with the deposition of a particular immunoglobulin class in the skin. These authors have shown that a statistically significant correlation exists between deposits of IgA in the dermal-epidermal junction of nonlesional skin and clinical disease activity. They found that IgA was absent in all nonlesional (sun-exposed) skin from 16 patients with clinical remission, while it was present in 7 of 23 patients with active disease.

The correlation of LBT findings with renal involvement remains a very debatable subject, as shown in Table 3. In 1968 Pohle and Tuffanelli[7] suggested a possible relationship between renal involvement and the presence of immunoglobulin deposits in normal-appearing skin of systemic LE patients. In 1971 Burnham and Fine[15] substantiated this relationship by reporting a correlation between immunoglobulin deposition in the skin and the presence of renal involvement. They found kidney involvement three times more frequently in patients with LBT-positive findings than in those with negative results. However, their study did not include histologic classification of the renal lesions.

In contrast, Caperton et al[50] observed no relationship between the LBT and the presence of renal disease in 29 patients followed up during a one-year period. On the basis of renal biopsy specimens from 12 patients, they also concluded that there was no

relationship between the renal pathology and the result of the LBT. Of great importance, however, is the fact that these investigators did a biopsy of light-exposed skin, whereas Burnham et al examined skin from light-protected sites.[51]

Grossman et al[31] studied 26 patients with systemic LE and found that 78% of the patients with active renal disease had LBT-positive results, but that 41% of the patients without renal disease also had positive staining. This difference was not statistically significant and these investigators concluded that the LBT could not be correlated with specific organ system involvement. Although biopsy specimens in this study were taken from light-protected skin, renal activity was determined by study of the urinary sediment, not by renal biopsy.

Comprehensive studies by Gilliam et al[19,52] present the best evidence for a correlation between positive LBT findings and renal disease. These investigators found that 18 of 26 patients (70%) with renal disease had LBT-positive results as compared with 5 of 16 patients (31%) without renal disease. More impressive were their findings in 32 patients who had renal biopsies performed. Previous studies[53,54] have clearly shown that there are different types of renal disease in systemic LE, with the prognosis of the renal disease dependent upon the type of glomerulitis present. Gilliam et al[19,52] found positive LBT results in 16 of 19 patients (84%) with the diffuse proliferative or membranous glomerulonephritis, the most severe forms of lupus renal disease. On the other hand, only 3 of 13 (23%) patients with positive findings had focal proliferative glomerulonephritis (a mild form of lupus renal disease) or normal kidney biopsy specimens. Thus, a clear correlation was demonstrated between a positive LBT result and the severe histopathologic forms of renal disease.

Gilliam et al[52] also showed that four of nine patients with LBT-positive findings who initially had no clinical or laboratory evidence of renal disease subsequently developed overt renal disease after an average period of four months, suggesting that the LBT may have predictive value in this regard. In contrast, none of 11 patients with initial negative skin biopsy sections later developed renal involvement during an average follow-up period of 16 months. Also, in all instances in which an immunoglobulin of a particular class was present in the skin, it was found in the simultaneous kidney biopsy as well. This further suggests a relationship between the LBT and renal disease.

Finally, Dantzig et al[14] have shown a correlation between a positive LBT finding and the more severe forms of lupus nephritis. These investigators found that 5 of 6 (83%) of the patients with membranous or diffuse proliferative glomerulonephritis had positive LBT results, while only 3 of 16 (19%) of the patients with focal proliferative glomerulonephritis or normal kidney biopsy sections had positive results of a skin biopsy.

Recent preliminary data by J. N. Gilliam, MD, and J. Pennebaker, MD, (oral communication, April 1976) suggest another possible prognostic use for the LBT. They analyzed the course of LE patients as a function of the type of immunoglobulin class present in the immunofluorescent band at the dermal-epidermal junction. They found that disease activity, the severe histopathologic forms of nephritis, and mortality are greater in those patients who have IgG alone or in combination with any other immunoglobulin, rather than IgM only deposited in the skin.

Studies seeking a relationship between a positive LBT reaction and specific organ system involvement other than renal disease have been unsuccessful.[19,31,52] No correlation has been shown to exist between a positive LBT finding and active skin lesions, CNS involvement, arthritis, serositis, or vasculitis.

Finally, in the future, the LBT may have a value as a possible monitor of the effect of various therapies. Gilliam et al[19,55] have shown that 13 of 17 (76%) patients with LBT-positive results who were taking prednisone (average dose of 24 mg/day) still had positive reactions after four months of treatment. Other studies have also shown that prednisone therapy does not substantially alter the LBT.[7,12,15] On the other hand, Gilliam[19,55] showed that only one of nine (11%) patients with LBT-positive findings receiving cyclophosphamide (average dose, 1.8 mg/kg/day) and prednisone (average dose, 24 mg/day) still had a positive reaction after four months of treatment. These data suggest that immunosuppressive drugs, by eliminating the presence of immune complexes, which certainly play a causative role in the development of renal lesions, may be useful therapeutic agents. Further studies in this area would certainly be of value.

COMMENT

The LBT is extremely useful in the evaluation of a patient with possible LE. The procedure is a very sensitive and specific diagnostic method for discerning LE. In addition, it has much value as a prognostic tool in a patient with an established diagnosis of LE. Finally, two points of caution should be mentioned. First, in performing and interpreting these tests, one must be careful to perform a biopsy at the appropriate skin site; ie, involved or uninvolved or light-exposed or light-protected skin. Second, it should be kept in mind that the LBT is a laboratory procedure. This, like all laboratory tests, should be used in conjunction with clinical findings and other serologic and immunopathologic data in arriving at a final medical decision.

Solar Simulator Tests Demonstrate Superior Substantivity*

SUPER SHADE LOTION [5% PABA] for SUN SENSITIVE PATIENTS

Superior in "Wash Off" Resistance and Cosmetic Elegance to The Leading "PABA" Formula

Super Shade Sun Blocking Lotion by COPPERTONE gives maximum sunburn protection for patients who enjoy the sun yet need the maximum filtering of the sun's ultraviolet rays. Super Shade has these advantages:

- WASH OFF RESISTANCE. The superior substantivity of Super Shade enables it to resist removal by perspiration and swimming. Reapplied as directed, it gives all day protection. Super Shade lets your patient stay in the sun 10 times longer without burning than with no protection.
- COSMETIC ELEGANCE: Super Shade is a white, creamy, non-greasy lotion. Unlike clear products, users can see where Super Shade has been applied. It permits an even uniform coverage with no gaps or unprotected areas.
- HELPS PREVENT SUN DAMAGE that may cause premature wrinkling, aging of the skin and skin cancer when used regularly as directed.

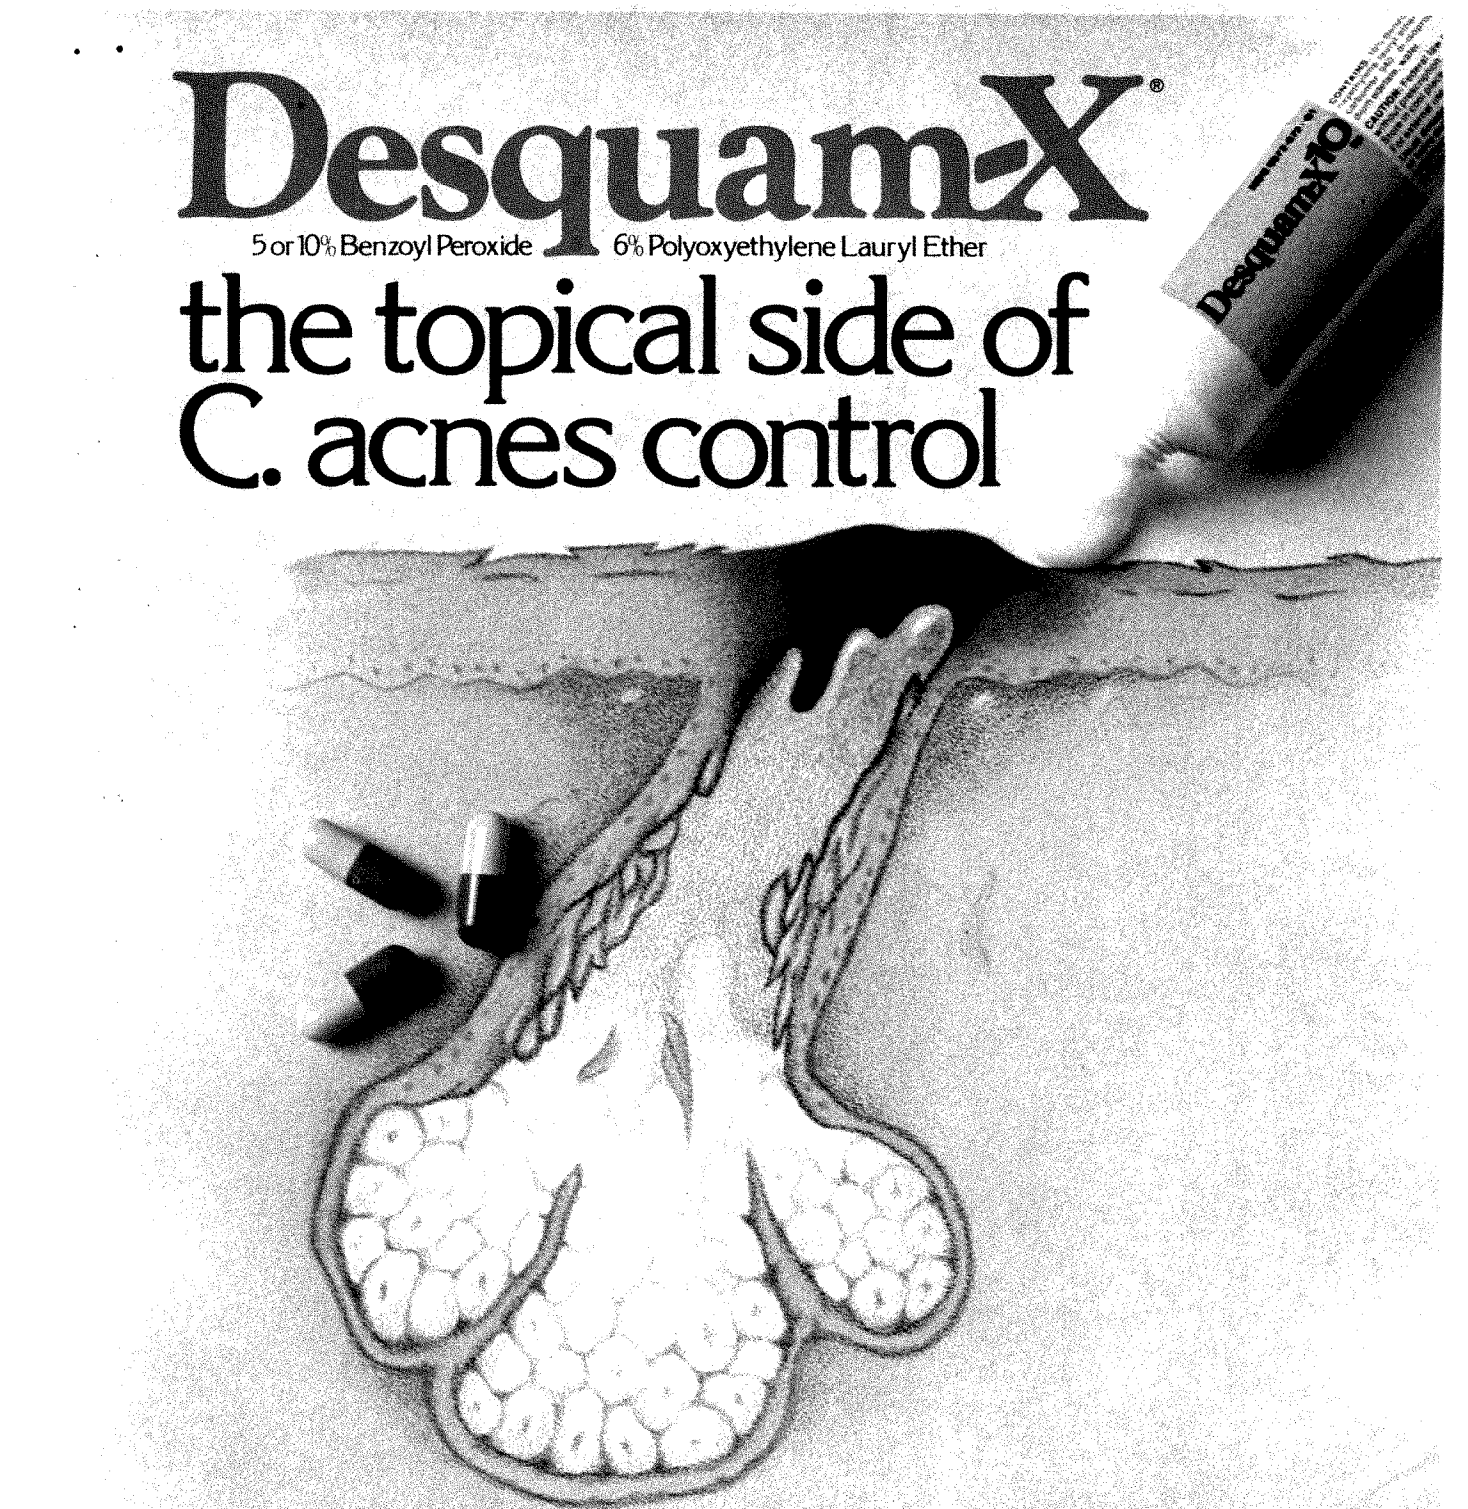
Active Ingredient: Para-Aminobenzoic Acid 5%. Alcohol 60%.

Sun Sensitive Patients Will Appreciate Your Recommendation of Super Shade.

Desquam-X®

5 or 10% Benzoyl Peroxide 6% Polyoxyethylene Lauryl Ether

the topical side of C. acnes control



Desquam-X5®

Desquam-X10®

CONTENTS: Desquam-X 5 contains 5% Benzoyl Peroxide, 6% polyoxyethylene lauryl ether, 37% ethyl alcohol, carbomer 940, di-isopropanolamine, disodium edetate and water.

Desquam-X 10 contains 10% Benzoyl Peroxide, 6% polyoxyethylene lauryl ether, 37% ethyl alcohol, carbomer 940, di-isopropanolamine, disodium edetate and water.

INDICATION: A topical aid for the control of acne vulgaris.

ACTION: Provides the desirable drying and desquamation needed in the topical treatment of acne. Desquam-X has been demonstrated to have anti-bacterial effects, especially against Corynebacterium acnes.

DIRECTION FOR USE: After washing as instructed, rub Desquam-X into affected areas twice daily. In fair-skinned individuals or under excessively dry atmospheric conditions it is suggested that therapy be initiated with one application daily. The desired degree of drying and peeling can be obtained by modification of the dosage schedule.

CONTRAINDICATIONS: Not to be used in patients known to be sensitive to any ingredient of Desquam-X.

PRECAUTIONS: Avoid contact with eyes and mucous membranes. For external use only. Keep this and all medication out of the reach of children.

NOTE: May bleach colored fabrics.

HOW SUPPLIED: Plastic tubes 1.5 oz. (42.5 gm.)

CAUTION: Federal law prohibits dispensing without prescription.

Short Reports

Segmental Neurofibromatosis

Robert M. Miller, MD, Robert S. Sparkes, MD

Neurofibromatosis (von Recklinghausen disease) is an autosomal-dominant disorder with a frequency of about 1 in 3,000.[1] It is characterized by abnormal cutaneous pigmentation and by numerous tumors that develop in association with elements of both the CNS and peripheral nervous system. The pigmented spots are known as café au lait spots; the tumors are neurofibromas. Both manifestations tend to be multiple and widely distributed over the body; and because the manifestations affect the skin, these problems are initially brought to the attention of the dermatologist. However, there has been relatively little attention paid in the dermatological literature to segmental cases of the disorder. We are reporting two such instances to emphasize the limited clinical manifestations and their possible implications.

Report of Cases

CASE 1.—A 15-year-old girl sought help for the treatment of acne. Examination results also disclosed multiple pigmented macules in her right axilla (Crowe sign). Several larger café au lait spots were found limited to a small area on the skin of the right side of the trunk. The lowest café au lait spot was 2 cm above and to the right of the umbilicus. There were none above the shoulder. On the right side of her back, there was one soft nodule, which proved to be a neurofibroma on biopsy. The remainder of the results of the physical examination revealed an intelligent girl who was healthy in other respects. Her mother stated that the axillary freckling and café au lait spots were present since birth. The neurofibroma, although not exactly known was estimated to be a couple of years old. She had one older brother and one older sister. The sister and parents were examined by one of us (R.M.M.) and were found to have no evidence of café au lait spots or neurofibromas. The brother, grandparents, aunts and uncles were questioned by the patient's parents by telephone after explicit instructions. They all denied axillary freckles, café au lait spots or nodules resembling neurofibromas.

CASE 2.—A 61-year-old woman had had many freckles in her left axilla and a few larger café au lait spots on her trunk since birth. During the past few years, she had developed soft-domed, 1-cm nodules on her left arm, left back, and the left base of the neck. Results of examination showed that all lesions were limited to the left side of the body. The lowest café au lait macule was 4 cm above and to the left of the umbilicus; the highest was on the back at the level of the axilla. Several nodules extended up the left arm from the wrist. There were a few on the neck and one on the back. Biopsy of a typical nodule revealed a neurofibroma. The patient had a son and a daughter, neither of whom had café au lait spots or neurofibromas. No definite history was available regarding siblings or parents, although she did not believe there was any family history of neurofibromatosis. Her general physical health was good; she was an intelligent, active woman.

Comment

These two patients showed relatively localized manifestations of neurofibromatosis with negative family histories. Although the café au lait spots and neurofibromas usually are distributed widely over the body in this disorder, we believe that these patients do have a form of neurofibromatosis because of the clinical appearance of the lesions and the biopsy confirmation of neurofibromas. It is tentatively concluded that they had "segmental neurofibromatosis." This form of the disorder may not be rare. Because we examined these two patients in a private-practice office within a short period of time, we conclude that segmental neurofibromatosis is not rare.

Four instances of similar manifestations were reported by Crowe et al.[1] The neurofibromas were limited to the extremities in two cases: the right sacral area in one and the back in the other. Café au lait spots were present in only two cases (one spot in each). The siblings and parents were free of the disease, as were the six children of the four patients. The authors assigned the term "sectorial" to these limited manifestations, and believed that somatic mutation may have been the basis for the limited distribution. They suggested that this distribution of manifestations may be relatively easy to observe with this disorder because of the skin involvement. Diekmann et al[2] described a 9-year-old girl with localized neurofibromatosis, including hypertrophy of the clitoris and the urogenital tract. Café au lait spots were present. Nicholls[3] described two cases. The first patient was a 64-year-old woman with mediastinal neurofibromata. There were five small neurofibromas in the skin area corresponding segmentally to the site of the lesion. The second patient was an 11-year-old girl who had café au lait patches and freckles affecting the right trunk and leg in the area of the skin supplied by the eleventh thoracic to the second sacral nerve roots; however, no neurofibromas were noted. Sava et al[4] described a 9-year-old girl with lipoma of the right buttocks, segmental hypertrophy of the right buttocks and thigh, radiologically significant body hypertrophy, and a pale, coffee-colored stain on the right buttocks. A very abnormal density of the nerve fibers was found in the lipoma, with notable perineural thickening and proliferation resembling a schwannoma.

Reprint requests to Dermatology Service, Veterans Administration Wadsworth Hospital Center, Los Angeles, CA 90073 (Dr Miller).

If it is assumed that these segmental cases are due to mutation at the same genetic locus as the more generalized inherited cases of neurofibromatosis, one has to ask why the manifestations are limited in their distribution. The unilateral and segmental pattern is in keeping with the distribution of nerves in the body. The negative family history for the disorder in the families indicates that the disorder has probably originated in the affected person and has not been inherited. In none of the segmental cases so far noted is there any apparent transmission of the disorder from the affected person to a child, although it is too early to be certain of this in younger patients, as in the 15-year-old girl we described in this report. As suggested by Crowe et al,[1] the most probable explanation is a somatic mutation that affected a single cell early in embryonic development and, through subsequent cell division, involved a number of progeny cells leading to the limited distribution in the patients. The relatively high gonadal or gametic mutation rate (1×10^{-4}) that has been suggested for this disorder[1] raises the possibility of a relatively unstable, highly mutable gene that might also be susceptible to increased mutation in somatic cells.

Other possible explanations also have to be considered. For example, the patchy occurrence of the tumors and the café au lait spots in the fully manifest variety, as well as in the limited distribution variety, may have the same mechanism. Although the explanation for this is not known in the fully expressed variety, there are other instances, such as in the Waardenburg syndrome, where there are spotty manifestations. To account for this distribution, as well as similar manifestations in other mammals, so-called pattern loci have been described. But this does not give further insight as to the mechanism involved. It may be possible also that there is a position effect occurring due to an unrecognized shift of genes in some cells from the active state to an inactive state in other cells, or vice-versa. And finally, there could be some unrecognized nongenetic factor that determines manifestation in one area of the body, but not in another.

Pancreatic Carcinoma With Dissemination to Umbilicus and Skin

Anup K. Chakraborty, MD; Atigadda N. Reddy, MD; Saul J. Grosberg, MD; Simon Wapnick, MD

Careful examination of the umbilical area may at times yield unexpected clues to the diagnosis and the pathologic origin of intra-abdominal disease. Metastases from the pancreas may implant on the umbilicus. The mode of distribution of umbilical and paraumbilical implants in our patient with pancreatic carcinoma was most eye-compelling, and forms the substance of this report.

From the Gastrointestinal Section, Department of Medicine (Drs Chakraborty, Reddy, and Grosberg), and the Department of Surgery (Dr Wapnick), Veterans Administration Hospital, Brooklyn, NY, and State University of New York Downstate Medical Center, Brooklyn.

Reprint requests to Gastroenterology Section, 800 Poly Pl, Brooklyn, NY 11209 (Dr Grosberg).

Report of a Case

A 62-year-old man was admitted to the hospital for shortness of breath and for swelling of the abdomen and legs. Results of physical examination were consistent with congestive heart failure. In addition, a firm, irregular, 3 × 4-cm node adherent to the overlying skin was palpable in the right axilla.

The abdomen was distended; shifting dullness and fluid wave were present. On digital examination, a rectal shelf was felt. The umbilicus was protuberant and was preempted by a nodular, tender, bluish-pink mass that was irregular in contour and outline. Distributed in a straight line at an angle of 45° from the umbilical mass anteriorly and superiorly to the right subcostal area was a group of satellite lesions that was approximately 1.5 cm in diameter. These were also hard, irregular in outline and contour, and slightly tender. They were connected to one another and to the right axillary node by tender, cord-like structures lying subcutaneously. No bruits or venous hums were heard over these lesions (Figure).

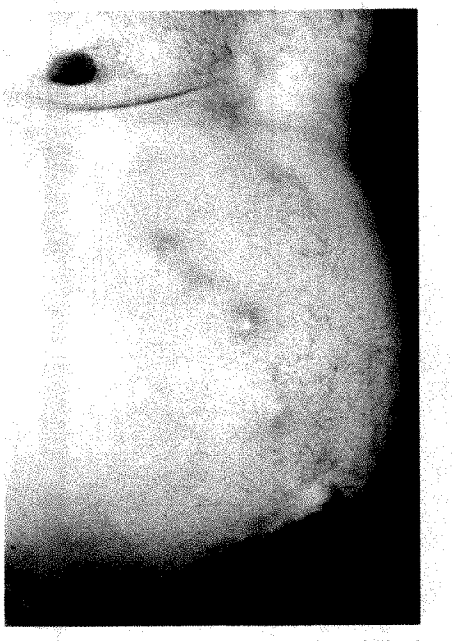
The following procedures were productive in delineating the nature of the lesion and its probable site of origin.

Biopsy specimens of the right axillary node and of the subcutaneous nodules showed metastatic adenocarcinoma. Celiac angiography showed entrapment and irregular narrowing of the branches of the celiac axis, as well as extrinsic compression of the splenic and portal veins (consistent with the presence of a mass in the body of the pancreas). Gastroduodenoscopy showed intraluminal protrusion of the medial wall of the descending duodenum, with mucosal congestion and scattered areas of superfi-

cial ulceration (consistent with invasive disease). Results of examination of the peritoneal fluid showed it to be an exudate in which atypical cells were seen. A scan of the liver with technetium Tc 99m sulfur colloid and gallium citrate 67 was interpreted as showing the presence of malignant neoplasm in the left lobe of the liver. We were drawn to the conclusion on the basis of the data submitted that the patient had a carcinoma of the pancreas that had seeded the abdominal cavity and liver.

Comment

The umbilical area represents the site of predilection for metastases from a host of intra-abdominal malignant neoplasms, the most common of which are the stomach, colon, kidney, ovary, biliary tree, and pancreas, as well as the female breast.[1-3] Although the exact modes of spread to the umbilicus are unknown, hematogenous and lymphatic spread and spread by contiguity have been implicated. Pancreatic carcinomas are known to rapidly metastasize to the lymphatic system by permeation, embolization, and retrograde spread in the presence of lymphatic obstruction.[4]



Abdomen showing ascites and umbilical and abdominal wall metastases.

In our patient the cord-like structures felt between the subcutaneous nodules most probably represent the thickened lymphatics permeated by the tumor cells. The same cord-like structures were readily traceable to the right anterior axillary nodes. These nodes normally drain the anterior abdominal wall up to the level of the umbilicus.

The clinical appearance of metastatic disease must be distinguished from endometriosis of the umbilicus, primary carcinoma of the umbilicus, benign umbilical granulomas caused by buried hairs and occasionally from infection. The finding of umbilical and skin metastases renders the primary malignant neoplasm inoperable. Our patient will receive protocol chemotherapy.

Contact Dermatitis Caused by ECG Electrode Jelly

Ralph J. Coskey, MD

A 4-year-old boy was seen because of contact dermatitis that resulted from the use of an ECG electrode jelly (Cambridge). Patch tests proved that gum tragacanth in the jelly was responsible for the eruption. This agent is found in many different products, including foods, troches, cosmetics, toothpastes, and textile sizings.

Report of Case

A 4-year-old boy was seen on March 23, 1976 because of persistent dermatitis on his chest and extremities. He had developed the eruption two months previously, shortly after an ECG had been taken. The eruption was confined to the areas where the electrode jelly had been used for contact between the skin and the electrodes.

A diagnosis of contact dermatitis was made. The eruption resolved after topical treatment with steroids. Patch tests were performed, and the patient was found to be allergic to the electrode jelly and one of its constituents, gum tragacanth (Table). The commercially prepared jelly also contained sodium chloride, washed sand, glycerin, oil of pine (one part in 10,000), and water.

Comment

In a review of the literature of the last 13 years, I found two reports describing either allergic contact dermatitis or irritation from ECG electrode jelly. Thus, contact dermatitis from the antibacterial agent parachlorometaxylenol contained in an ECG paste (Redux) was recently reported in three cases.[1] Marked excoriation from electrode jelly applied to the skin in long-term (several hours) monitoring of the electrical activity of the heart also has been reported.[2]

In the case of my patient, gum tragacanth was the ingredient that caused the dermatitis. Tragacanth is used to suspend heavy insoluble powders, as an excipient for tablets and to impart consistency to troches. It also is used in the preparation of emulsions and emulsifying agents and

Ingredients were as follows: Mercaptobenzothiazole Mix, 0.25% mercaptobenzothiazole, 0.25% cyclohexylbenzothiazyldisulfide, 0.25% morpholinylmercaptobenzothiazole; Thiuram Mix, 0.25% tetramethylthiuram disulfide, 0.25% tetramethylthiuram monosulfide; 0.25% tetraethylthiuram disulfide, 0.25% dipentamethylenethiuram disulfide; Naphthal Mix, 0.5% phenyl-β-naphthylamine, di-β-naphthyl-p-phenylenediamine; Carba Mix, 1% 1,3-diphenylguanidine, 1% bis (diethyldithiocarbamato) zinc, bis (dibutyldithiocarbamato) zinc.

may be found in foods, candies, adhesives, cosmetics, toothpastes, depilatories, and other topical agents. In addition, it is used in textile sizing, textile printing, and dyeing with insoluble color lakes.[3,4]

There have been very few reports of allergy due to gum tragacanth. Feinberg and Schoenkerman[5] described a patient who had an eczematous eruption of the hands who had used a lotion with gum tragacanth. This patient had a marked reaction from tragacanth. Brown and Crepea[6] described a man with asthma and generalized urticaria that they attributed to gum tragacanth found in a tripelennamine tablet (Pyribenzamine). Gelfand[7] reported the cases of ten patients who developed one or more of the following symptoms: rhinitis, gastrointestinal symptoms, urticaria, cough, angioneurotic edema and/or asthma after ingestion of one or more of the following gums—tragacanth, karaya, and arabic.

My patient had been exposed to gum tragacanth in many foods, and has not developed allergic symptoms. Thus, he appears to only be allergic to the agent topically.

Timothy Pegnim of Cambridge Instrument Co, provided the ingredients of the electrode jelly.

KENALOG® SPRAY
Triamcinolone Acetonide Aerosol N.F.

DESCRIPTION: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) provides 3.3 mg. triamcinolone acetonide per 50 grams in an isopropyl palmitate vehicle with alcohol (4.7%) and propellants.

INDICATIONS: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) is indicated for relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS: Topical steroids are contraindicated in viral diseases of the skin, such as vaccinia and varicella, and in patients with a history of hypersensitivity to any product component. This preparation is not for ophthalmic use. Topical steroids should not be used when circulation is markedly impaired.

WARNINGS: Usage in Pregnancy— Although topical steroids have not been reported to have an adverse effect on the fetus, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

PRECAUTIONS: Administer suitable antifungal or antimicrobial therapy if infection exists; if there is not a prompt, favorable response, discontinue the corticosteroid until the infection has been adequately controlled. Discontinue the drug and institute appropriate therapy if irritation develops. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. When used about the face, the eyes should be covered and inhalation of the spray avoided.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids either with or without occlusive dressings: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, miliaria, hypertrichosis, acneform eruptions, maceration of the skin and hypopigmentation; contact sensitivity to a particular dressing material or adhesive may occur occasionally. Some patients (particularly those with very dry skin or dry lesions) may find the cooling effect of the spray objectionable or complain of a transient burning or stinging sensation.

For full prescribing information, consult package insert.

HOW SUPPLIED: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) is available in spray dispenser cans of 50 and 150 g. with adapter.

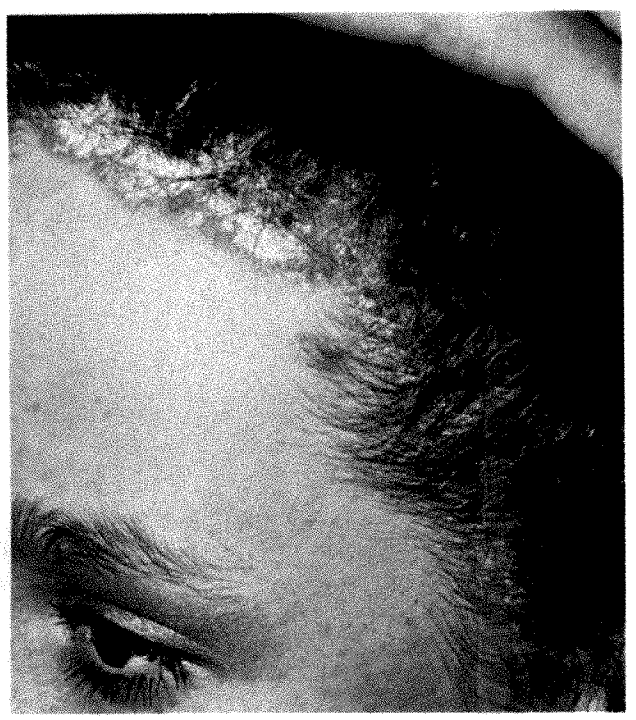
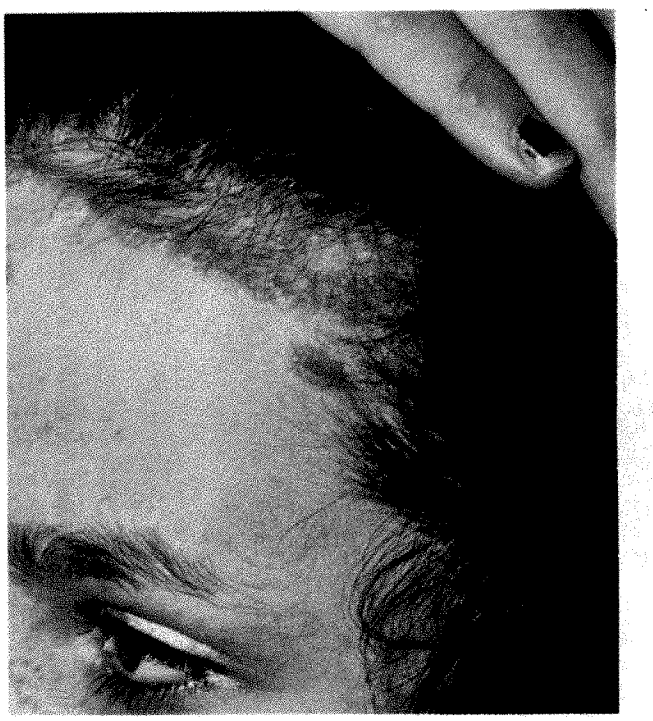
ANOTHER CASE FOR KENALOG®
TRIAMCINOLONE ACETONIDE

"INTRACTABLE" SCALP PSORIASIS





MARCH 4, 1977

A 15-year-old patient complaining of severe, intractable psoriasis of the scalp. Previous therapy with tar shampoo, keratolytic agents and fluorinated topical steroids had been unsuccessful. Because prior topical agents had been difficult to apply, Kenalog® Spray b.i.d. was prescribed.

Patient reported that pruritus had been relieved promptly. Marked improvement observed at this time: absence of scales, decrease in erythema and central clearing of plaques. Patient continuing on Kenalog® Spray b.i.d.
Case history on file at Squibb Institute for Medical Research.

Acne illustrated by artist.

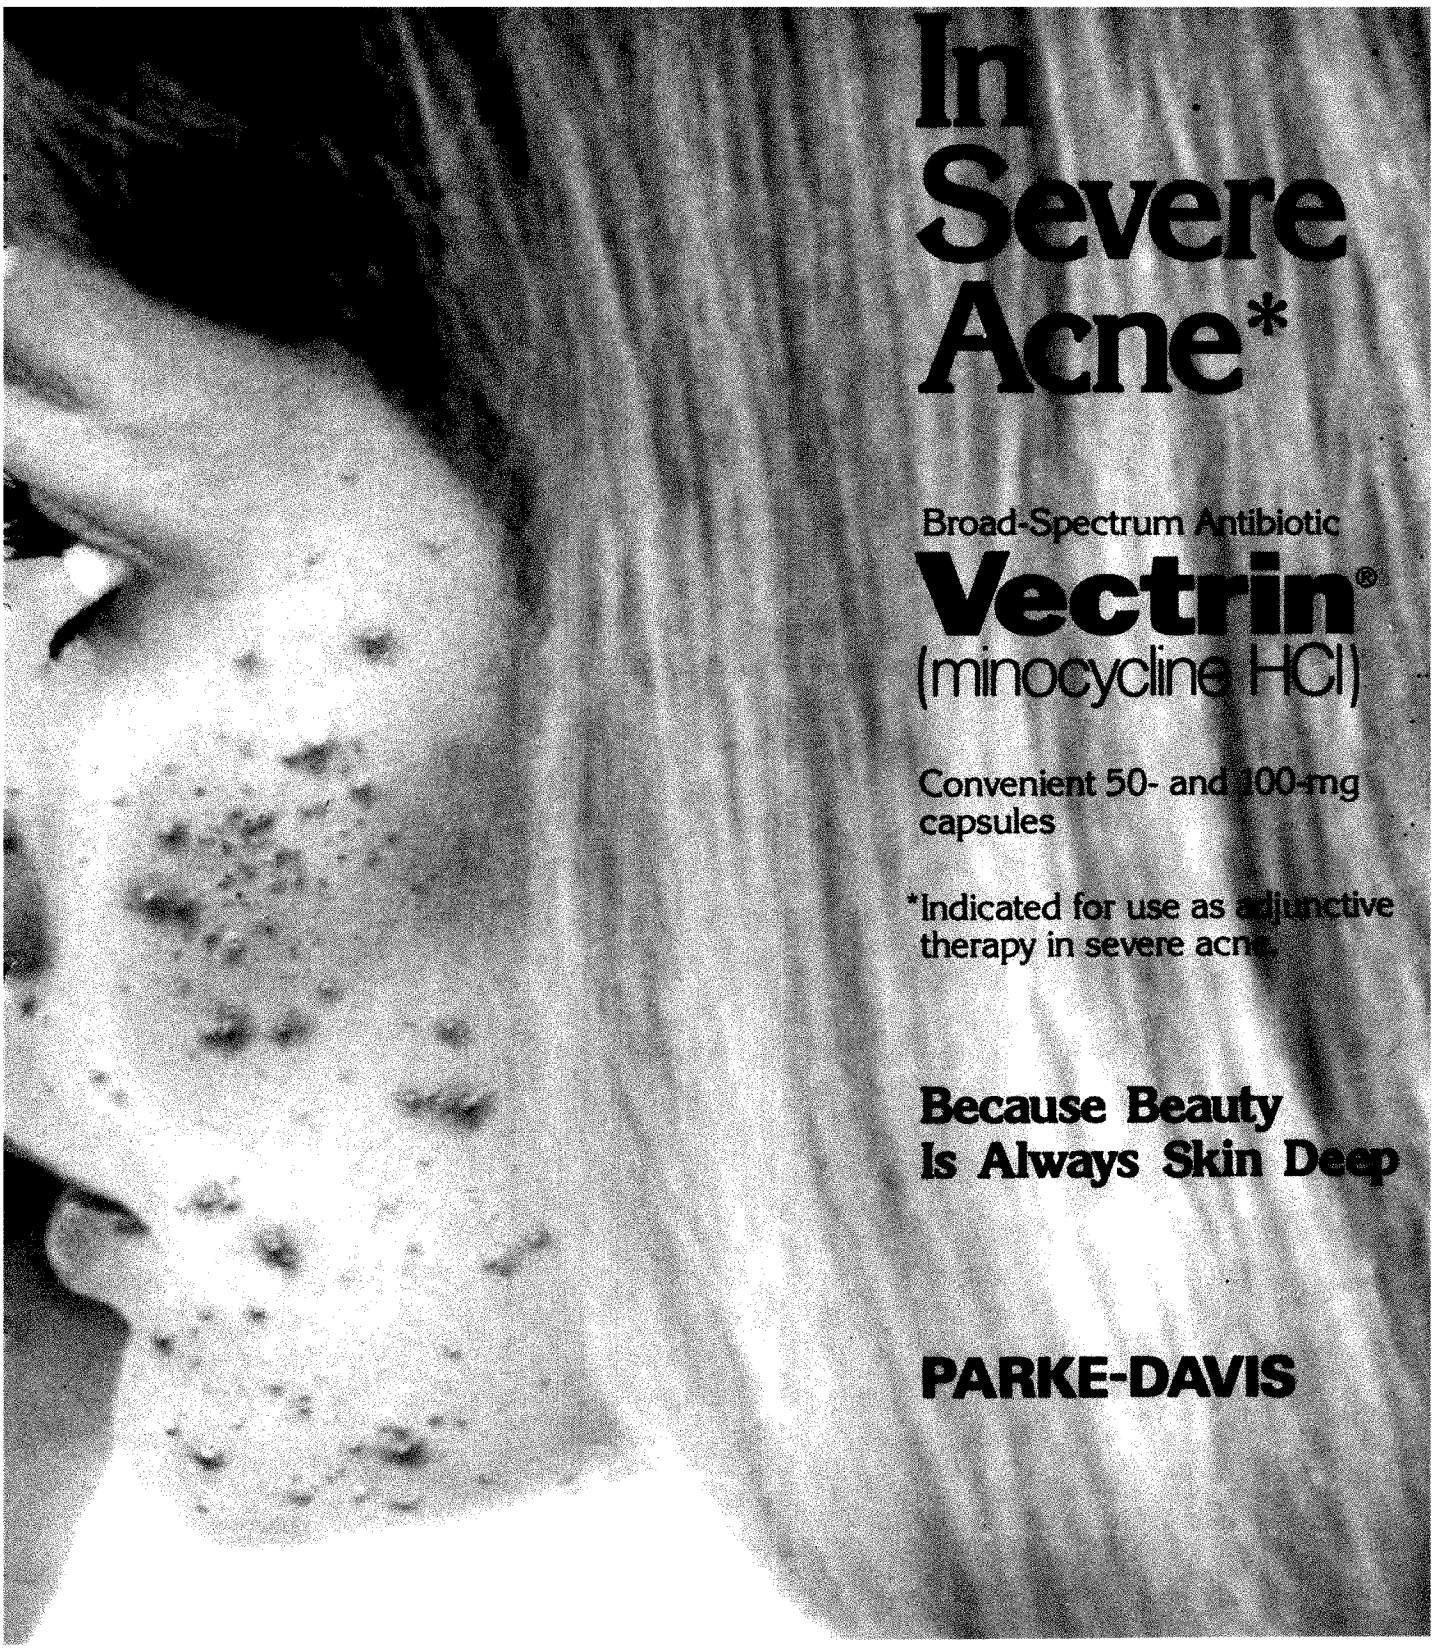
VECTRIN Capsules, 100 mg
(minocycline HCl capsules, USP)
Brief Summary of Prescribing Information

Indicated in severe acne as adjunctive therapy. Consult package insert for complete prescribing information.

Contraindication: Hypersensitivity to any tetracycline.

Warnings: When need for intensive treatment outweighs potential dangers, perform renal and liver function tests before and during therapy; also follow serum concentrations. In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, use lower total doses, and, in prolonged therapy, determine serum levels. The use of tetracyclines during tooth development (last half of pregnancy, infancy, and childhood to the age of 8 years) may cause permanent discoloration of the teeth (yellow-gray-brown). This is more common during long-term use but has been observed following repeated short-term courses. Enamel hypoplasia has also been reported. Tetracyclines, therefore, should not be used in this age group unless other drugs are not likely to be effective or are contraindicated. Photosensitivity manifested by an exaggerated sunburn reaction has been observed in some individuals taking tetracyclines. Advise patients apt to be exposed to direct sunlight or ultraviolet light that such reaction can occur, and discontinue treatment at first evidence of skin erythema. Studies with minocycline HCl indicated that photosensitivity did not occur. However, reports have been received. In patients with significantly impaired renal function, the antianabolic action of tetracycline may cause an increase in BUN leading to azotemia, hyperphosphatemia, and acidosis. **CNS side effects:** (light-headedness, dizziness, vertigo) have been reported, may disappear during therapy, and always disappear rapidly when drug is discontinued. Caution patients who experience these symptoms about driving vehicles or using hazardous machinery while taking this drug. **Pregnancy:** In animal studies, tetracyclines cross the placenta, are found in fetal tissues, and can have toxic effects on the developing fetus (often related to retardation of skeletal development). Embryotoxicity has been noted in animals treated early in pregnancy. The safety of minocycline HCl for use during pregnancy has not been established. **Newborns, infants, and children:** All tetracyclines form a stable calcium complex in any bone-forming tissue. Prematures, given oral doses of 25 mg/kg every six hours, demonstrated a decrease in fibula growth rate reversible when drug was discontinued. Tetracyclines

PD-JA-1463-2-P (1-76)



In Severe Acne*

Broad-Spectrum Antibiotic

Vectrin®

(minocycline HCl)

Convenient 50- and 100-mg capsules

*Indicated for use as adjunctive therapy in severe acne.

Because Beauty Is Always Skin Deep

PARKE-DAVIS

are present in the milk of lactating women who are taking a drug in this class.

Precautions: Use may result in overgrowth of non-susceptible organisms, including fungi. If superinfection occurs, antibiotics should be discontinued and appropriate therapy instituted. In venereal diseases when coexistent syphilis is suspected, darkfield examination should be done before treatment is started and blood serology repeated monthly for at least four months. Patients on anticoagulant therapy may require downward adjustment of such dosage. Test for organ system dysfunction (eg, renal, hepatic, and hemopoietic) in long-term use. Treat all group A beta-hemolytic streptococcal infections for at least 10 days. Avoid giving tetracycline in conjunction with penicillin.

Adverse Reactions: GI: Anorexia, nausea, vomiting, diarrhea, glossitis, dysphagia, enterocolitis, inflammatory lesions (with monilial overgrowth) in anogenital region. **Skin:** Maculopapular and erythematous rashes. Exfoliative dermatitis (uncommon). Photosensitivity is discussed above. (See Warnings.) **Renal toxicity:** Rise in BUN, dose-related. (See Warnings.) **Hypersensitivity reactions:** Urticaria, angioneurotic edema, anaphylaxis, anaphylactoid purpura, pericarditis, exacerbation of systemic lupus erythematosus. In young infants, bulging fontanels have been reported following full therapeutic dosage; disappearing rapidly when drug was discontinued. **Blood:** Hemolytic anemia, thrombocytopenia, neutropenia, eosinophilia. **CNS:** (See Warnings.) When given over prolonged periods, tetracyclines may produce brown-black microscopic discoloration of thyroid glands; no abnormalities of thyroid function studies are known to occur.

NOTE: Concomitant therapy: Antacids containing aluminum, calcium, or magnesium impair absorption; do not give to patients taking oral tetracycline. Studies to date indicate that absorption of VECTRIN (minocycline hydrochloride) is not notably influenced by foods and dairy products.

Full prescribing information available upon request.

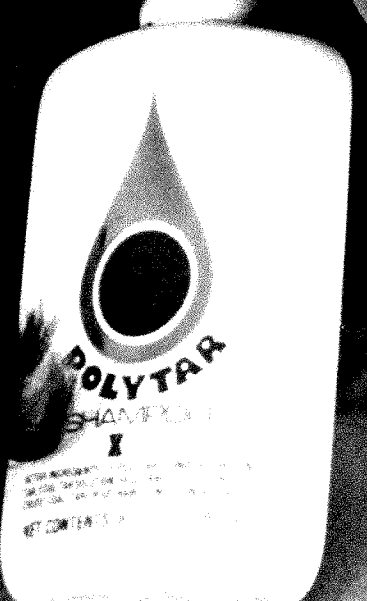
Broadening the spectrum of effectiveness for tar therapy in dandruff and seborrhea

Polytar® Shampoo contains not one but four tars (juniper tar, pine tar, crude coal tar and LCD) to maximize the benefits of tar therapy with unsurpassed cosmetic elegance. The exclusive Polytar blend of tars is prepared in a rich base with **added hair conditioner** and a mildly acid pH.

Rich, white soapless lather leaves hair clean, lustrous and manageable.

Polytar®
Shampoo



Active Ingredients: 1% Polytar (juniper tar, pine tar, coal tar, cade oil, vegetable oil, cocamide DEA) in a rich base with hair conditioner.

Available in 4 fl. oz., 8 fl. oz. and 1 gal. sizes.

Psoriasis and Bullous Pemphigoid

To the Editor.—Bullous pemphigoid was described as a distinct clinical entity by Lever[1] in 1953 and has been reported to have occurred with several autoimmune diseases, ie, systemic lupus erythematosus (SLE),[2] polymyositis,[3] and rheumatoid arthritis.[4] It has also been occasionally reported with other cutaneous diseases: Kaposi sarcoma,[5] lichen planus,[6] and pemphigus.[7]

We report here on a patient with psoriasis in whom bullous pemphigoid developed after ultraviolet exposure.

Report of a Case.—A 59-year-old man was hospitalized in June 1975 with a six-month history of psoriasis. Two weeks before admission he had a generalized psoriatic flare that evolved into an exfoliative erythroderma. Past medical history was unremarkable. Physical examination revealed generalized erythroderma, with distinct psoriatic plaques on the elbows, knees, legs, back, and chest. Laboratory studies were as follows: hemoglobin, 13.6 gm/100 ml; hematocrit, 42.9%; total leukocyte count 9.6%, with 25% band forms, 40% polymorphonuclear leukocytes, 18% eosinophils, 1% basophils, 12% lymphocytes, and 4% monocytes. Results from urine analysis were normal. Results from stool tests for occult blood were normal three times; a chest x-ray film was normal; ECG was normal; and 12-factor automated chemical analysis had normal parameters.

The patient was started on a Goeckerman regimen. He received daily tar baths, followed by graduated exposure to ultraviolet light (UVL) (UV-B). Seven days after the institution of UVL therapy, a generalized bullous eruption developed over the patient's entire body.

Immunofluorescence studies disclosed the presence of IgG and C3 on the skin basement membrane zone (BMZ). A serum anti-BMZ antibody titer of 40 was also noted. Ultraviolet light and tar therapies were discontinued; wet dressings and topical steroids were instituted. In view of his psoriasis, the patient was not given steroids for systemic effect. After 15 days of intense topical therapy, the psoriasis had improved and new blisters no longer developed.

The patient remained blisterfree for one month. Repeat direct immunofluorescence again revealed IgG and C3 on the BMZ and an anti-BMZ serum titer was 40. The patient was given azathioprine, 100 mg/day. His blisters gradually disappeared during a period of approximately five weeks.

He has had no recurrence of blisters during the past nine months. All previous sites have healed, leaving hyperpigmented macular areas. Indirect immunofluorescence studies now fail to demonstrate BMZ serum antibodies. Direct immunofluorescence studies still demonstrate weak pure IgG BMZ deposition. The azathioprine has been reduced from 100 to 50 mg/day. The psoriasis is well controlled at present.

Cram et al[8] have shown that UVL exposure of normal-appearing skin of patients with bullous pemphigoid can produce fresh lesions with typical histological and immunohistochemical changes. We think this patient's clinical course may represent the same phenomenon.

Dapsone-Induced Neuropathy

To the Editor.—In regard to the article by Fredericks et al (ARCHIVES 112:1158-1160 1976), the case of sulfone neuropathy conforms to those previously reported. Neuropathy was confined to motor nerves and appeared only after prolonged high-dose therapy. We describe here a case that demonstrates features of sulfone neuropathy not usually seen, ie, occurrence after low-dose treatment, and sensory nerve involvement.

Report of a Case.—A 25-year-old man had been in good health except for severe cystic acne vulgaris of 2½ years' duration. Initial treatment elsewhere was with prednisone, 20 mg daily for two years, without significant improvement. Six months before admission he consulted us; prednisone therapy had been recently discontinued and he was now treated with 1 gm of tetracycline and 500 mg of erythromycin daily. He showed only slight improvement, and three months later sulfone therapy was begun. Results of a RBC glucose-6-phosphate dehydrogenase test were normal. Initial dosage was 50 mg daily, and this was increased to 200 mg daily during a two-week period. The patient was maintained on a regimen of erythromycin and tetracycline. However, after receiving dapsone therapy for 6½ weeks he noted difficulty in walking, and after eight weeks he could no longer stand on his toes.

Examination of the skin revealed acne cysts, erythematous papules, and pustules on the face, back, and chest. There was considerable scarring in these areas. Large striae were present on all extremities. Results of physical examination were otherwise normal except for the neurological findings that showed an abnormal gait with dragging of both feet. Ankle jerks were absent bilaterally. Moderate weakness was observed in the gastrocnemius, anterior, and posterior tibialis muscles bilaterally; considerable weakness was present in the flexor and extensor halluces longus and in the digitorum longus. On sensory examination, there was loss of vibratory sense in the feet, with greater involvement in the toes than in the ankles. Pinprick and position senses were normal. No motor or sensory abnormalities were noted in the upper extremities. Electrodiagnostic studies revealed a motor axonal neuropathy in the lower extremities.

Laboratory investigation revealed no abnormalities except for moderate anemia and reticulocytosis secondary to sulfone administration.

One week after dapsone therapy was discontinued, there was a definite increase in muscle strength. After six weeks, sensory and motor function had continued to improve although it had not completely returned to normal.

Comment.—This patient illustrates several interesting features of dapsone-induced peripheral neuropathy. First, severe weakness developed after our patient received a low total dose of dapsone (only 7.7. gm). Furthermore, the daily dose regimen of 200 mg is lower than in any case previously reported. Second, the neuropathy appeared after only 6½ weeks of dapsone therapy; in only one other

case has it developed so rapidly. Third, a sensory loss as well as a motor deficit in the lower extremities occurred in our patient. Of the eight reported cases, only two have had both sensory and motor involvement.[1,2]

Bi-Directional Isomorphism: Co-existence of Psoriasis Vulgaris and Familial Benign Chronic Pemphigus

To the Editor.—We wish to report on the co-existence in two patients, found to be first cousins, of psoriasis vulgaris and familial benign chronic pemphigus (FBCP).

Report of Cases.—Case 1.—A woman aged 44 who came to us in 1961 with a maculopapular erythema of the axillae, perineum, natal cleft, and sub-mammary region for six years, and dry scaly psoriasis elsewhere, was regarded as having infected flexural psoriasis. After four months' treatment, she was clear. Ten years later she was referred again and after three months' treatment her lesions settled. She was referred by a third practitioner 11 months later, with a rash in the groins, and with blisters for the first time. This time the skin lesions did not respond to outpatient treatment and she was admitted to hospital for biopsy that showed a suprabasal acantholytic cleft with no dyskeratosis, and "villous" budding of the basal layer, diagnostic of FBCP. The flexures have been kept under control with occasional dilute potassium permanganate bathing and magenta paint. She now has no lesions of FBCP and the only manifestations of psoriasis are finger-nail pits and a plaque on one knee.

Case 2.—A woman aged 47, came to us in 1971 with a 40-year history of mild but widespread psoriasis that never needed hospital treatment, but that was more difficult to manage during the past four years in that some flexural lesions were painful and exudative. She showed extensive chronic psoriasis with moist flexural lesions with pustulation similar to incipient pustular psoriasis (Zumbusch). She had arthralgia of some fingers, but clinical examination was normal. The psoriasis responded satisfactorily to tar preparations and dithranol. On discharge home, her lesions were controlled with tar ointment for the glabrous lesions and potassium permanganate bathing, magenta paint, and fluocinolone acetonide 0.025% (Synalar) cream to the flexures. On admission again in October 1971, with widespread scaling psoriatic plaques and moist inflamed lesions in the intertriginous areas, pustules on the neck were noted. The psoriasis responded to routine measures and was controlled for 18 months, but on readmission in April 1973, with extensive chronic psoriasis and troublesome flexural lesions, she also had extensive nail pitting and onycholysis and psoriatic arthropathy in several interphalangeal joints. She was treated satisfactorily as before. A few months later, it was realized that she was the first cousin of the woman in case report 1 (Fig 1). A biopsy specimen from a vesicular plaque on the chest wall confirmed the diagnosis of FBCP (Fig 2). Both conditions have been kept under control since, using topical steroid/anti-microbial creams and the measures already mentioned.

Comment.—Several investigators have shown that various factors provoke characteristic lesions in FBCP. Haber and Russell[1] reported on two sisters with FBCP, observing that the sites of predilection could be accounted for by friction, moisture, and warmth; in one, lesions with typical histologic findings developed after the application of leukoplast to normal skin on the trunk.

Burns et al[2] showed that application of cultured *Candida Albicans* to previously uninvolved skin was successful in producing lesions of FBCP. Long-wave ultraviolent light rays

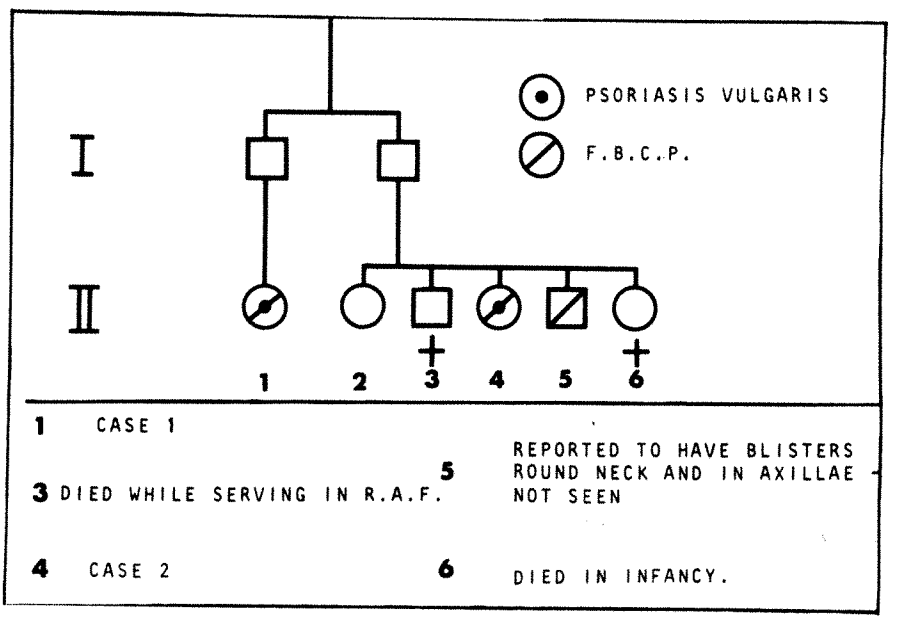

Fig 1.—Pedigree to show relationship between patients in cases 1 and 2.

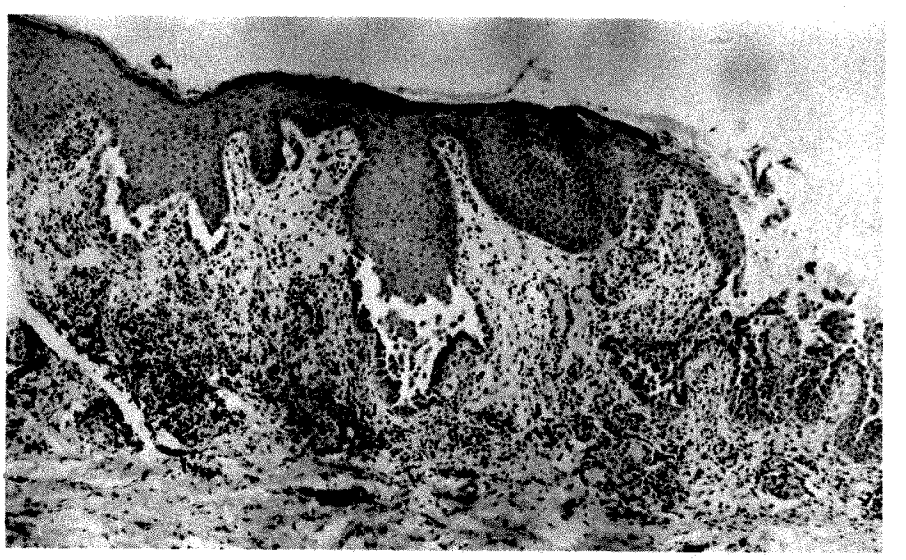

Fig 2.—Histology of vesicular area of psoriatic plaque on anterior chest wall of patient in case 2, showing typical suprabasal cleft formation and acantholysis of familial benign chronic pemphigus.

have also been shown to produce acantholysis[3] in patients known to have FBCP and in some of their relatives. That the lesions of FBCP can be an expression of isomorphism is supported by the case of Izumi et al[4] where injury with liquid nitrogen, hydration under polythene occlusion, and a positive patch test to neomycin sulfate, induced clinical and histological FBCP. Chorzelski[5] reported two cases of FBCP in which he induced acantholysis by carbon dioxide-freezing a burn at 60 C, by application of disinfectant, and by experimental staphylococcal infection. One of the subjects in their case reports had eczema and was known to be sensitive to sticking plaster, which could induce acantholysis; the other had psoriasis and demonstrated acantholytic features of FBCP in a psoriatic plaque. There has been only one other report[6] of two cases in which a clinical diagnosis of psoriasis was made and a later diagnosis of FBCP after biopsy of exudative lesions. Our second case provides a striking example of a patient in whom the lesions of FBCP occurred on nonflexural sites, preceded by typical psoriasis.

We report the cases to draw attention to the diagnostic difficulties that may occur when two conditions exhibiting isomorphism coexist in the same patient and to support the view that the sites of the lesions in FBCP can be determined by that phenomenon.

Since this article was submitted for publication, we have read of similar difficulties experienced by two other clinicians in the management of a 67-year-old female patient (ARCHIVES 112:1571-1574, 1976).

Syncope Associated With Liquid Nitrogen Therapy

To the Editor.—Although experienced dermatologists are aware of the possibility of syncope as a complication of liquid nitrogen therapy for warts, this problem needs further emphasis.

Report of Cases.—Three patients recently fainted in our clinic. Two of the patients, both teenagers, fainted after five warts on their hands were treated with liquid nitrogen. One abruptly slumped, bruising his left temple and cutting his chin on a nearby sink. This patient had fainted once previously, at the age of 12, while visiting his brother in the hospital. The third patient, in his twenties, fainted just as the liquid nitrogen was brought into the treatment room. None of the patients had previously been treated with liquid nitrogen. All the patients were treated in the morning and had not eaten breakfast. All were seated in a chair for the cryosurgery when they fainted. Two of the patients fainted precipitously, before the physician could adequately assist them. One lost consciousness within a few seconds of feeling faint; the other did not report any ill feeling before fainting.

Comment.—Liquid nitrogen application to warts produces pain and emotional stress. For the same reasons, other forms of dermatologic surgery are performed in the recumbent position. We believe that this precaution should be taken with cryosurgery. This is especially important if the patient has not eaten breakfast or has many warts and a history of previous syncope.

Carcinoma Occurring in Rhinophyma

To the Editor.—Rhinophyma, a glandular hyperplastic type of acne rosacea, has been reported to be associated with carcinoma.[1-5] We are reporting a case with basal and basosquamous carcinoma that provides morphologic evidence that the neoplasm arose directly from the rhinophyma.

Report of a Case.—A 65-year-old man first noted a slight swelling of his nose in 1956. In 1967 he had a small pigmented lesion excised from his nose that he stated was benign. The diagnosis of rhinophyma was made in 1973 because of excessive sebaceous activity and the presence of multiple cysts along the dorsum and tip of the nose and malar eminences. He had a chronic malodorous discharge from his nose but did not note any frank episode of infection.

In June 1975, biopsy of the rhinophyma at another hospital revealed basal cell carcinoma. He was then referred to Oakland Veterans Administration Hospital for further surgical treatment.

Physical examination showed a patient with considerably oily facial skin and with scattered epidermal cystic lesions over his malar prominences and periorbital regions. The patient's nose showed a large, bulbous rhinophyma of the tip that extended from the upper lateral, medial malar, and the lateral malar cartilages. It had deeply pitted follicles that readily exuded a creamy white material on pressure. A small scar was present at the site where the previous biopsy specimen had been taken. There was no gross evidence of tumor. The rhinophyma and basal cell carcinoma were surgically excised at the Oakland Veterans Administration Hospital.

Microscopic examination revealed typical features of rhinophyma. There was chronic inflammation, fibrosis, and dilated follicles with outward-extending hyperplastic finger-like projections. The cellular morphology of these projections ranged from no to severe dysplasia, to carcinoma in situ (Fig 1) and to carcinoma of basal and basosquamous types (Fig 2). Solar elastosis also was evident.

Comment.—Even though basal cell carcinoma occurs commonly on the nose, Acker and Helwig[6] consider the incidence of this tumor in cases of rhinophyma to be so high that a causal relationship must obtain. By means of the χ^2 table, the distribution of basal cell carcinoma in their patients with rhinophyma was compared to a large reported study of basal cell carcinoma without rhinophyma. They found a greater preponderance of basal cell carcinoma on the nose in patients with rhinophyma and considered that basal cell carcinoma will develop in greater than 5% of patients with rhinophyma.

The present report supports Helwig's statistical information and provides morphologic evidence that basal cell carcinoma arises directly from rhinophyma. In Papillary buds arising from dilated follicles, we found a spectrum of changes ranging from hyperplasia, to dysplasia, to carcinoma in situ, to invasive carcinoma. We consider this to provide a morphogenetic pathway for the development of basal cell carcinoma in rhinophyma. These finger-like projections, formed of basal cells, are a well-known feature of rhinophyma that occurs in 60% of these cases[6] but to our knowledge this case represents the first evidence for malignant transformation of these projections.

Chronic inflammation, a feature of

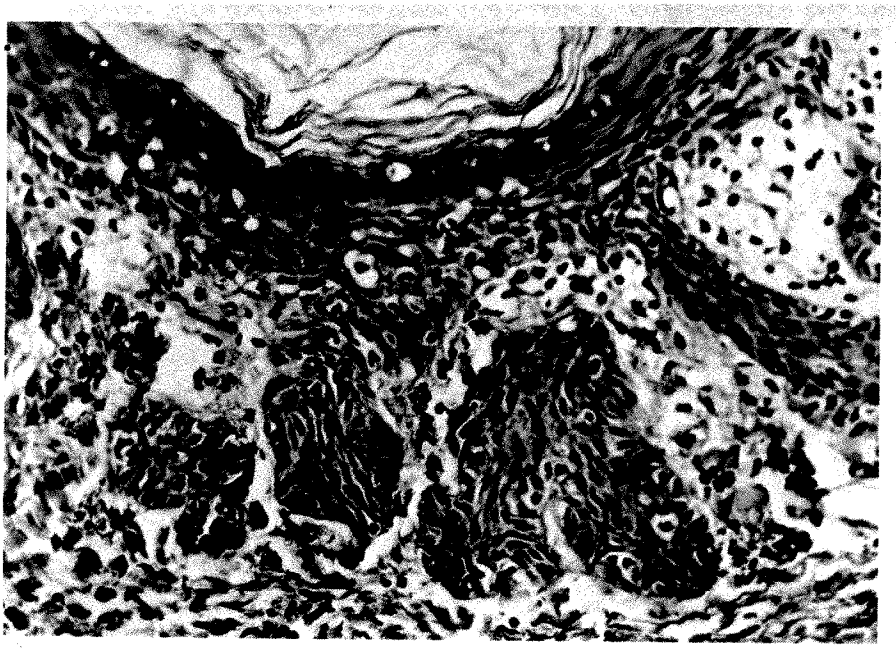

Fig 1.—There are finger-like projections extending from dilated follicle showing severe dysplasia and focal carcinoma in situ (hematoxylin-eosin, original magnification ×400).

Fig 2.—Basal cell carcinoma arising from dilated follicle (hematoxylin-eosin, original magnification ×80).

rhinophyma, may be related to the development of carcinoma. Squamous cell carcinomas are associated with chronic ulcers, chronic osteomyelitis, and burn scars.[5] Although basal cell carcinomas are not usually associated with chronic inflammatory processes, it is of interest that the tumor in the present case was partially basosquamous. Basal cell carcinomas, however, are sometimes associated with scars,[7] and the presence of fibrosis in rhinophyma may be a contributing factor.

We consider it unlikely that the tumor in this case is related to solar radiation, despite the presence of solar elastosis. Most skin carcinomas arise in sun-damaged skin,[5] as with the nose, and it has been postulated that sun exposure and sebaceous glands interact synergistically to generate basal cell carcinomas.[8] However, actinic radiation penetrates only superficially, and the tumor in this case arose deep to the solar elastosis from dilated follicles.

Acquired Zosteriform Cavernous Hemangiomas: Brief Clinical Observation

To the Editor.—We were prompted to submit the following case report because of an extremely unusual distribution pattern of cavernous hemangiomas. We have been unable to find a similar example of such a patient in our search through the recent English literature. We would also like to suggest a potential hazard of the simple punch biopsy technique for deep dermal or subcutaneous nodules.

Report of a Case.—A 62-year-old man was admitted to Michael Reese Medical Center, Chicago, for the evaluation of progressive arthralgias and arthritis. During this admission, a dermatological consultation was obtained for the evaluation of large, multiple, nodular lesions of his trunk. The nodules were first noted 30 years ago. The lesions had been completely asymptomatic and had not varied in color or size. He denied a family history of similar lesions. His medical history and review of systems were noncontributory.

Physical examination revealed a well-developed man in moderate discomfort from diffuse arthralgias. Examination of the skin of the trunk revealed multiple, firm, freely movable, variably sized and shaped, deep dermal and subcutaneous nodules. They were flesh colored and arranged in a zosteriform pattern over the T-8 and T-9 dermatomes extending from the paraspinal to the midclavicular area (Fig 1).

Significant laboratory studies revealed a

normochromic anemia, a Westergren ESR of 114 mm/hr (normal for men, 0 to 20 mm/hr), and an antinuclear antibody titer of 1:1,280 with a speckled and homogeneous pattern. A chest roentgenogram revealed mild cardiomegaly and multiple small calcifications in the soft tissues lateral to the left rib cage. An upper and lower gastrointestinal series and a proctoscopic examination were normal.

One of the nodules on the lateral trunk was excised in toto. Hematoxylin-eosin sections revealed a moderately well-circumscribed fibrous and vascular nodule in the subcutis. Within the nodule were irregularly dilated and variously sized tortuous vascular channels containing RBC, and fibrinous material (Fig 2). The walls of the vascular channels varied from thick, muscular, and fibrous to thin and dilated ones lined with a single layer of endothelial cells. In some areas, there was a proliferation of small capillary-sized vessels, each vessel separated by thin strips of a collagenous stroma. Surrounding the hemangioma was fibrous wall that extended and partially replaced surrounding subcutaneous fat. Hemosiderin pigment was noted in small amounts throughout the collagenous stroma. The calcifications seen on chest x-ray film were not found on histological examination.

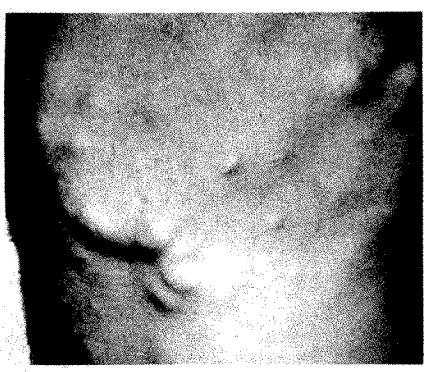

Fig 1.—Nodular cavernous hemangiomas in dermatome distribution involving chest wall of left side.

Comment.—To obtain an accurate differential diagnosis of zosteriform lesions of the skin and subcutis, one can classify them into vascular and nonvascular categories. The most commonly occurring vascular lesions known to present in a unilateral or dermatome distribution are nevus flammeus,[1,2] unilateral telangiectasias,[3-5] angiokeratoma corporis circumscriptum, and angioma serpiginosum.[2] These lesions can be readily distinguished from those of our patient on clinical morphology alone. Maffucci's hemangiomatosis can be eliminated from the differential diagnosis because of the absence of dyschondroplasia and noticeable bone deformities on roentgenographic and physical examinations. Of the common nonvascular lesions that may occur in a linear or dermatome pattern, one should consider those of congenital origin (eg, Darier-White disease and unilateral epidermal nevi) and of acquired origin (eg, lichen planus, herpes zoster, and lichen striatus). These can also be differentiated by their clinical morphology.

Nodular unilateral or dermatome lesions that cannot be easily differentiated solely on clinical morphology include multiple lipomas, neurofibromas,[6] leiomyomas, blue rubber bleb nevi,[7] lymphangioma cavernosum, vascular hamartomas,[1,7] and metastatic tumors. To differentiate these lesions from those of our patient requires a tissue biopsy.

Several observations can be made from the findings from this patient. First, one should now consider in the diagnostic possibilities of unilateral or dermatome lesions the entity zosteriform cavernous hemangiomas. Second, individuals found to have such vascular tumors in one area should be carefully evaluated for similar lesions in other sites. This is especially important in patients with hepatomegaly, gastrointestinal bleeding, seizures, or bone pain. In addition, the roentgenographic findings of soft tissue calcifications in a dermatome area may be suggestive but are not pathognomonic of zosteriform cavernous hemangiomas.

Dermatologists presented with unknown nodules in the skin are almost reflexly inclined to use a punch biopsy on such lesions. We would simply suggest, in the light of our case, that some caution be used under such circumstances.

Double-Blind Trial of 1% Clotrimazole Cream and Whitfield Ointment in the Treatment of Pityriasis Versicolor

To the Editor.—We have recently completed a double-blind trial of clotrimazole (Lotrimin, [Canesten (Br)]) compared with benzoic and salicylic acid (Whitfield) ointment in the treatment of pityriasis versicolor. Clotrimazole is a tritylimidazole deriva-

tive with a wide spectrum of antifungal activity including in vitro fungistatic activity against Malassezia furfur.[1] One percent clotrimazole cream is as effective as Whitfield ointment and more acceptable to the patient. Culture of Malassezia furfur showed a constant and persistent sensitivity to clotrimazole, suggesting its suitability for treatment of relapse. Clinical assessment of hypopigmented lesions at follow-up is not as reliable a test of cure as microscopy of scrapings.

Method.—During a two-year period, all patients seen in the skin department and found to be positive for Malassezia furfur on microscopy of skin scrapings were included in the trial. The patients were allotted at random to treatment with Whitfield ointment (3% salicylic acid and 6% benzoic acid in an emulsifying base) or 1% clotrimazole cream. Neither the clinician nor the patient knew which preparation was being used. All patients were instructed to apply the preparation twice daily to the affected areas for four weeks. Patients were assessed at four and eight weeks and at the end of the trial. Scrapings were cultured on pityrosporum agar, composed of malt extract, 36 gm; peptone (mycological), 6 gm; ox-bile, 20 gm; polysorbate (Tween) 80, 10 ml; Oxoid Agar No. 1, 10 gm; glycerol, (BDH) 5 ml; distilled water to 1 liter. Chloramphenicol (50 μg/ml) and cycloheximide (400 μg/ml) were also added. Cultures were incubated at 30 C for up to five days. Yeasts were identified morphologically and by their inability to grow on Sabourand dextrose agar. Sensitivity to clotrimazole was performed in which a stock solution of 10 mg/ml clotrimazole in ethanol was prepared and diluted in pityrosporum agar to give final concentrations of 6.25, 5.0, 2.5, 1.25, and 0.625 μg/per milliliter, respectively. Control plates with and without ethanol and without clotrimazole were included in each series.

Results.—Forty-five patients entered the trial. The 31 who completed eight weeks' treatment and surveillance gave a history of pityriasis versicolor varying from three months to ten years. More than 75% were 20 to 28 years old. No patient had been treated for pityriasis versicolor in the previous three months. Four weeks' treatment with either clotrimazole cream (14 patients) or Whitfield ointment (17 patients) was equally effective in curing pityriasis versicolor, 80% of the patients being mycologically clear four weeks after the end of the treatment. There was no statistically significant difference between the efficiency of the two preparations (χ^2 test with Yates correction). Burning and/or irritation was twice as common with Whitfield ointment and was noted by six patients. No other side effect occurred.

All isolates of Malassezia furfur were sensitive to clotrimazole, with a mean inhibitory concentration of 2.5 to 5.0 μg/ml.

This trial was started in 1973 since then other reports have demonstrated the clinical efficacy of clotrimazole in the treatment of pityriasis versicolor.[2,3] In a double-blind trial of 1% clotrimazole cream and Whitfield ointment in 32 patients with pityriasis versicolor, there was no statistically significant difference in response.[4] Whitfield ointment and sodium thiosulfate solution have long been used in the treatment of pityriasis versicolor and recently selenium sulfide detergent suspension has been advocated.[5-7] Vigorous application of selenium sulphide, however, runs the risk of causing toxic effects as a result of systemic absorption.[8] Complete cure has been claimed using repeat treatment with selenium sulfide every three months.[9] Repeat treatment is perhaps advisable after use of any topical agent. Clotrimazole would seem especially suitable for this because we have demonstrated that no resistance develops to it with persistent infection.

The attendance at long-term follow-up in this trial was low, preventing a meaningful analysis of relapse rates. Clinical assessment of patients with hypopigmented lesions at follow-up was not a reliable criterion of infection. Such lesions were not all positive mycologically, suggesting that hypopigmentation is a postinfective and postinflammatory phenomenon. Mycology should, therefore, be performed as a test of cure in these cases.

Ferrous Iron and Porphyria Cutanea Tarda

To the Editor.—In recent studies ferrous iron has been implicated in the pathogenesis of porphyria cutanea tarda (PCT) because of its inhibition of uroporphyrinogen decarboxylase and uroporphyrinogen III cosynthetase.[1,2] Taljaard et al[3] suggested that beneficial effects of chloroquine treatment may be related to reduction in a specific pool of liver iron. These authors demonstrated increased urinary iron excretion in several patients with PCT who were treated with chloroquine sulfate. Since we have not found any other reports concerning urinary iron excretion in patients with PCT, we would like to describe briefly an additional case.

Report of Case.—In March 1976, a 60-year-old woman consulted us with an eight-month history of blisters developing over the dorsa of the hands after sunlight exposure. She subsequently noted some tightening of the skin over the arms and neck. In the past six weeks she had noted no new blisters. The patient reported that her urine appeared darker than usual and had a foul odor. She was taking no medications.

Physical examination revealed numerous erythematous, slightly atrophic areas over the dorsa of the hands and fingers at sites of previous blister formation. Milia were numerous. No vesicles or bullae were found. Diffuse, hypopigmented, indurated plaques of scleroderma-like changes were present over the arms, nape, upper chest, and lateral areas of the face. The urine showed intense coral-red fluorescence under the Wood lamp. Results from later studies in the hospital showed no abnormalities. Results of liver function studies and a liver scan were normal, as were serum iron levels and serum iron-binding capacity. Urinary uroporphyrin excretion was 2,240 μg for 24 hours (normal, 40 to 160 μg). The diagnosis of PCT was made. Hydroxychloroquine (Plaquenil) sulfate was given orally at a dose of 100 mg every

Urinary Porphyrin and Iron Excretion in a Patient		
Date	Uroporphyrin, μg/24 hr	Iron, mEq/Liter
3/21	2,249	88
3/23	1,720	110
3/29	2,106	244
4/19	2,818	720
6/30	388	160

other day. Therapy was initiated on March 26, 1976, and the urinary excretion of uroporphyrins and iron was measured repeatedly (Table). On April 21, the dose was increased to 200 mg every other day and then to 200 mg daily on June 24. The patient's hand lesions cleared and therapy was discontinued on Aug 20, 1976.

Comment.—Interestingly, the level of this patient's urinary excretion of iron increased and then decreased after hydroxychloroquine administration, as urinary porphyrin excretion often does. Although the increase in the level of urinary iron excretion with hydroxychloroquine therapy does not finally implicate iron in the pathogenesis of the disease nor diminished iron load in its treatment response, it does provide a possible explanation for the success of hydroxychloroquine-chloroquine therapy.

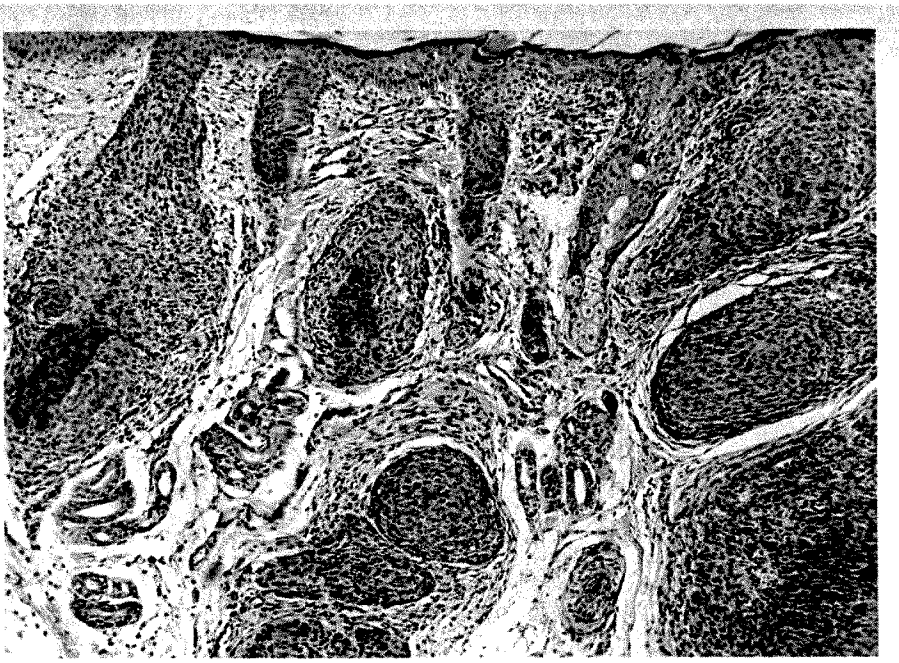
Congenital Disseminate Organoid Tumors

To the Editor.—We recently had the opportunity to observe a newborn infant with distinctive generalized organoid tumors that appeared to represent poorly differentiated attempts at hair formation.

Report of a Case.—A 3,416-gm full-term male infant was born with milia-like papules present everywhere on the body surface except the palms and soles. Normal hair was present in normal concentration and distribution. There were metatarsus varus of the left ankle and pectus excavatum. The rest of the physical examination was normal. At five days after birth the infant experienced respiratory distress followed by low-grade fever and diarrhea. Progressive cardiopulmonary distress ended life at the 44th day. Values for all urine, stool, blood, spinal fluid, and skin cultures were negative. At autopsy, endocardial fibroelastosis in the outflow tract of the heart was found. Extensive pleomorphic inflammatory cell infiltrates were present in the media of the aorta. The pancreas contained foci of lymphocytic aggregations.



Groups of follicular units in dermis (×30).

Several skin biopsy specimens obtained before death contained single or multiple groups of poorly differentiated epidermoid cells in the mid-dermis. Most of the cells were grouped in globular masses and consisted of large vesicular cells admixed evenly with smaller dark cells. Eosinophilic hyalinized PAS-staining fibrillar material was found within these cellular groups. Occasionally, the epidermoid cells assumed a whorl formation (Fig). Within some of the masses, some basaloid cells tended to form buds.

The abnormal configurations were found either entirely within the dermis or connected to the epidermis. The dermal collagen contained an increase in fibrocytes.

Comment.—The congenital and disseminated nature of this adnexal tumor seems to be unique. The lesions numbered in the hundreds and consisted of scattered or closely set 1- to 2-mm milioid papules on the face, arms, trunk, and extremities.

Because the basaloid cells assumed bud formation, their orientation was perpendicular to the epidermis and the vesicular cells within the tumoral masses assumed a whorl-like pattern; we believe the tumors represented attempts at hair follicle formation. The presence of two cell types, clearer larger cells and smaller dark cells with fibrillar PAS and eosinophilic material, supports the broader diagnosis of organoid tumor.

Basal cell hamartomas with follicular infundibulum differentiation and plate-like basal cell proliferation were described by Mehregan and Butler[1] and Johnson and Hookerman[2] in a 52-year-old man with periorbital syringoma-like tumors. Our patient's tumor differed by its containing varying degrees of differentiation of the entire follicular structure, by its presence at birth, and by its widespread nature.

A rare form of trichoepithelioma (also a hair follicle hamartoma)[3,4] associated with alopecia in adults may be distributed in a disseminate manner. However, these contain globules of undifferentiated cells that form epithelial tracts, lobules, or a lace-like network of cells.

We believe diffuse congenital organoid tumors in infancy are another example of the varied form organoid tumors may assume.

Trioxsalen Bath and Ultraviolet Light Treatment of Psoriasis

To the Editor.—Eighteen light-tolerant patients with widespread psoriasis were treated with 15 minutes of a 37 C warm bath with 50 mg of trioxsalen in 100 liters of water. The trioxsalen added was dissolved in 100 ml of 70% alcohol. Immediately after the bath, the skin was irradiated with a set of lamps for ten to 300 seconds at a distance of 60 cm.[1] The lamp gives 0.8M W/sq cm of ultraviolet (UV)-B and 13M W/sq cm of UV-A. The treatment was given five days per week. One arm was left for treatment with coal tar bath, UV light, and stiff dithranol paste.[2] After two to five weeks, the psoriasis had almost or completely healed on the trioxsalen-treated skin. The arm treated with the Ingram regimen[2] healed slower in nine patients, faster in one, and at the same rate in the others. It is possible that the light dose used in the Ingram regimen was too low. When comparing the effects it is essential that each method is used under optimal conditions. The light-sensitizing effect of the bath is even initially stronger and disappears more rapidly than after application of a local trioxsalen alcohol solution. The risk for accidental sunlight reactions is therefore less. The bath has the advantage over oral psoralen treatment in that it gives stronger sensitization with shorter treatment times and minimizes the risk for the internal side effects.

2. Ingram JT: Approach to psoriasis. *Br Med J* 2:591-594, 1953.

Drs Fischer and Juhlin have presented an interesting and apparently effective method of treatment for psoriasis. However, this approach must be considered, potentially, quite dangerous in most areas of the United States, where exposure to the sun is available following the psoralen emersion. As noted by Arora and Willis, photosensitization by topically applied psoralen compounds persists at least 24 hours after exposure (Arch Dermatol *112:327-332, 1976). This potential for photosensitization may last even longer. Thus, this therapy regimen should be considered with a great deal of caution.*—Ed.

Benign Chronic Bullous Dermatosis of Childhood

To the Editor.—Prystowsky and Gilliam (*Arch Dermatol* 112:837-838, 1976) described a case that they labeled as "benign chronic bullous dermatosis of childhood," in which IgA was found deposited in a linear pattern along the dermoepidermal junction. The authors cited "the absence of a granular immunofluorescent pattern" as one factor that "excluded" the diagnosis of dermatitis herpetiformis. Since linear deposition of IgA at the dermoepidermal junction may be seen in 12% of biopsy specimens taken from adults with dermatitis herpetiformis,[1] this particular finding by no means excludes this diagnosis. As the authors point out, there is much confusion regarding the nosology of bullous diseases in childhood. The interesting finding of Prystowsky and Gilliam adds to this confusion.

½
Therapeutic effectiveness with half the dose

Schering

Once-a-day dosage

NEW Fulvicin® P/G*

brand of griseofulvin [ultramicrosize], USP

(specially processed) **125 mg. tablets**

***"P/G" means a new polyethylene glycol system for enhanced absorption –**

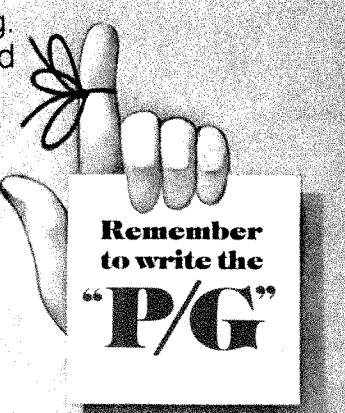
A 250 mg. daily dose (two 125 mg. tablets) of new FULVICIN P/G can replace 500 mg. of griseofulvin (microsize), USP. This is made possible by a special process in which the ultramicrosize griseofulvin crystals are partly dissolved in polyethylene glycol and dispersed through the tablet matrix for enhanced absorption.

Patient convenience –

FULVICIN P/G can be prescribed as two 125 mg. tablets once a day. Compliance is further assured by the easy-to-swallow size of the tablets.

Patient savings –

FULVICIN P/G is up to 35 per cent less expensive per dose than all microsize griseofulvin formulations.**



**Based on list-price comparison.

Schering

NEW P/G
Fulvicin P/G
griseofulvin [ultramicrosize], USP
(specially processed) 125 mg. tablets

ical Considerations: INDICATIONS FULVICIN P/G Tablets are indicated the treatment of ringworm infections of the skin, hair and nails, namely, a corporis, tinea pedis, tinea cruris, tinea barbae, tinea capitis, tinea uum (onychomycosis) when caused by one or more of the following genera ungi: *Trichophyton rubrum, Trichophyton tonsurans, Trichophyton menta phytes, Trichophyton interdigitalis, Trichophyton verrucosum, Trichophyton gnini, Trichophyton gallinae, Trichophyton crateriform, Trichophyton sulph um, Trichophyton schoenleini, Microsporum audouini, Microsporum canis, rosporum gypseum, and Epidermophyton floccosum.* Note: Prior to rapy, the type of fungi responsible for the infection should be identified. The of this drug is not justified in minor or trivial infections which will respond to ical agents alone. Griseofulvin is not effective in the following: Bacterial ections, Candidiasis (Moniliasis), Histoplasmosis, Actinomycosis, Sporo hosis, Chromoblastomycosis, Coccidioidomycosis, North American Blas lycosis, Cryptococcosis (Torulosis), Tinea versicolor, and Nocardiosis. NTRAINDICATIONS This drug is contraindicated in patients with porphyria, atocellular failure, and in individuals with a history of hypersensitivity to eofulvin. WARNINGS *Prophylactic Usage.* Safety and efficacy of griseofulvin prophylaxis of fungal infections have not been established. *Animal icology.* Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of diet, resulted in the development of liver tumors in several strains of mice ticularly in males. Smaller particle sizes result in an enhanced effect. Lower dosage levels have not been tested. Subcutaneous administration of tively small doses of griseofulvin once a week during the first three weeks of has also been reported to induce hepatomata in mice. Although studies in er animal species have not yielded evidence of tumorogenicity, these studies e not of adequate design to form a basis for conclusions in this regard. In acute toxicity studies, orally administered griseofulvin produced hepato ular necrosis in mice, but this has not been seen in other species. turbances in porphyrin metabolism have been reported in griseofulvin ted laboratory animals. Griseofulvin has been reported to have a hic-ne like effect on mitosis and cocarcinogenicity with methylcholanthrene utaneous tumor induction in laboratory animals. *Usage in Pregnancy.* The ty of this drug during pregnancy has not been established. *Animal roduction Studies.* It has been reported in the literature that griseofulvin found to be embryotoxic and teratogenic on oral administration to pregnant Pups with abnormalities have been reported in the litters of a few bitches ted with griseofulvin. Additional animal reproduction studies are in gress. Suppression of spermatogenesis has been reported to occur in rats investigation in man failed to confirm this. PRECAUTIONS Patients on onged therapy with any potent medication should be under close ervation. Periodic monitoring of organ system function, including renal atic, and hematopoietic, should be done. Since griseofulvin is derived from cies of penicillin, the possibility of cross sensitivity with penicillin exists. ever, known penicillin-sensitive patients have been treated without culty. Since a photosensitivity reaction is occasionally associated with eofulvin therapy, patients should be warned to avoid exposure to intense ural or artificial sunlight. Should a photosensitivity reaction occur, lupus hematosus may be aggravated. Griseofulvin decreases the activity of arin type anticoagulants so that patients receiving these drugs concomi ly may require dosage adjustment of the anticoagulant during and after eofulvin therapy. Barbiturates usually depress griseofulvin activity, and comitant administration may require a dosage adjustment of the antifungal nt. ADVERSE REACTIONS When adverse reactions occur, they are most monly of the hypersensitivity type, such as skin rashes, urticaria, and rarely, lonecrotic edema, and may necessitate withdrawal of therapy and ropriate countermeasures. Paresthesias of the hands and feet have been rted rarely after extended therapy. Other side effects reported occasionally oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, gue, dizziness, insomnia, mental confusion, and impairment of performance outine activities. Proteinuria and leukopenia have been reported rarely. inistration of the drug should be discontinued if granulocytopenia occurs. n rare, serious reactions occur with griseofulvin; they are usually associated high dosages, long periods of therapy, or both.

Amir H. Mehregan, MD, Recorder

Recurrent Digital Fibrous Tumor of Childhood. Presented by RALPH J. COSKEY, MD.

This 14-month-old girl was first seen because of skin-colored nodular lesions involving the fourth and fifth toes of the right foot. These were first noted at age 6 months and have increased in size. They were both excised at age 10 months but recurred two months later. A new lesion has appeared in the past month involving the third toe of the same foot.

Histopathologic examination by Dr A. H. Mehregan reports massive proliferation of elongated and spindle-shaped fibroblasts and collagenous tissue forming intersecting bundles. The elastic fibers are absent within the tumor area. Phosphotungstic acid-hematoyxlin stain demonstrates numerous round dense bodies in the cytoplasm of proliferating fibroblasts characteristic of the recurrent digital fibrous tumor of childhood (Figure).

Discussion

H. RAHBARI, MD: Among various forms of juvenile fibromatoses, the recurrent digital fibrous tumor of childhood shows distinctive clinical and histologic findings.[1] There are 21 published cases of this condition consisting of ten boys, ten girls, and one person of unknown gender. In 12 the patients' lesions were on the fingers and in eight on the toes. One child had lesions both on the fingers and toes. Nine patients had single lesions and 12 had multiple ones. In seven instances, the lesions were present at birth. This growth is notable for its unresponsiveness to surgical treatment and its tendency for recurrence. It is histologically differentiated from other types of fibrous tumors by the presence of round bodies 3 μ in diameter in the cytoplasm of fibroblasts. With Mallory's trichrome stain, these bodies appear red against collagen that stains blue and with phosphotungstic acid-hematoxylin the round bodies stain deep purple and are easily recognized. The possibility of the viral nature of the dense bodies was raised because of the positive staining with methyl green-pyronine that suggested the presence of RNA. Viral culture studies and electron microscopy, however, failed to support this hypothesis.[2] The round intracellular bodies are most likely accumulated abnormal by-products of metabolically deranged fibroblasts or are possibly related to the abnormal fibrillar protein covering of elastin.

RICHARD HARRELL, MD: In one case of this type I injected the lesion with steroid solution. The lesion has flattened but has not yet completely resolved.

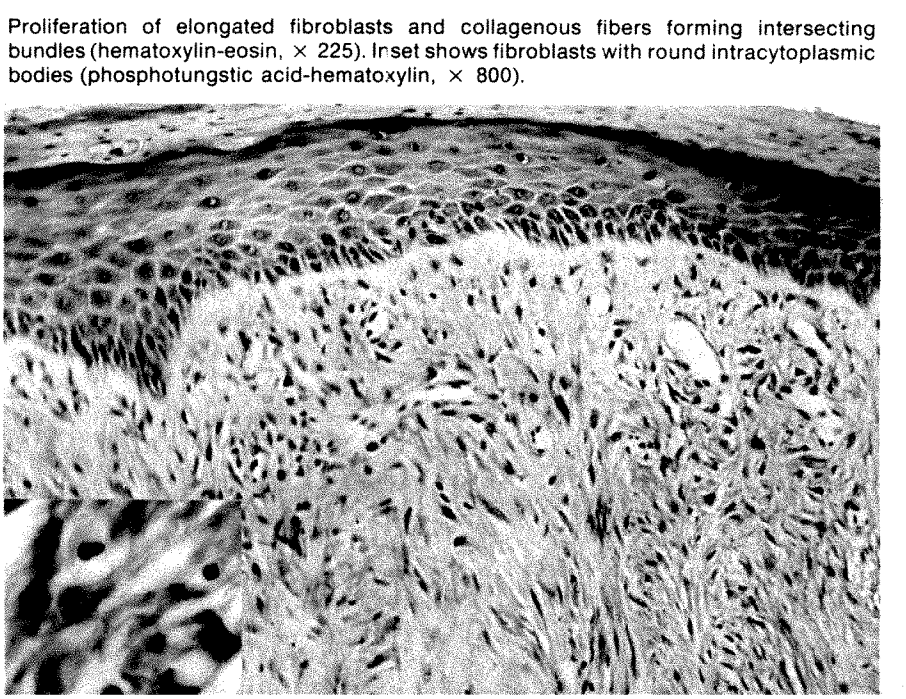
Lamellar Ichthyosis. Presented by KATHERINE TAYLOR, MD.

This 29-year-old man has had dry skin since infancy. He is the only member in his family who is affected, with three normal siblings. There is a thick and coarse scale covering the entire skin surface giving a parchment-like quality. The palms and soles are greatly hyperkeratotic and he has difficulty grasping with his fingers. The conjunctivae are injected and both eyes exhibit ectropions. There is also diffuse hair loss on the scalp. Histologic sections show mild thickening of the epidermis with hypergranulosis and adherent orthokeratotic hyperkeratosis. The dermis shows a mild perivascular round cell infiltrate.

Discussion

KATHERINE TAYLOR, MD: We have treated this patient and another patient with X-linked recessive ichthyosis with

Proliferation of elongated fibroblasts and collagenous fibers forming intersecting bundles (hematoxylin-eosin, × 225). Inset shows fibroblasts with round intracytoplasmic bodies (phosphotungstic acid-hematoxylin, × 800).



topical application of 5% lactic acid in an emulsion of equal parts of a water-miscible ointment base and water (Eucerin cream) for a period of six months. In the patient with X-linked recessive ichthyosis the results were dramatic in less than two weeks. The patient presented today experienced at least 50% improvement. Thus far we have not observed any untoward reaction to the topical medication.

Earl Rudner, MD: I tried lactic acid cream on a patient with ichthyosis hystrix, which is histologically similar to the epidermolytic hyperkeratosis. There was no beneficial response.

Porokeratosis in a Patient With Psoriasis.

Presented by JOHN WEISS, MD; JAMES PEDERSON, MD; ANA ENG, MD

This 54-year-old man first noticed silvery scaling on his knees and elbows 20 years ago and was told he had psoriasis. He has been treated with various topical preparations, including steroids and tars. Two years ago, more bothersome and less responsive lesions began to develop that were more localized and keratotic than previous ones. Approximately one year ago another, morphologically different, lesion began to develop. This lesion is flat and symptomatic and has been unresponsive to therapy. There is no family history of similar skin problems. He has had Laennec cirrhosis and esophageal varices since 1960.

Examination of his skin shows a generalized, mild erythema. Diffuse, heavy scaling is noted on the scalp, dorsums of the hands and feet, and the legs. Numerous keratotic, conical, nodular lesions are most prominent on the extremities. A distinctly different, more numerous lesion is noted in a generalized distribution. This lesion has a well-defined keratotic, and slightly raised border. The central portion is erythematous, flat, and, without scale. All nails are dystrophic. Mucous membranes are not involved. Laboratory studies showed elevated SGOT, lactic dehydrogenase, serum alkaline phosphatase, and serum bilirubin levels. The complete blood cell count, BUN, serum uric acid levels and results of urinalysis were within normal limits. A biopsy specimen of a flat lesion with a well-defined keratotic border was found to be consistent with porokeratosis.

Topical steroids alone and in combination with keratolytics, including retinoic acid solution, have failed to alter the lesions.

Discussion

RICHARD WINKELMANN, MD: The patient has had cirrhosis for a minimum of five years and has had bleeding esophageal varices. This is an important background fact. He has a 20-year history of a psoriatic process that is said to be absent now and a two-year history of a rapidly and extensively progressive, keratosquamous, and nodular disease that has involuted into some unusual lesions. This patient presents a number of morphologically speculative problems.

SIDNEY BARSKY, MD: I thought he had psoriasis plus some small areas of porokeratosis. Histologically, one of the two slides was consistent with psoriasis and the other suggested porokeratosis with a prominent cornoid lamellae. I do not think the patient has disseminated actinic porokeratosis for he has porokeratotic lesions on covered areas. The relationship between these two diseases is not clear.

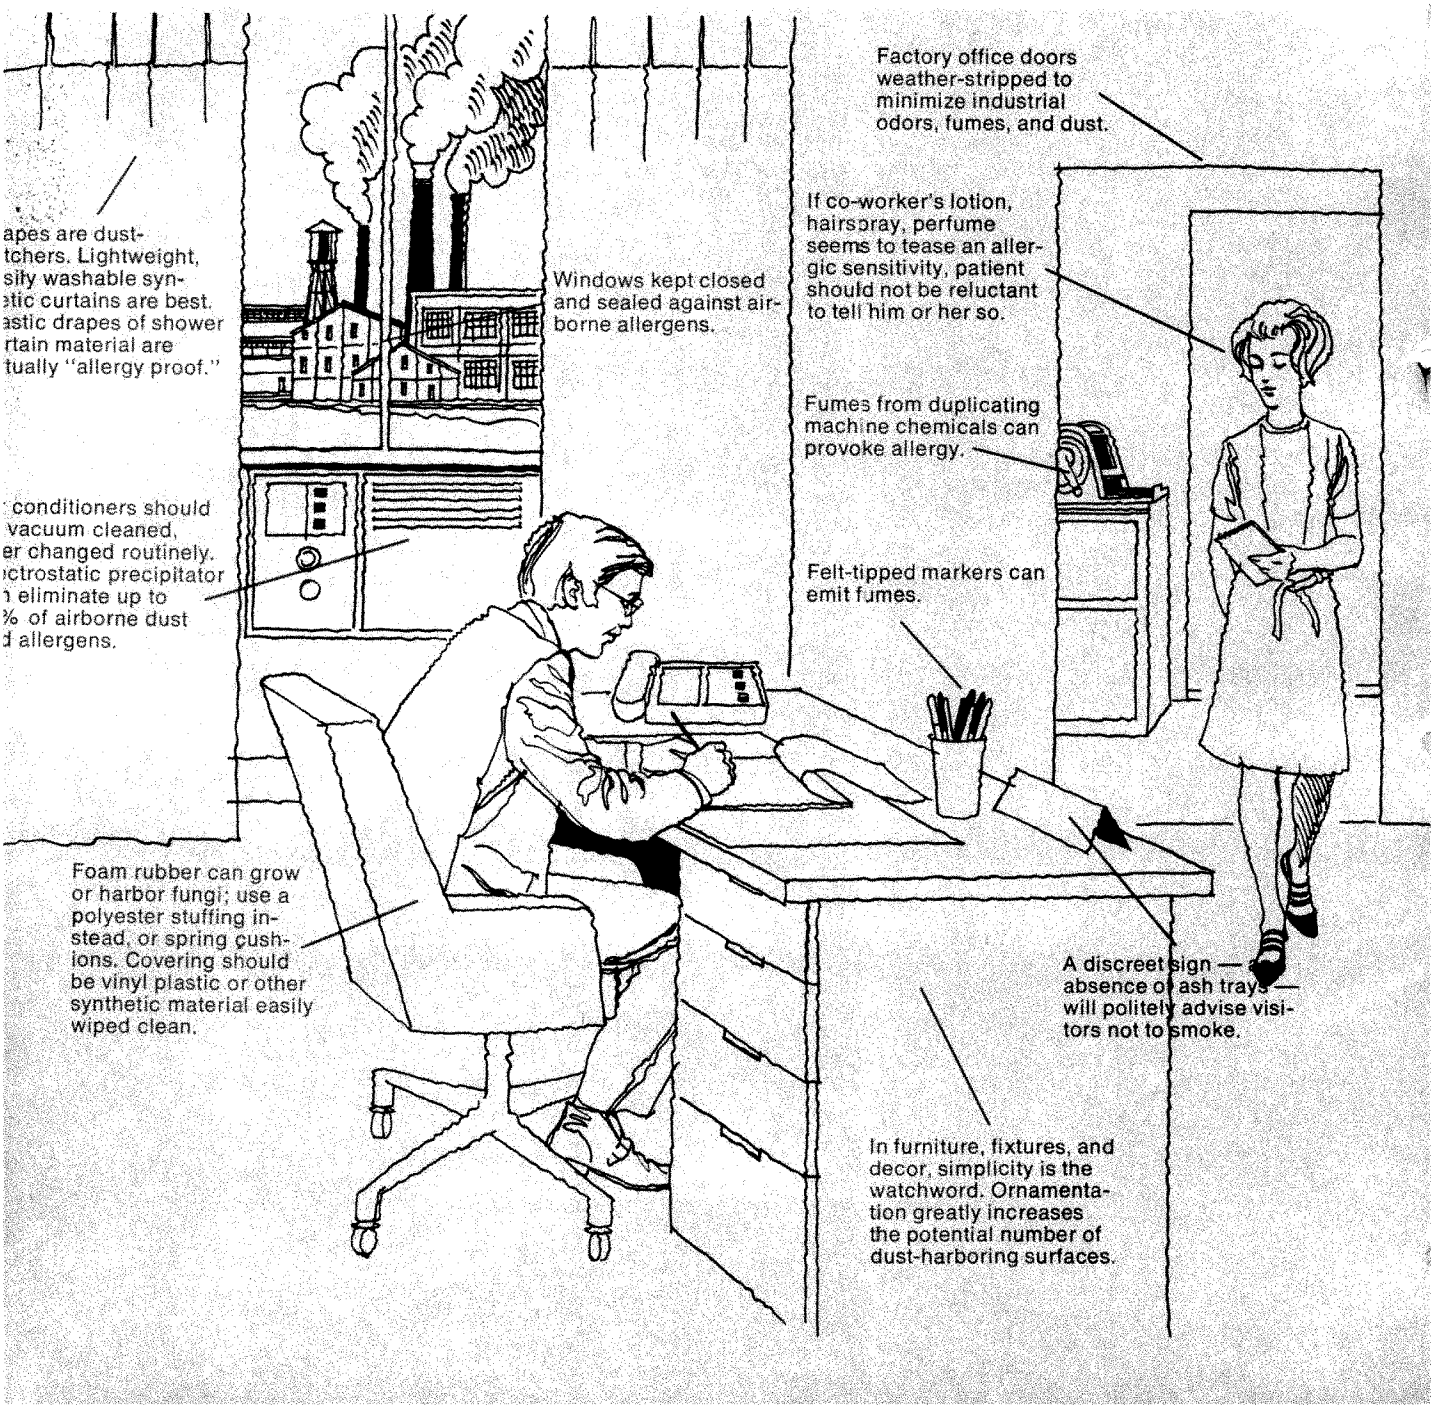
ANA ENG, MD: I diagnosed this case as one of porokeratosis of Mibelli by histopathological examination before seeing the patient clinically. However, the clinician at the time disagreed. This was when the patient showed only the verruca-like, fleshy growths on his extremities (Fig 1, arrow 1). After a few months, the typical lesions of porokeratosis of Mibelli developed (Fig 1, arrow 2). He also showed small, confluent erythematous papules on his extremities, back, and chest (Fig 1, arrow 3). A biopsy specimen of these papules showed the histopathological features of psoriasis, which on serial sections merged into areas showing cornoid lamellae. Figure 2 (arrows) shows the cornoid lamella seen in a keratotic lesion. This feature is present uniformly on multiple biopsy specimens and is typified by columns of parakeratosis, beneath which are perinuclear vacuolar changes of the cells in the granular layer. In warts, one may find parakeratotic layers of cells and vacuolated granular cells, but the columns of parakeratotic cells are not as sharply demarcated from adjacent normal epidermis as in porokeratosis. The parakeratotic cells in porokeratosis extend deeply in a V-shaped manner into the underlying prickle cell layer. The gross configuration and the epidermal changes of keratoacanthoma are absent.

Fig 1.—Different clinical variants of porokeratosis of Mibelli. Arrow 1 indicates verruca-like fleshy growths; arrow 2, typical lesions of porokeratosis of Mibelli; arrow 3, small confluent erythematous papules.

Fig 2.—Cornoid lamella (arrows) as typical histological feature of porokeratosis of Mibelli.

Ways to help allergy patients avoid "a bad day at the office"

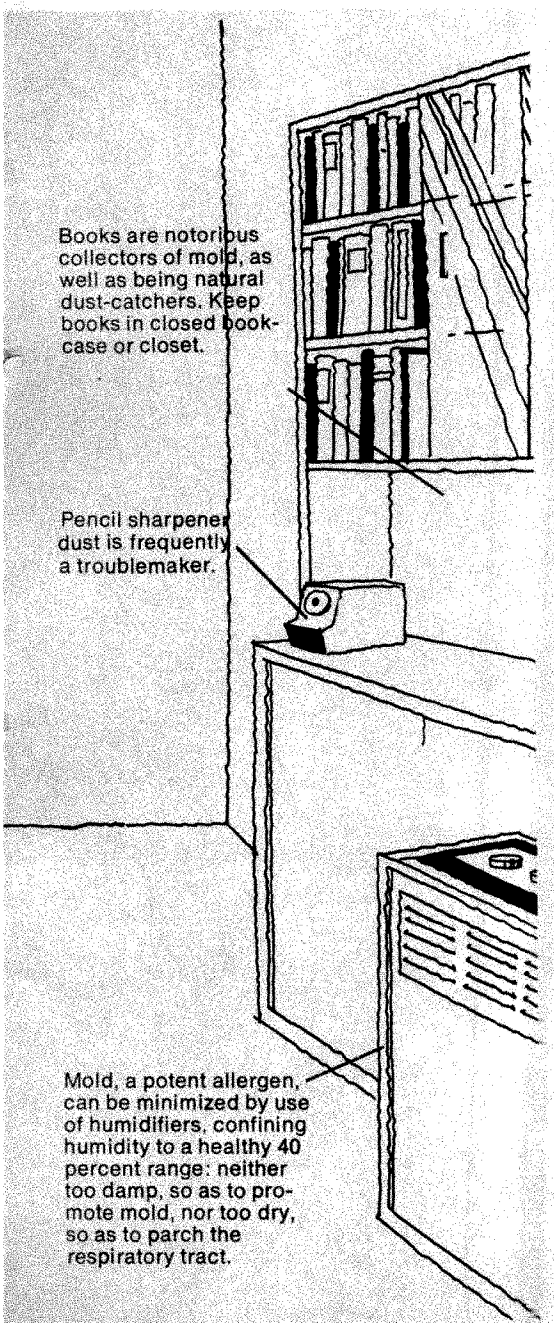
Your allergy patients who are office workers may spend a quarter of their adult life in a hostile environment — from an allergen standpoint. Here are suggestions that might, with the help of an understanding employer, lessen the allergic burden.



All measures to minimize exposure can be helpful. Still, allergic symptoms may occur and an antihistamine will be needed to bring these reactions under control. Dimetane Extentabs keep working for 10-12 hours, are economical, and are likely to produce good results in stubborn as well as routine cases, usually without drowsiness or overstimulation.

DIMETANE Extentabs®

(BROMPHENIRAMINE MALEATE, NF 8 mg. and 12 mg.)



Indications: Perennial and seasonal allergic rhinitis; vasomotor rhinitis; allergic conjunctivitis due to inhalant allergens and foods; mild, uncomplicated allergic skin manifestations of urticaria and angioedema; amelioration of allergic reactions to blood or plasma; dermatographism; as therapy for anaphylactic reactions *adjunctive* to epinephrine and other standard measures after the acute manifestations have been controlled. **Contraindications:** *Use in Newborn or Premature Infants.* This drug should **not** be used in newborn or premature infants. *Use in Nursing Mothers.* Because of the higher risk of antihistamines for infants generally and for newborns and prematures in particular, antihistamine therapy is contraindicated in nursing mothers. *Use in Lower Respiratory Disease.* Antihistamines should NOT be used to treat lower respiratory tract symptoms including asthma. Antihistamines are also contraindicated in the following conditions: hypersensitivity to brompheniramine maleate and other antihistamines of similar chemical structure; monoamine oxidase inhibitor therapy (see Drug Interaction section). **Warnings:** Antihistamines should be used with considerable caution in patients with: narrow angle glaucoma; stenosing peptic ulcer; pyloroduodenal obstruction; symptomatic prostatic hypertrophy; bladder neck obstruction. *Use in Children.* In infants and children, especially, antihistamines in **overdosage** may cause hallucinations, convulsions, or death. As in adults, antihistamines may diminish mental alertness in children. In the young child, particularly, they may produce excitation. *Use in Pregnancy.* Experience with this drug in pregnant women is inadequate to determine whether there exists a potential for harm to the developing fetus. *Use with CNS Depressants.* Dimetane has additive effects with alcohol and other CNS depressants (hypnotics, sedatives, tranquilizers, etc.). *Use in Activities Requiring Mental Alertness.* Patients should be warned about engaging in activities requiring mental alertness, such as driving a car or operating appliances, machinery, etc. *Use in the Elderly (approximately 60 years or older).* Antihistamines are more likely to cause dizziness, sedation, and hypotension in elderly patients. **Precautions:** As with other antihistamines, Dimetane has an atropine-like action and, therefore, should be used with caution in patients with: history of bronchial asthma; increased intraocular pressure; hyperthyroidism; cardiovascular disease; hypertension. **Drug Interactions:** MAO inhibitors prolong and intensify the anticholinergic (drying) effects of antihistamines. **Adverse Reactions:** The most frequent adverse reactions are italicized: *General:* Urticaria, drug rash, anaphylactic shock, photosensitivity, excessive perspiration, chills, dryness of mouth, nose, and throat. *Cardiovascular System:* Hypotension, headache, palpitations, tachycardia, extrasystoles. *Hematologic System:* Hemolytic anemia, thrombocytopenia, agranulocytosis. *Nervous System: Sedation, sleepiness, dizziness, disturbed coordination,* fatigue, confusion, restlessness, excitation, nervousness, tremor, irritability, insomnia, euphoria, paresthesias, blurred vision, diplopia, vertigo, tinnitus, acute labyrinthitis, hysteria, neuritis, convulsions. *G.I. System: Epigastric distress,* anorexia, nausea, vomiting, diarrhea, constipation. *G.U. System:* Urinary frequency, difficult urination, urinary retention, early menses. *Respiratory System: Thickening of bronchial secretions,* tightness of chest and wheezing, nasal stuffiness. **Overdosage:** Antihistamine overdosage reactions may vary from central nervous system depression to stimulation. Stimulation is particularly likely in children. Atropine-like signs and symptoms – dry mouth; fixed, dilated pupils; flushing; and gastrointestinal symptoms may also occur. *If vomiting has not occurred spontaneously,* the patient should be induced to vomit. This is best done by having him drink a glass of water or milk after which he should be made to gag. Precautions against aspiration must be taken, especially in infants and children. *If vomiting is unsuccessful,* gastric lavage is indicated within 3 hours after ingestion and even later if large amounts of milk or cream were given beforehand. Isotonic and ½ isotonic saline is the lavage solution of choice. *Saline cathartics,* as milk of magnesia, by osmosis draw water into the bowel and therefore, are valuable for their action in rapid dilution of bowel content. *Stimulants* should **not** be used. Vasopressors may be used to treat hypotension. **Dosage and Administration:** DOSAGE SHOULD BE INDIVIDUALIZED ACCORDING TO THE NEEDS AND THE RESPONSE OF THE PATIENTS. *Adults:* One to two 4 mg tablets three or four times a day. One Extentab (8 or 12 mg) every eight to twelve hours or twice daily. Two to four teaspoonfuls of elixir three or four times a day. *Children over six.* One 4 mg tablet three or four times a day. One Extentab (8 or 12 mg) every twelve hours. One or two teaspoonfuls of elixir three or four times a day. *Children under six.* 0.5 mg of brompheniramine maleate per kg of body weight per 24 hours, or 15 mg per M^2 per 24 hours, divided into 3-4 doses.

Books

Medical Mycology, Chester W. Emmons, PhD, Chapman H. Binford, AB, MD, John P. Utz, MD, et al, 592 pp, with 554 illus, $19.50, Lea & Febiger, 1977.

The third edition of *Medical Mycology* by Emmons et al continues in the scholarly approach of the first editions and adds to the previous volumes. Not only is there an increase in pages but there are also additional illustrations and figures. The index is complete, cross-referenced, and easy to use. A substantial bibliography follows each chapter. The color plates are beautiful and one only wishes there were more of them. A new chapter on common contaminants, with clear illustrations, should prove useful to most medical mycology laboratories. An entire chapter has been devoted to phaeomycotic cysts, a poorly understood clinical entity to many workers in this discipline. The added table on "serologic, immunologic and skin tests in mycoses" summarizes nicely the available tests and indicates their usefulness. The additional information on new modalities of therapy for the mycoses is surely essential to all specialists in this field. In summary, this text is up to date, lucid, concise, and encompasses all aspects of medical mycology. It is especially pertinent today with the large number of immunosuppressed patients in whom complications develop because of pathogens as well as what were once considered to be contaminants. The text has a multispecialist appeal and will continue to be a valuable source of reference for dermatologists, internists, mycologists, surgeons, and researchers.

PAUL H. JACOBS, MD
Stanford, Calif

Enfermedades de la Boca: Semiologia, Patologia, Clinica y Terapeutica de la Mucosa Bucal, vol 3, by Julio Diaz, Luis Oscar Villapol, Ruben Berdichesky, Jorge Abulafia, and Juana Schneiderman, 973 pp, illus, Buenos Aires, Editorial Mundi, 1976.

This, the third volume of this encyclopedic treatise on diseases of the mouth, was to be the last volume. However, the authors tell us in the introduction that a fourth volume will be needed to finish this monumental undertaking. There has been some repetition, but this does not detract greatly from the overall value of the texts to date. The third volume complements the previous two works, and together they should serve as a complete primer and atlas of oral diseases.

The third volume is 973 pages long (exclusive of index) and is divided into eight chapters that cover primary diseases of the various oral structures, malformation and dysplasias, congenital and hereditary malformations and dysplasias, metabolic diseases with oral manifestations, connective tissue disorders, endocrine diseases, facial and cephalic neuralgias, psychiatric disorders, and blood disorders.

The book is generously endowed with charts and clinical photographs, which generally are of superior quality in selection. The bibliographies are reasonably extensive, although not selective, and sufficiently up to date. In particular, the chapter on primary diseases of the oral tissues was excellent. For example, the discussion on the various types of cheilitis is the most extensive and most expertly done of any I have read, and it bridges the gap between the old and new only as an expert clinician, such as Grinspan, could have done. The same is true for the discussion of the various types of glossitis and disorders of the gingivae, which are discussed equally expertly and make the book worth buying for this reason alone.

There was considerable waste of valuable space given over to preliminary general discussions of problems, such as basic genetics, and unnecessary theoretical considerations of disorders such as systemic lupus erythematosus, diabetes mellitus, and hyperlipidemia, among others. However, since the book is also intended for a wide readership, including dentists, this was probably considered prudent. Yet it does detract from the scientific merit of the book and extends the length of this treatise unnecessarily.

These volumes are a must for medical libraries and for those physicians particularly interested or working in this area. They will be most valuable for dentists, oral pathologists, and dermatologists. I would recommend to the authors that, rather than make further additions to these volumes, they revise the earlier volumes so that the texts will continue to be a source book of information of diseases of the mouth.

Rochester, Minn

DESCRIPTION

Synalar® (fluocinolone acetonide) has the chemica
6α, 9α-difluoro-16α-hydroxyprednisolone-16, 17-acetc

Synalar® Solution 0.01%—contains 0.01% fluocinolon
acetonide in propylene glycol with citric acid.

Synalar® Ointment 0.025%—contains 0.025% fluocin
acetonide in white petrolatum.

Synalar-HP® Cream—contains 0.2% fluocinolone ac
in a water-washable aqueous base of stearyl alcoh
alcohol, mineral oil, propylene glycol, sorbitan mon
stearate, polyoxyethylene sorbitan monostearate ar
citric acid, with methylparaben and propylparaben
preservatives.

Synemol™ (fluocinolone acetonide) has the chemicc
6α, 9α-difluoro-16α-hydroxyprednisolone-16, 17-aceto

The vehicle is a water-washable aqueous emollient
stearyl alcohol, cetyl alcohol, mineral oil, propylene
sorbitan monostearate, polyoxyethylene sorbitan mc
stearate and citric acid.

INDICATIONS

For relief of the inflammatory manifestations of cortic
steroid-responsive dermatoses.

CONTRAINDICATIONS

Topical steroids are contraindicated in vaccinia anc
varicella.

Topical steroids are contraindicated in those patient
history of hypersensitivity to any of the components o
preparation.

Synalar-HP Cream should not be used on infants up
years of age.

PRECAUTIONS

If irritation develops, the product should be discontin
appropriate therapy instituted.

In the presence of an infection the use of an approp
antifungal or antibacterial agent should be instituted
favorable response does not occur promptly, the cort
steroid should be discontinued until the infection has
adequately controlled.

If extensive areas are treated or if the occlusive techn
used, the possibility exists of increased systemic absor
of the corticosteroid and suitable precautions should
taken.

Although topical steroids have not been reported to h
adverse effect on pregnancy, the safety of their use ir
pregnant females has not absolutely been establishe
Therefore, they should not be used extensively on pre
patients, in large amounts, or for prolonged periods c

Topical steroids are not for ophthalmic use.

Synalar-HP Cream should not be used for prolonged p
and the quantity per day should not exceed 2 g of
formulated material.

ADVERSE REACTIONS

The following local adverse reactions have been repo
with topicalcorticosteroids: burning, itching, irritation,
dryness, folliculitis, hypertrichosis, acneform eruptions,
hypopigmentation.

Synalar Cream and Ointment, Synemol Cream.

The following may occur more frequently with occlusi
dressings than without such therapy: maceration of th
secondary infection, skin atrophy, striae, miliaria.

HOW SUPPLIED

Synalar® (fluocinolone acetonide)
Cream 0.025%—15, 60 g tubes; 120, 425 g jars.
Cream 0.01%—15, 45, 60 g tubes; 120, 425 g jars.
Ointment 0.025%—15, 60 g tubes; 425 g jars.
Solution 0.01%—20, 60 cc plastic squeeze bottles.
Synalar-HP® (fluocinolone acetonide) 0.2% Cream—5
tubes.
Synemol™ (fluocinolone acetonide)
Cream 0.025%—15, 60 g tubes.

These preparations are available on prescription only.

and here.
Tinver®
sodium thiosulfate USP 25%, salicylic acid USP 1%
where tinea versicolor is seen and
where malassezia furfur is suspected
Please see following page for prescribing information.

DESCRIPTION:
Sodium thiosulfate 25%, salicylic acid 1%, isopropyl alcohol NF 10%, propylene glycol USP, menthol USP, disodium edetate, colloidal alumina, and purified water.

INDICATIONS:
For topical use in the treatment of tinea versicolor (Malassezia furfur infection).

PRECAUTIONS:
If signs of irritation or sensitivity develop, discontinue use. Do not use on or about the eyes.

ADMINISTRATION:
Thoroughly wash, rinse and dry the affected areas before application of medication. Apply a thin film of lotion to all affected areas and other susceptible areas twice a day. Although diagnostic evidence of the disease may disappear in a few days, it is advisable to continue treatment for a much longer period. Clothing should be boiled to prevent reinfection.

HOW SUPPLIED:
6 fl. oz. plastic dispenser bottles.

CAUTION:
U.S. Federal law prohibits dispensing without prescription.

News and Notes

The Patch Test Clinic.—The fourth annual Patch Test Clinic will be held during the Academy of Dermatology meeting in Dallas in December 1977. Residents and physicians in practice are requested to work up cases for presentation at the Clinic Symposium, where they will be discussed by a panel of experts and the presenter. The following three categories of presentations are to be considered: (1) the most instructive case; (2) the most thoroughly worked up case; and (3) the most unusual case. Awards to honor achievement will be given to winners in these three categories.

Those interested should submit a history and photomicrographs of the clinical lesions as well as patch test results of as many cases as you wish to submit in each of the three categories to: William L. Epstein, MD, Department of Dermatology, UCSF, San Francisco, CA 94143. Prepare now for the deadline of Nov 1, 1977.

Flaps.—The American Society for Dermatologic Surgery announces a course entitled "Dermatologic Surgery—Flaps." The course will be held at the University of California Medical Center, San Francisco, Oct 22 through 23, 1977. The course moderator will be Theodore Tromovitch, MD. For further information write to Extended Programs in Medical Education, University of California School of Medicine, San Francisco, CA 94143.

Position Open: Assistant Research Biochemist.—This position is open in the Department of Dermatology. Qualifications are as follows: postdoctoral experience and publications demonstrating productivity in biochemical oncology. Applicant must be competent in radioisotopic techniques, tissue culture of pigment cells, cell fractionation, and isolation and identification of metabolites by high pressure liquid chromatography. Also, must be familiar with electron microscopy and electronprobe x-ray microanalysis.

Effective Date of Appointment: July 1, 1977 through Dec 31, 1979. Address applications, including curriculum vitae, to: Dr Scott Blois, Blo 400, Room A-16, University of Ca fornia San Francisco, San Francisc CA 94143. An Equal Opportunity Affirmative Action employer.

Hair Transplant Symposium.—Th American Society for Dermatolog Surgery and the American Acaden of Facial Plastic and Reconstructi Surgery are sponsoring the Annu Hair Transplant Symposium an Workshop, Feb 10 and 11, 1978 in H Springs, Ark. The course moderat will be D. Bluford Stough III, MD. F further information write to Stou Dermatology and Cutaneous Surge Clinic, Doctor's Park, Hot Spring AR 71901.

Pediatric Dermatology Symposium This three-day symposium to be he at Stanford (Calif) University on Se 14-16, 1977, will focus on dermatolog problems observed in children, inclu ing viral, bacterial, fungal, and par sitic diseases, psoriasis, atopic derm titis, poison oak, warts, moles, e This is an American Medical Assoc tion-accredited postgraduate semin For information, contact Paul Jacobs, MD, Department of Dermat ogy, Stanford University Medi Center, Stanford, CA 94305, or pho (415) 497-6101.

General Meeting.—The American S ciety for Dermatologic Surgery w hold a general membership meeti Dec 4, 1977 in Dallas. Details will announced in the society's newslett or interested parties may write Daniel E. Gormley, MD, ASDS sec tary, 210 S Grand Ave, Suite 3 Glendora, CA 91740.

ASDS Annual Meeting.—The Am ican Society for Dermatologic Surg will hold its fourth annual Clinical a Scientific Meeting March 30 to Ap 2, 1978 at Vacation Village in S Diego. The course moderator will Theodore Tromovitch. For reservat information write to Mr. Rob Brown, The Incentive Co, 2207 Che nut St, Philadelphia, PA 19103.

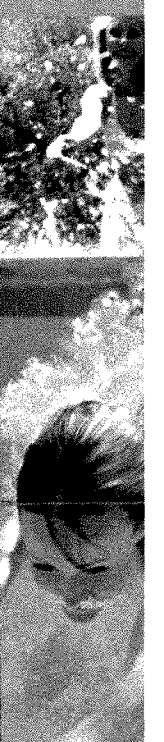
AZTEC® SUNSCREEN LOTION.

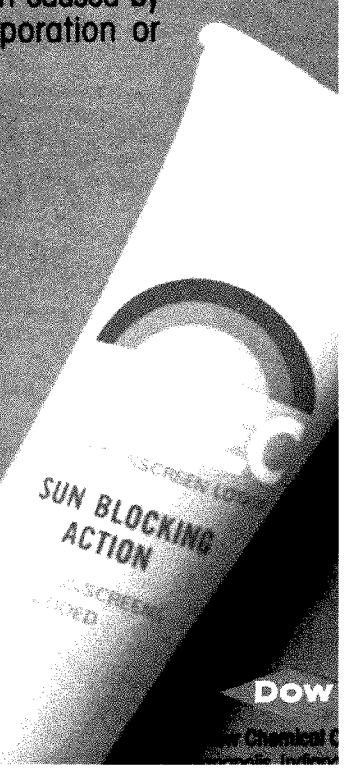
Protects better becau
it stays on longer.
Even after swimming.

Almost all professional sunscreen products protect against overexposure to the sun. Aztec does it with two complementary sunscreening agents for full coverage in the critical 280-315 nm range.

Maintaining protection during activity is another matter altogether. Swimming, perspiration, even toweling can easily wipe other lotions away, leaving your sun-sensitive patients exposed.

Only Aztec contains a patented acrylate polymer base which forms an umbrella-like matrix on the skin. This matrix holds both sunscreening agents on the skin for maximum protection...inhibits the loss of protection caused by swimming, evaporation or wiping away.





®Trademark of The Dow Chemical Company

For your professional recommendation.

AZTEC® SUNSCREEN LOTION.

Protects better, even after swimming.

HOECHST-ROUSSEL PHARMACEUTICALS INCORPORATED

Announces a New topical fluorinated corticosteroid in a Unique Emollient Cream Base

NEW TOPICORT (DESOXIMETASON

THE SPECIALLY DEVELOPED, PRESERVATIVE-FREE BASE COMBINES THE EMOLLIENCE OF AN OINTMENT WITH THE COSMETIC ACCEPTABILITY OF A CREAM IN A WATER-IN-OIL EMULSION.

Well-documented efficacy and safety: Anti-inflammatory, antipruritic, vasoconstrictive Topicort (desoximetasone) has been demonstrated safe and effective in relieving the inflammatory manifestations of corticosteroid-responsive dermatoses.

Worldwide clinical experience: For up to 4 years, Topicort (desoximetasone) has been marketed by Hoechst in over 30 foreign countries. Extensive clinical trials in the United States, conducted by 23 investigators under a wide variety of climatic conditions, confirm the many years of worldwide experience.

A wide range of conditions in corticosteroid-responsive dermatoses: Topicort (desoximetasone) is useful on wet as well as dry lesions, in both acute and chronic cases, with a profile of adverse reactions similar to that seen with other topical corticosteroids.

Emollient Cream 0.25%

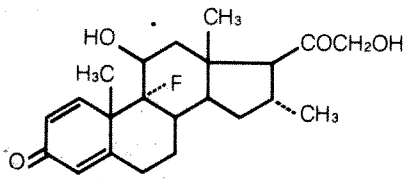
Available: 15-gram tubes.
In corticosteroid-responsive dermatoses
Convenient B.I.D. dosage.

Please consult full prescribing information on following page.

0710

TOPICORT®(desoximetasone) EMOLLIENT CREAM 0.25%

Description: Topicort® (desoximetasone) Emollient Cream 0.25% contains the active synthetic corticosteroid desoximetasone. The chemical name of desoximetasone is 9α - fluoro - 11β, 21 - dihydroxy - 16α - methylpregna - 1,4 - diene-3,20-dione. The chemical structure is:



Each gram of Topicort® (desoximetasone) Emollient Cream 0.25% contains 2.5 mg desoximetasone in an emollient cream consisting of isopropyl myristate, cetylstearyl alcohol, white petrolatum, mineral oil, lanolin alcohol and purified water.

Actions: Topicort® (desoximetasone) Emollient Cream is primarily effective because of its anti-inflammatory, antipruritic and vasoconstrictive actions.

Indications: Topicort® (desoximetasone) Emollient Cream is indicated for the relief of inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications: Topical steroids are contraindicated in vaccinia, varicella and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

Precautions: If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled.

Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time, or if occlusive technique is used.

If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Adverse Reactions: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria.

Dosage and Administration: Apply a thin film of Topicort® (desoximetasone) Emollient Cream 0.25% to the affected skin areas twice daily. Rub in gently.

How Supplied: Topicort® (desoximetasone) Emollient Cream 0.25% is supplied in 15-gram tubes.

Cordran® (Flurandrenolide)

Description: Cordran® (flurandrenolide, Dista) is a potent corticosteroid intended for topical use. **Actions:** Cordran is primarily effective because of its anti-inflammatory, antipruritic and vasoconstrictive actions. **Indications:** For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses. **Contraindications:** Topical corticosteroids are contraindicated in vaccinia and varicella and in patients with a history of hypersensitivity to any of their components. **Precautions:** If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, an appropriate antifungal or antibacterial agent should be used. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, there is a possibility of increased systemic absorption of the corticosteroid, and suitable precautions should be taken. Although topical corticosteroids have not been reported to have an adverse effect on pregnancy, the safety of their use on pregnant women has not been absolutely established. Therefore, they should not be used extensively, in large amounts, or for prolonged periods of time on pregnant patients. These products not for ophthalmic use. **Adverse Reactions:** The following local adverse reactions have been reported with topical corticosteroid formulations: acneform eruptions, burning, dryness, folliculitis, hypertrichosis, hypopigmentation, irritation, itching. The following may occur more frequently with occlusive dressings: maceration of the skin, miliaria, secondary infection, skin atrophy, striae. **Administration and Dosage:** For moist lesions, a small quantity of the cream or lotion should be rubbed gently into the affected areas two to three times a day. For dry, scaly lesions, the ointment is applied in a thin film to affected areas two or three times daily.

Conditions for Acceptance of Color Illustrations

Illustrations in full color are accepted for publication in ARCHIVES OF DERMATOLOGY if the editor believes that color will add significantly to the published manuscript.

When color illustrations are accepted, the American Medical Association will pay part of the expense of reproduction and printing, the remainder to be borne by the author or the institution with which he is affiliated. After deducting AMA's contribution, the author's share is $275 for up to six square finished illustrations. Additional illustrations and special effects, such as outlining, opaquing, or surprinting, will be billed to the author at cost.

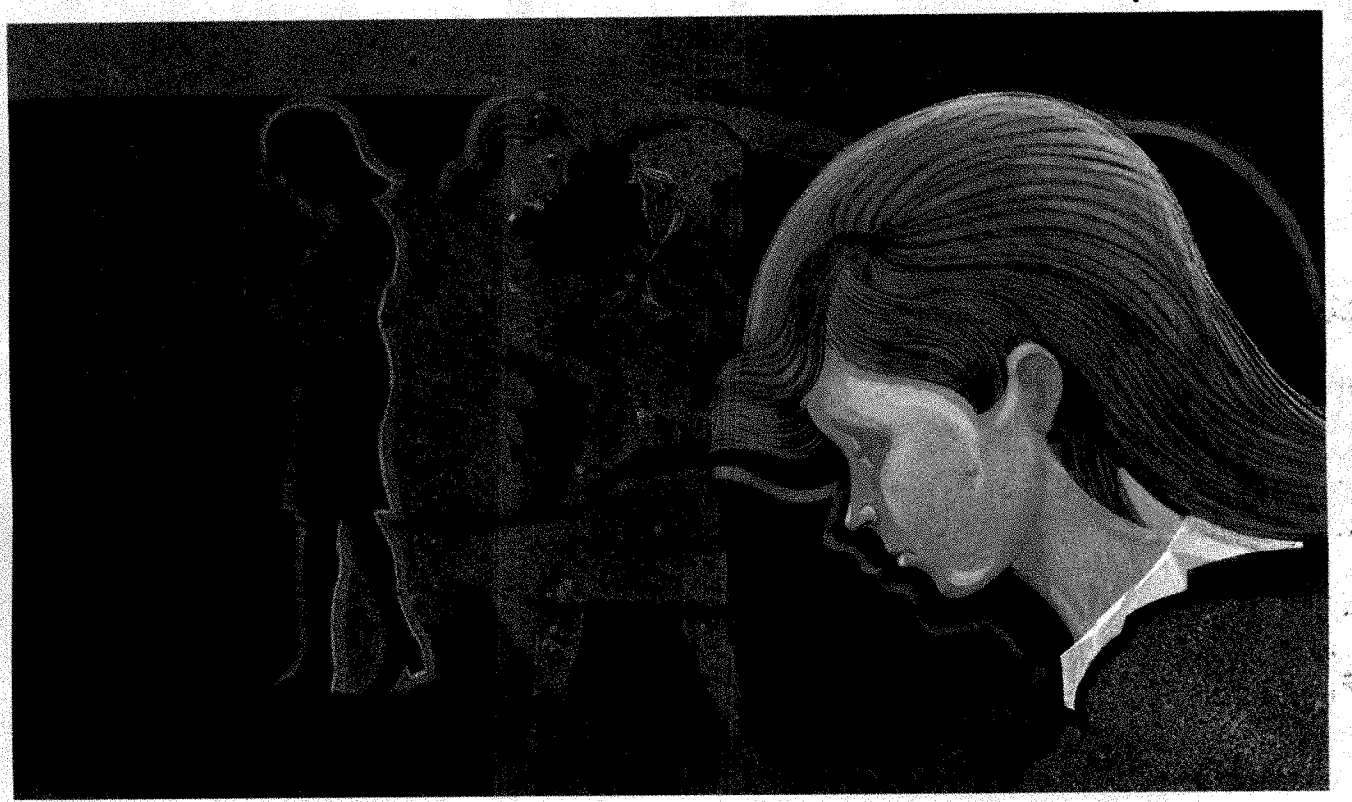
Color transparencies must be submitted for evaluation. Do not send color prints unless accompanied by original transparencies. If transparencies are mounted in frames or glass, the material should be carefully packed in gauze and sent with the manuscript in a separate container or between two pieces of pressboard.

Advertising and Subscription Information

ADVERTISING OFFICES: 535 N Dearborn St, Chicago, IL 60610, Area Code 312, 751-6000; and 600 Third Ave, New York, NY 10016, Area Code 212-867-6640.

ADVERTISING PRINCIPLES: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

CHANGE OF ADDRESS: Please notify the publisher at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.



"Adolescents especially, may suffer severe loss of self-esteem in our appearance-conscious society as a result of their acne. Some may be more seriously affected emotionally than others and withdraw from normal social interaction."[1]

Help Prevent Both Psychic...And Physical Scarring!

BENZAGEL®

(5% or 10% benzoyl peroxide, 6% polyoxyethylene lauryl ether)

and your counselling are BASIC to Successful Topical Therapy

"Results...Subjective and objective clinical results with this form of therapy were impressive. A rapid improvement could be seen within two weeks...Cysts, pustules and papules decreased in numbers, with a simultaneous reduction of accompanying inflammation. The distinct decline of oily conditions was dramatic."[2]

5 BENZAGEL® ACNE GEL & 10 BENZAGEL® ACNE GEL

Description: 5% or 10% benzoyl peroxide, 6% polyoxyethylene lauryl ether and 40% alcohol in an astringent gel containing colloidal magnesium aluminum silicate, hydroxypropyl methylcellulose, citric acid, fragrance and purified water.

Action: Provides drying, desquamative and antiseptic activity.

Indication: An aid in the treatment of acne.

Dosage and Administration: Wash affected areas prior to application. Apply once or more daily or as directed by physician.

Contraindications: Should not be used by patients having known sensitivity to either benzoyl peroxide or polyoxyethylene lauryl ether.

Precautions: For External Use Only. Not for ophthalmic use. Keep away from eyes and mucosae. Very fair individuals should begin with a single application at bedtime allowing overnight medication. May bleach colored fabrics. Keep this and all other medications out of the reach of children.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Plastic tubes, 1½ oz. and 3 oz.

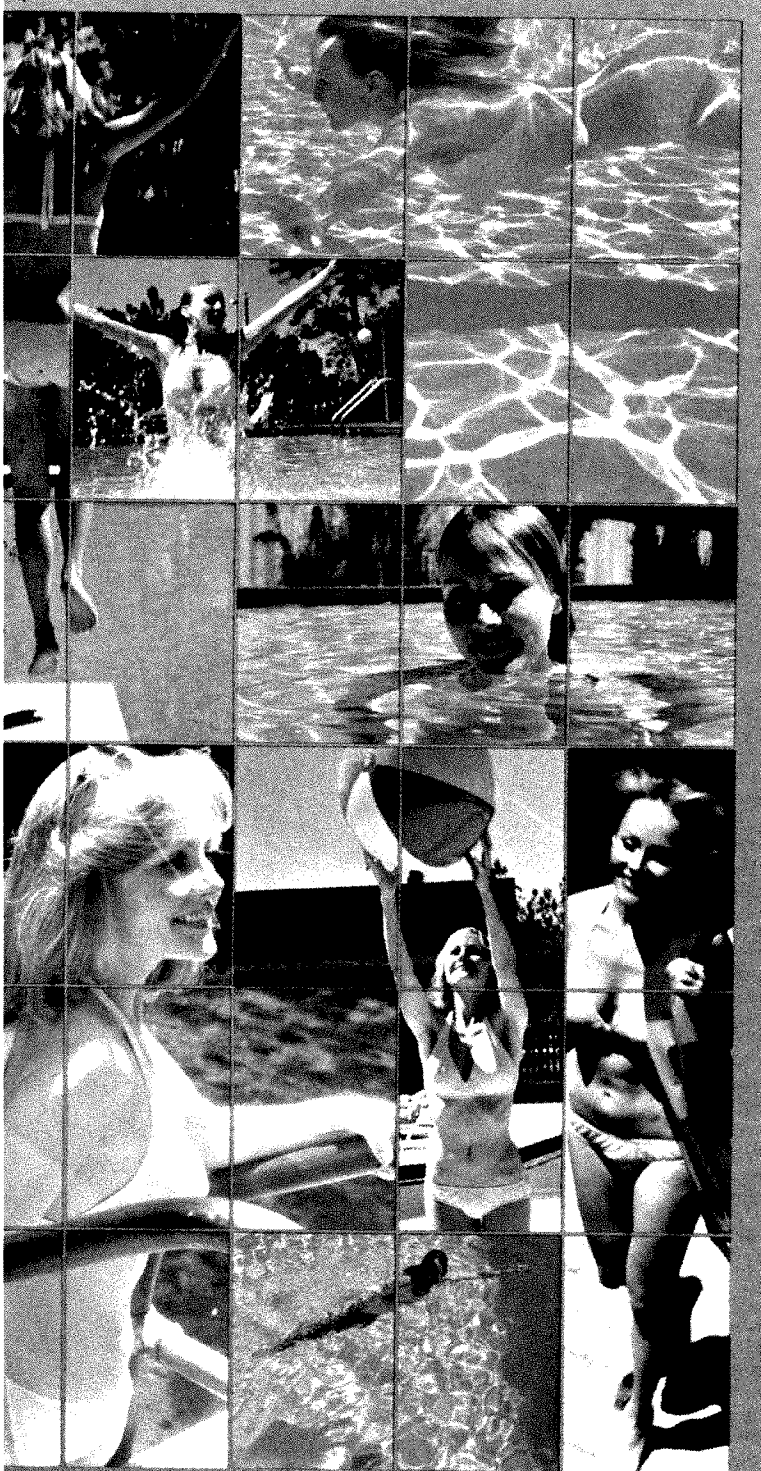
AZTEC® SUNSCREEN LOTION.



Protects better because it stays on longer. Even after swimming.

Almost all professional sunscreen products protect against overexposure to the sun. Aztec does it with two complementary sunscreening agents for full coverage in the critical 280-315 nm range.

Maintaining protection during activity is another matter altogether. Swimming, perspiration, even toweling can easily wipe other lotions away, leaving your sun-sensitive patients exposed.

Only Aztec contains a patented acrylate polymer base which forms an umbrella-like matrix on the skin. This matrix holds both sunscreening agents on the skin for maximum protection...inhibits the loss of protection caused by swimming, evaporation or wiping away.

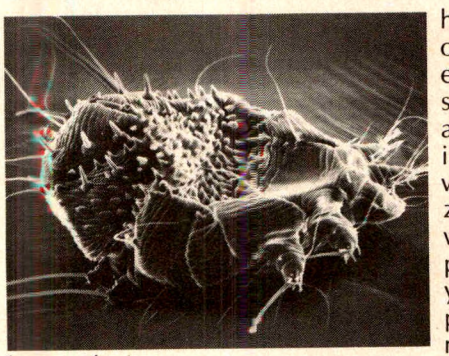
THE ONLY WAY TO END THE EPIDEMIC IS OVER HER DEAD BODY.

Kill the female itch mite (*sarcoptes scabiei*) and you've stopped the current scabies epidemic. Because when she burrows deep into the stratum corneum, she defies diagnosis and resists removal by surface-acting medications and cleansers. Her success has been making headlines around the country—with reports of scabies outbreaks in rural and suburban areas as well as in the cities.



A quick and simple diagnosis. Scabies can mimic a number of dermatological conditions,[1-3] such as urticaria, furunculosis and dermatitis—as well as syphilis with which it may coexist. But there's an almost foolproof way to recognize it. Even in the absence of the fierce nocturnal itching[3] and the lesion distribution characteristic of the disease (hands, wrists and elbows in 9 out of 10 cases),[1] a quick microscopic look can confirm your scabies diagnosis.

To demonstrate the itch mite, look for an unscratched, inhabited burrow (wherever the patient says he itches at that very moment is a likely spot). Use a strong light, a magnifying glass and a surgical blade to which a drop of mineral oil is added. Scrape several sites. Transfer the material to a slide, cover and examine under low power magnification.[1,3,4] (If you don't spot any parasites in egg, larvae or adult stages, look for their red fecal compactions. They can be just as diagnostic.)

Kwell: penetrating action to kill mites, their eggs and larvae. Once you've found scabies, there's a positive way to eradicate it. Kwell (1% gamma benzene hexachloride) Lotion or Cream. It penetrates to reach the scabietic burrows, kills the female mites and, of course, the less tenacious males, as well as their eggs and any larvae that may have hatched. In fact, Kwell works so consistently and well against scabies that it has been the most widely prescribed scabicide for three decades.

Nearly 100% effective. The clinical record of Kwell has never been surpassed by any other pediculicide. It is "nearly 100% effective,"[1] and often works with a single application (a second or third application may be made at weekly intervals, if needed). Your patients will appreciate the low risk of sensitization and irritation.[5,6] And you will appreciate that Kwell works so predictably that it serves to confirm your diagnosis of scabies. Not many pharmaceutical preparations can match *that* record of dependability.

Contraindications: Kwell is contraindicated in individuals who develop hypersensitivity to the product or to any of its components.

Precautions: If accidental ingestion occurs, prompt institution of gastric lavage will rid the body of large amounts of the toxicant. However, since oils favor absorption, saline cathartics for intestinal evacuation should be given rather than oil laxatives.

Central nervous system manifestations can be antagonized by the administration of pentobarbital or phenobarbital in sufficiently large doses to the limit of their therapeutic effectiveness. It is not desirable to depress the patient to the point of hypnosis. However, persons poisoned with stimulants may tolerate large doses of barbiturate without undue depression and with great benefit. Intravenous calcium gluconate may be used in conjunction with the barbiturates. Epinephrine should not be used because ventricular fibrillation may result.

If accidental contact with eyes occurs, flush with water. If irritation or sensitization occurs, discontinue the product and consult physician.

Adverse Reactions: Eczematous eruptions due to sensitization of this product have been reported.

Available on prescription as Kwell Lotion in 2 and 16 fl. oz. bottles, and as Kwell Cream in 2 oz. and 1 lb. jars. See package insert for complete prescribing information.

KWELL® gamma benzene hexachloride

THE SCABICIDE OF CHOICE.

An unsurpassed standard of therapy

PSORIASIS
The Capricious Dermatosis

LIDEX® (fluocinonide) 0.05%
A Stabilizing Influence

Psoriasis. Mere mention of the word can make an afflicted patient cringe. And, because of the capricious, unpredictable nature of the disease, the patient rarely knows where or when it will recur.

Obviously, the goal is control. And, though varied treatment modalities are available today, none offers universal

fficacy for all patients, all of the time.

Yet, very often a highly effective topical teroid, like Lidex, (fluocinonide) can elp stabilize psoriasis.

Lidex. A highly effective topical steroid vith anti-inflammatory, vasoconstrictive, ntipruritic actions.

100% dissolved for optimal penetration, important in stages that exhibit thickened, scaly lesions.

Totally free of preservatives.

Available in cream, ointment, and Topsyn® (fluocinonide) gel.

SYNTEX

SYNTEX LABORATORIES, INC.

Artist's rendition of psoriasis

(See following page)

LIDEX® (fluocinonide)
0.05% Cream and Ointment

TOPSYN® (fluocinonide)
0.05% Gel

Summary of prescribing information

Description·

LIDEX cream 0.05%, LIDEX ointment 0.05% and TOPSYN gel 0.05% contain the active compound fluocinonide. Fluocinonide, which is the 21-acetate ester of fluocinolone acetonide, has the chemical formula 6α, 9α, -difluoro-11β, 16α, 17α, 21-tetrahydroxypregna-1,4-diene-3, 20-dione, cyclic 16, 17-acetal with acetone 21-acetate. LIDEX cream contains fluocinonide in FAPG® cream, a specially formulated cream base consisting of stearyl alcohol, polyethylene glycol 6000, propylene glycol, 1, 2, 6-hexanetriol and citric acid. This white cream vehicle is greaseless, non-staining, anhydrous and completely water miscible. The base provides emollient and hydrophilic properties. In this formulation, the active ingredient is totally in solution.

LIDEX ointment contains fluocinonide in a specially formulated ointment base consisting of Amerchol CAB (mixture of sterols and higher alcohols), white petrolatum, propylene carbonate and propylene glycol. It provides the occlusive and emollient effects desirable in an ointment. In this formulation the active ingredient is totally in solution.

TOPSYN gel contains fluocinonide in a specially formulated gel base consisting of propylene glycol, propyl gallate, disodium edetate, and Carbopol 940 (carboxypolymethylene) with NaOH and/or HCL added to adjust the pH. This clear, colorless, thixotropic vehicle is greaseless, non-staining and completely water miscible. In this formulation, the active ingredient is totally in solution.

Indications

LIDEX cream and ointment and TOPSYN gel are intended for the relief of inflammatory manifestations of corticosteroid responsive dermatoses.

Contraindications

Topical steroids are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions

If irritation develops, the cream, ointment or gel should be discontinued and appropriate therapy instituted. In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted.

If a favorable response does not occur promptly, the corticosteroid cream, ointment or gel should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, the possibility exists of increased systemic absorption and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

LIDEX® (fluocinonide) cream and ointment and TOPSYN® (fluocinonide) gel are not for opthalmic use.

Adverse reactions

The following local adverse reactions have been reported with topical corticosteroids:

burning	folliculitis
itching	acneform eruptions
irritation	hypopigmentation
dryness	striae
secondary infection	skin atrophy

Dosage and administration

A small amount should be gently massaged into the affected area three or four times daily, as needed.

How supplied

LIDEX 0.05% Cream—15 g 30 g and 60 g tubes.
LIDEX 0.05% Ointment—15 g 30 g and 60 g tubes.
TOPSYN Gel 0.05% 15 g and 60 g tubes.

All soaps for dry
kin are not alike...
especially Oilatum®
atum Soap is an old dry skin cleanser with an exciting
concept!
e there are several newer cleansers now available, most
tain hydrogenated oils, lanolin or mineral oil to provide
olliency.
w evidence[1], reported in the British Journal of Derma-
gy, suggests that a formula rich in linoleic acid "rapidly
tored to normal the abnormally high rates of transepi-
al water loss."
Oilatum Soap's pure vegetable oil is rich in this same
leic acid!
ditionally, Oilatum Soap is available in two forms—scented
unscented. Most dry skin cleansers don't offer you
choice... one which assumes considerable importance
en you have to consider the problem of patient
sitivity to perfumes.

Nursing Procedures for Skin Diseases

by **Eileen Huckbody** SRN RFN RCNT

Offers specialized instruction on remedial procedures covering varied aspects of nursing skin diseases. Useful to nurses studying dermatology, working in wards with skin patients and in the community, particularly among the aged, where skin changes often present difficult problems. Skin afflictions in school children and skin allergies arising within occupational environments are also covered.

b.i.d. Diprosone®

brand of
betamethasone dipropionate
Cream 0.05%
(Potency expressed as betamethasone)

Twice a day for prompt relief of corticosteroid-responsive dermatoses

In contact dermatitis

90% of patients showed marked or moderate improvement in seven days*
34 of 38 contact dermatitis patients responded to therapy.

In atopic dermatitis

86% of patients showed marked or moderate improvement in seven days*
133 of 155 atopic dermatitis patients responded to therapy.

In psoriasis

62% of patients showed marked or moderate improvement in only seven days*
116 of 188 psoriasis patients responded to therapy.

Additional benefits:

- Rapid onset of response.
- Economy and convenience of b.i.d. dosage.
- Occlusive dressings infrequently needed.
- Sensitivity is rare.
- Choice of convenient package sizes—in 15 Gm. and moneysaving 45 Gm. tubes.

Diprosone® brand of betamethasone dipropionate
Cream 0.05%/Ointment 0.05%

Clinical Considerations:

DESCRIPTION DIPROSONE is betamethasone dipropionate (9-fluoro-11β, 17,21-trihydroxy-16β-methylpregna-1,4-diene-3,20-dione 17,21-di propionate). Each gram of DIPROSONE **Cream** 0.05% contains 0.64 mg. betamethasone dipropionate (equivalent to 0.5 mg. betamethasone) in a hydrophilic, emollient cream consisting of purified water, mineral oil, white petrolatum, polyethylene glycol 1000 monocetyl ether, cetostearyl alcohol, phosphoric acid, and monobasic sodium phosphate with 4-chloro-*m*-cresol as preservative. Each gram of DIPROSONE **Ointment** 0.05% contains 0.64 mg. betamethasone dipropionate (equivalent to 0.5 mg. betamethasone) in an ointment base of mineral oil and white petrolatum. **CONTRAINDICATIONS** DIPROSONE **Cream** and **Ointment** are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of such preparations. **PRECAUTIONS** If irritation develops with the use of DIPROSONE **Cream** or **Ointment,** treatment should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been absolutely established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time. DIPROSONE **Cream** and **Ointment** are not for ophthalmic use. **ADVERSE REACTIONS** The following local adverse reactions have been reported with topical corticosteroids: burning; itching; irritation; dryness; folliculitis; hypertrichosis; acneiform eruptions; hypopigmentation. The following may occur more frequently with occlusive dressings than without such therapy: maceration of the skin; secondary infection; skin atrophy; striae miliaria. **DOSAGE AND ADMINISTRATION** Apply a thin film of DIPROSONE **Cream** to the affected skin areas twice daily, in the morning and at night. Clinical studies of DIPROSONE have indicated that applications twice a day are generally adequate. Apply a small quantity of DIPROSONE **Ointment** to the affected skin areas twice daily, in the morning and at night.

Contains no parabens or other potentially sensitizing preservatives.

MEDICINE LIBRARY

Brief summary of prescribing information

INDICATIONS. Uticort Gel (betamethasone benzoate) is intended for relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS. Topical steroids are contraindicated in viral diseases of the skin, such as varicella and vaccinia. Topical steroids are contraindicated in patients with a history of sensitivity to any of the components of the preparation.

This preparation is not for ophthalmic use.

PRECAUTIONS. If irritation develops, the gel should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid,

Although topical steroids have not been reported to have effect on pregnancy, the safety of their use in pregnant fem absolutely been established. Therefore, they should not be sively on pregnant patients, or in large amounts, or for prolon of time.

Due to the alcohol content of the vehicle, Uticort Gel (bet benzoate) may cause mild, transient stinging without irritatio excoriated skin.

ADVERSE REACTIONS. The following local adverse reaction reported with topical corticosteroids: burning sensations, it tion, dryness, folliculitis, secondary infection, skin atrophy, s trichosis, acneform eruptions, and hypopigmentation.

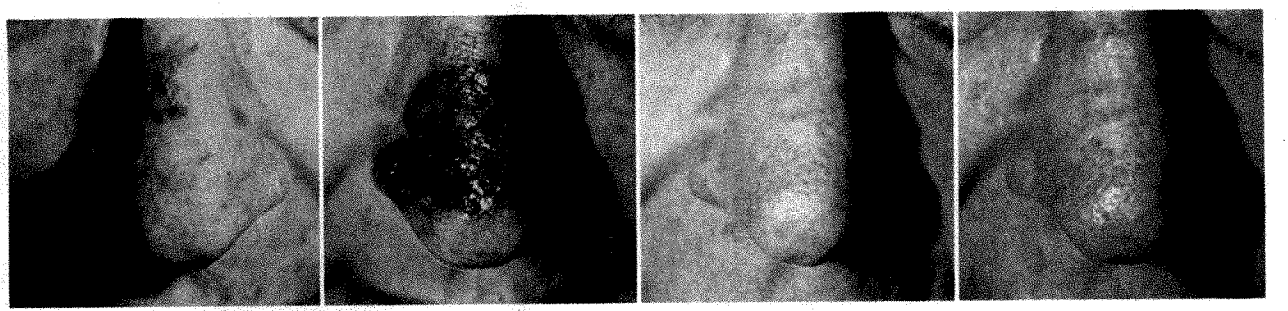
DOSAGE AND ADMINISTRATION. Apply to affected areas times daily as needed.

HOW SUPPLIED. N 0071-3025 Uticort Gel is supplied in 15 tubes.

ROCHE

Roche Laboratories announces an additional therapeuti application for Efudex® 5% Cream fluorouracil/Roche

now indicated for superficial basal cell carcinoma



8/8/69
Before treatment a superficial, scaly, slightly excoriated lesion was present. Biopsy revealed the lesion to be a superficial basal cell carcinoma.

9/25/69
After 7 weeks of treatment with Efudex (fluorouracil) 5% Cream, lesion site is clearly delineated, markedly erythematous; surrounding skin shows no reaction to medication. Treatment terminated.

12/10/70
Follow-up approximately 14 months after treatment; healing has occurred with minimal scarring.

4/18/74
Patient has been followed continuously since treatment. **No evidence of recurrence.**

Efudex (fluorouracil) 5% Cream is recommended as an effective topical alternative to surgery for multiple lesions and difficult treatment sites.

A proven cytotoxic agent that exerts a marked effect on cells that grow more rapidly.

Cosmetically gratifying results, with minimal or no scarring. No systemic toxicity. Normal tissue rarely affected. Convenient, economical b.i.d. application.

Prolonged exposure to ultraviolet light may accelerate reaction to medication. If an occlusive dressing is used, there may be an increase in the incidence of inflammatory reactions in the adjacent normal skin.

An exclusive Roche formulation

Efudex® 5% Cream
fluorouracil/Roche

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Multiple actinic or solar keratoses; superficial basal cell carcinomas when conventional methods are impractical (5% strength only).
Contraindications: If occlusive dressing is used, may increase inflammatory reactions in adjacent normal skin. Avoid prolonged exposure to ultraviolet rays. Safe use in pregnancy not established.
Precautions: If applied with fingers, wash hands immediately. Apply with care near eyes, nose and mouth. Solar keratoses failing to respond should be biopsied; perform follow-up biopsies in superficial basal cell carcinoma.
Adverse Reactions: Local—pain, pruritus, hyperpigmentation and burning at application site most frequent; also dermatitis, scarring, soreness, tenderness, suppuration, scaling and swelling. Also reported—insomnia, stomatitis, irritability, medicinal taste, photosensitivity, lacrimation, telangiectasia, leukocytosis, thrombocytopenia, toxic granulation and eosinophilia.
Dosage and Administration: *Actinic or solar keratosis*—apply sufficient quantity to cover lesions, twice daily. Usual length of therapy is 2 to 4 weeks. *Superficial basal cell carcinomas*—apply sufficient quantity **(only 5% strength recommended)** to cover lesions, twice daily. Continue treatment for at least 3 to 6 weeks, but possibly as long as 10 to 12.
How Supplied: Solution, 10-ml drop dispensers containing 2% or 5% fluorouracil on a weight/weight basis. Cream, 25-Gm tubes containing 5% fluorouracil in a vanishing cream base.

LENOX HILL HOSPITAL
Announces a Symposium on

TUMORS OF THE EYELIDS, ORBIT AND OCULAR ADNEXAE

October 27, 28, 29, 1977

This Symposium will be devoted to the diagnosis, pathogenesis and treatment of tumors of the eyelids and orbit, emphasizing basal cell carcinoma of the eyelids. The course will be presented by outstanding ophthalmologists, ophthalmic plastic surgeons, plastic surgeons, x-ray therapists, dermatologists, immunotherapists, cryosurgeons and pathologists.

The format will consist of lectures, panel discussions, surgical films and videotapes of surgery.

THE FACULTY WILL INCLUDE:
Albert Hornblass, M.D., Course Director
Edgar Berry, M.D.
Charles Beyer, M.D.
Jackson Coleman, M.D.
Anthony Domonkis, M.D.
Andrew Ferry, M.D.
Paul Henkind, M.D.
Crowell Beard, M.D.
Henry Gougelman, M.D.
Lazlo Bird, M.D.
Morris Leider, M.D.

CHARLES C THOMAS • PUBLISHER

CRYOSURGICAL ADVANCES IN DERMATOLOGY AND TUMORS OF THE HEAD AND NECK *edited by* **Setrag A. Zacarian,** *Boston Univ., Boston, Massachusetts. Forewords by* **John G. Bellows** *and* **Edward Krull.** *(11 Contributors)* This treatise is a most comprehensive review of cryosurgery for management of benign and malignant tumors of the skin, oral cavity, and head and neck. The fundamentals of cryogenesis, the development of the cryolesion, temperature monitoring, double freeze-thaw cycles and the pathogenesis of cryonecrosis are all reviewed in depth. The selection of various cryosurgical instruments and their respective applications and limitations are frankly discussed. Experimental data and supportive evidence in the area of cryoimmunology are explored and fully outlined. The contributors, all pioneers and outstanding professionals in their respective areas, guide the clinician through the laboratory aspects of cryosurgery, from the carefully controlled animal studies to the vast clinical experiences of tumor cryosurgery. They outline the cryosurgical management of patients with acne, benign lesions, and common and advanced skin cancers as well as the rare lentigo maligna. The less common but significant and difficult area of eyelid tumors is thoroughly discussed, clearly delineating the preservation of the lacrimal duct from freezing. The current success in the management of trichiasis with cryosurgery is also examined. *'77, 296 pp. (7 x 10), 473 il. (122 in color), 31 tables, $33.00.*

THE ULTRASTRUCTURE OF COLLAGEN: Its Relation to the Healing of Wounds and to the Management of Hypertrophic Scar *edited by* **J. J. Longacre.** *(35 Contributors)* Ever since the earliest recorded writings of man, scar has been a word with unpleasant connotations related to mutilation, disfigurement and loss of function. However, if it were not for the final conversion of granulation tissue into mature scar, no wound would heal firmly. These natural forces must be harnessed and made beneficial to man. This text relates the ultrastructure of collagen to the healing of wounds and the surgical management of hypertrophic scar and includes advanced knowledge on causation, treatment and prevention of hypertrophic scarring. A few of the topics discussed include wound sepsis, the basis of the histological demonstration of tension in collagen, burn contractures and keloids, the relation of collagen metabolism and hypertrophic scars, collagen degradation in normal and abnormal tissues, distribution of oxygen and its significance in healing tissue, the role of environmental factors on connective tissue cell metabolism, scanning and transmission electron microscopic studies, and behavior of scar tissue through its evolution with and without surgery. *'76, 537 pp. (6 3/4 x 9 3/4), 537 il., 28 tables, $41.50*

THE DOCTOR'S LAWYER: A Legal Handbook for Doctors *by* **Marc J. Lane,** *Chicago Bar Association, Chicago.* This handbook can help any doctor in maximizing opportune legal situations and in avoiding the obvious and not-so-obvious pitfalls of his practice and of life in general. A concise, common sense analysis of one legal concept introduces each chapter. Then, in checklist or outline form, the topic is logically developed. Without having to wade through pages of prose, the doctor can discover, for example, if the cost of traveling to an educational seminar is tax deductible, whether he should lease his laboratory equipment or buy it outright, and whether or not he should go into partnership. *'74, 112 pp. (8 1/2 x 11), 6 il., 5 tables, $12.75*

SKIN SURGERY (4th Ed.) *edited by* **Ervin Epstein** *and* **Ervin Epstein, Jr.,** *both of the Univ. of California Medical School. (45 Contributors)* Forty-five prominent authorities in such fields as dermatology, surgery and plastic surgery have contributed their expertise to this greatly expanded Fourth Edition. Over 150 new pages and more than 400 new illustrations have been added to bring this book up-to-date and in line with the rapidly growing interest in the field. The original five sections have been retained, but the format within these sections has been completely revamped and revised to accommodate new developments in cold steel surgery, electrosurgery, special procedures and special locations of disease. In addition, three new sections have been added which focus on chemosurgery, cryosurgery and investigative surgical therapy of the skin. A sampling of specific topics includes anesthesia, medicolegal problems, tattoo removal, eyelid surgery, and do-it-yourself instruments. The depth and clarity of this book make it a must for anyone involved or interested in surgery of the skin. *'77, 864 pp. (7 x 10), 1081 il. (19 in color), 37 tables, $98.75*

DERMATOPHYTES IN HUMAN SKIN, HAIR AND NAILS *by* **James T. Sinski,** *Univ. of Arizona, Tucson.* This book will aid dermatologists, medical technologists, microbiology students and laboratory administrators who are concerned with the microscopic examination of human skin, hair and nails for possible dermatophyte infection. This photographic essay is concerned with the typical, as well as the atypical morphology of fungi in human skin, nails and hair, with emphasis being placed on the differentiation of causal organisms as they are seen in clinical materials. The depiction of a number of artifacts seen during these examinations is also included since these may be confused with fungal elements. A number of choices of equipment for acquiring and storing a sample are given based on the site of the human body to be sampled, the funds available for equipment, and the physical characteristics of the laboratory. Practical suggestions for the processing of a specimen for microscopic examination are given, including reagents and equipment used. *'74, 64 pp. (6 3/4 x 9 3/4), 35 il., $7.95*

NAIL DISEASES In Internal Medicine *by* **Pietro de Nicola,** *Univ. of Pavia, Pavia, Italy, and* **Mario Morsiani** *and* **Giorgio Zavagli,** *both of the Univ. of Ferrara, Ferrara, Italy.* Anatomy, histology, embryology, chemical composition and histochemistry of the nail are presented in a short introductory chapter. The principal part of the book is concerned with the clinical aspects of nail disorders, including the most relevant nail symptoms. A clear description is presented of all nail symptoms, most of which are not well known and deserve consideration in clinical practice. Original illustrations, most of which are color plates, are particularly helpful in the description of nail symptoms and disorders. *'74, 128 pp., 18 il. (8 in color), $10.50*

BEHAVIORAL SCIENCE IN CLINICAL MEDICINE *by* **Stewart Wolf,** *Univ. of Texas, Galveston, and* **Helen Goodell,** *Cornell-New York Hospital Medical Center, New York.* The importance of understanding the patient before practice, diagnosis and treatment can be effective is illustrated in this text. The authors discuss behavioral science in the context of human ecology, man's needs and expectations, the significance of medical education, the cultivation of the individual, values, and fulfillment. *'76, 256 pp., 22 il., $14.50*

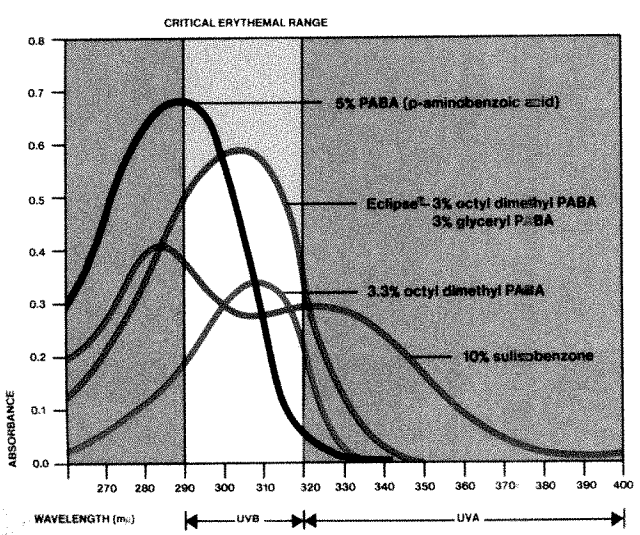
ECLIPSE®

(3% glyceryl PABA and 3% octyl dimethyl PABA)

For your patients

who can't-or won't-stay out of the sun.

For some, it's occupation. For others, the social desirability of a tan. Whatever the reason, many of your patients may be spending more time in the sun than you'd like.



Unique Eclipse formulation combines two PABA derivatives for maximum UVB absorption.

They need Eclipse—a highly effective sunscreen that works immediately upon application, resists wash-off, and contains our exclusive Aquacare® base to help relieve sun and wind-dried skin.

Can other sunscreens do all that? Take a minute to read the labels: we're confident you'll recommend Eclipse.

- Absorbs more than 99% of erythemogenic solar UVB.
- Spreads smoothly and predictably for even protection.
- Permits slow tanning.
- Resists wash-off; protects after swimming or sweating.
- Formulated in Aquacare® to relieve sun and wind-dried skin.

The Official AMA Uniform Health Insurance Claim Form

Accepted by Medicare, Commercial Carriers, many Blue Shield Plans, and many states for Medicaid.

Developed by the AMA in cooperation with carriers, government agencies, and other groups, this form is the most current and most widely used claim reporting form available. It significantly reduces the time and cost of claims reporting. **Note:** A number of private firms are marketing an outdated, more expensive version of this form. To be certain you are using the most current and acceptable form to third party insurers, we encourage you to use the official AMA form. Order today.

HALOG® CREAM (Halcinonide Cream 0.1%)

Each gram of Halog Cream (Halcinonide Cream 0.1%) contains 1 mg. halcinonide (0.1%) in a cream base.

INDICATIONS: This product is intended for topical application for adjunctive therapy and symptomatic relief of inflammatory manifestations of acute and chronic corticosteroid responsive dermatoses.

CONTRAINDICATIONS: Topical steroids are contraindicated in vaccinia, varicella, and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

PRECAUTIONS: *General*—If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled. Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time. If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Occlusive Dressing Technique—The use of occlusive dressing increases the percutaneous absorption of corticosteroids; their extensive use increases the possibility of systemic effects. For patients with extensive lesions it may be preferable to use a sequential approach, occluding one portion of the body at a time. The patient should be kept under close observation if treated with the occlusive technique over large areas and over a considerable period of time. Occasionally, a patient who has been on prolonged therapy, especially occlusive therapy, may develop symptoms of steroid withdrawal when the medication is stopped. Thermal homeostasis may be impaired if large areas of the body are covered. Use of the occlusive dressing should be discontinued if elevation of the body temperature occurs. Occasionally, a patient may develop a sensitivity reaction to a particular occlusive dressing material or adhesive and a substitute material may be necessary. If infection develops, discontinue the use of the occlusive dressing and institute appropriate antimicrobial therapy.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions, and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria. Contact sensitivity to a particular dressing material or adhesive may occur occasionally (see PRECAUTIONS).

For full prescribing information, consult package insert.

HOW SUPPLIED: In tubes of 15 and 60 g. and in jars of 240 g. (8 oz.).

National Dermatology Manpower Requirements

The Experience of Prepaid Group Practices

Melvin Krasner, David L. Ramsay, MD, MEd

• Ten prepaid group health plans across the country were surveyed as part of an effort to estimate the need for dermatologists in the United States. Although generalizing the experiences of prepaid group practices to the general population is at best an imprecise approach, the dramatic shortage suggested by the data cannot be completely ascribed to the method used. Whereas the average ratio in the surveyed plans was 2.8 dermatologists per 100,000 subscribers, there are only about 1.9 dermatologists providing patient care per 100,000 persons in the general population. The difference between prepaid plan subscribers and the general population in annual visits to dermatologists is even more dramatic: 193 per 1,000 subscribers compared to 84 per 1,000 population.

(*Arch Dermatol* 113:903-905, 1977)

The physician staffing experience of prepaid group health plans (PGP) is often used as a basis for projecting national patient care requirements for physician specialists.[1,2] This approach has the appeal of being fairly simple, yet, as a reflection of functioning health care systems, it embodies a measure of reliability absent from theoretical methods. The prepaid plans are presumed to provide quality medical care sufficient to meet all the needs of their membership, and thus serve as possible models for the nation as a whole under conditions of free access to care.

Nonetheless, a number of important weaknesses are inherent in this approach, although appropriate modification can mitigate some of the shortcomings.[3] The principal problems with extrapolating from the experiences of group health plans are the following: (1) The behavior of physicians and patients is substantially influenced by the financial and administrative organization of prepaid plans, making generalization to other settings inappropriate. (2) The demographic and socioeconomic profile of the membership of prepaid plans generally differs from that of the American population as a whole. (3) Some medical services for enrollees are obtained outside the plan and the need for these services is not reflected in the plan's staffing pattern. (This fact also raises questions about quality and access.)

The effects of the last two factors can be estimated, and projections of specialty requirements can be adjusted accordingly. The first problem, however, encompasses a number of complex relationships that must be understood before specialty staffing patterns can be generalized to other organizational settings. Prepaid practices may exert administrative control or supervision over physician recruitment and behavior; even in the absence of controls, the economic incentives present in prepaid practices are completely different from those in other practice arrangements.[4] The effect of prepayment on patient utilization for preventive, diagnostic, or therapeutic care is another important consideration. Nonmonetary rationing of medical services through excessive waiting time, inaccessability of specialty care, or other barriers to access may also play an important role. Also, the functional overlap among specialties leaves an opportunity for varying specialty staffing patterns even when providing a similar mixture of services.

It has also been argued that the large-scale organization of prepaid group practices, by virtue of efficiencies directly related to size, permits greater productivity;[5] this assertion has been challenged, however, and the existence of such a relationship remains unclear at present.[6]

SURVEY OF PREPAID PLANS

The American Academy of Dermatology Manpower Study, as a small part of a comprehensive assessment of the need for and availability of dermatologic care in the United States, recently conducted a survey of dermatologists' staffing patterns among a number of major PGPs across the country. In addition, information on the volume of visits for dermatologic problems, number and type of auxiliary personnel, and related subjects was elicited in the

*Includes 4,881 visits made to acne clinic independently conducted by specially trained clinic assistant. These visits excluded from Visits per Full-Time Equivalent Dermatologist.

†Full time equivalence is assumed at 220 days per year and seven hours per day. Figures may not correspond perfectly because of rounding. The data presented involved limited extrapolation on the basis of information provided by the group plans.

Academy survey. It was hoped that this information would help explain the wide variation in dermatologist-to-subscriber ratios identified in the past and would suggest a method for meaningful generalization from PGPs. A summary of the findings is presented in the Table.

The substantial variation in dermatologist-to-enrollee ratios among the plans indicates the need for caution in generalizing the specialty staffing pattern of a single PGP or a group of PGPs to other settings. Particularly outstanding is the experience of the Yale University Health Plan, where the equivalent of 1 full-time dermatologist is required to handle 20,000 enrollees or 5 dermatologists per 100,000. This plan is unusual because of the unique subscriber population it serves. More than half of its enrollment is in the 15- to 29-year age group, and, according to the information obtained in the national Health Interview Survey, this group appears to have a relatively high utilization rate for dermatologic care. Among individuals aged 17 to 24 years, 2.4% seek dermatologic care, as compared to 1.5% for all age groups combined.[7] Educational level also appears to have a positive influence on utilization, and this factor is probably operative here as well.

At the other end of the continuum, the Health Insurance Plan of Greater New York reports only 1.2 dermatologists per 100,000 enrollees. The data show that this low ratio is maintained by heavy physician workloads as well as a low utilization rate. Some observers have attributed the latter to a lack of ready access to specialists[8]; they present data for an aged population showing four times as much utilization under conditions of complete access.

Although it appears that highly trained auxiliary personnel play an important role in providing dermatologic care in some PGPs, initial review of the information on ancillary personnel in the PGPs did not provide a satisfactory explanation of the inter-PGP variation in dermatologist-to-population ratio or dermatologist productivity.

By omitting the extreme observations, ie, the Yale Health Plan and HIP, a simple mean of 2.5 dermatologists per 100,000 enrollees is obtained. The weighted average, based on the number of subscribers in each plan, is 2.8 dermatologists per 100,000 enrollees. In an effort to generalize the PGP experience to the nation as a whole, federal analysts in a study of medical specialty manpower applied an additive adjustment of 0.3 dermatologists per 100,000 persons to compensate for age and income differences between PGP subscribers and the general population and an additional 0.5 dermatologists per 100,000 to offset the greater productivity realized in group practices.[3] Recent data assembled by the American Medical Association, however, reveal that large group practices do not necessarily achieve the highest levels of productivity.[9] Therefore, it appears that a more conservative adjustment of 0.4 dermatologists per 100,000 population (based on the 0.3 age-income factor and an 0.1 productivity factor) would be appropriate. Based upon the weighted average of 2.8 dermatologists per 100,000 population described above, the national need would then be approximately 3.2 dermatologists per 100,000 population.

According to a recent tabulation of AMA data, there were 3,416 dermatologists principally involved in patient care in the United States in March 1976, a recent survey by the American Board of Dermatology found that there were 768 residents in dermatology training programs in this country (Clarence S. Livingood, MD, written communication from American Board of Dermatology to the General Accounting Office, July 23, 1976). In addition, the American Academy of Dermatology Manpower Study identified 139 dermatologists involved in patient care who were missing from the AMA data. Also found missing were 79 dermatologists whose professional activity could not be determined. If half, or 40, of this latter group and about 35 osteopathic dermatologists are assigned to the

patient care category, an estimate of 3,630 dermatologists primarily active in providing patient care is derived. Relating this figure to the American population of 215 million yields a figure of 1.7 dermatologists per 100,000 persons. Since dermatology residents provide a substantial amount of patients care, it may be preferable to include them, in which case the dermatologist-to-population ratio would be 2.0 per 100,000. However, if residents are assumed to provide only half as much care as the average practicing dermatologist, the corresponding ratio would be 1.9 dermatologists per 100,000 persons. Comparing any of these figures with national requirements based on group health plan statistics indicates a national deficit of more than 2,000 dermatologists.

Another basis for measuring the availability and utilization of care is the number of visits made to dermatologists. Recent data from the National Ambulatory Medical Care Survey show that there were approximately 15.7 million office visits to dermatologists per year (May 1973 through April 1974), or 73 per 1,000 population.[10] Based on information from the National Health Interview Survey,[11] this number is appropriately increased to 84 visits per 1,000 population to allow for dermatologic patient care provided outside of private physicians' offices (eg, clinics or company health units). When comparing the present national average of 84 visits to dermatologists per 1,000 population with an average of 193 dermatologist visits per 1,000 enrollees in the surveyed group practice plans (again omitting the two extreme observations), it is evident that, if the demand experienced in these plans were to be realized nationally, there may be a greater than twofold increase in patient demand for services.

COMMENT

In summary, the information on PGPs would indicate a need for a substantial increase in the number of dermatologists in the United States if free access to care were instituted. However, a final cautionary note is in order. The fact that one cannot easily make adjustments for many of the unique features of PGPs that affect specialty manpower needs and the fact that there is wide variation in staffing among the PGPs themselves (even after extreme values are omitted) cast considerable doubt on the validity and reliability of this approach. Only by detailed analysis of the patient care, organization, and other characteristics of prepaid group practices that would identify and measure the effects discussed earlier would the effectiveness of PGP staffing patterns as a tool in planning medical specialty services for the nation be improved. Such analysis is clearly beyond the scope of the present study, but comprehensive investigation of this subject is definitely needed and should be encouraged.

Another limiting feature is using PGPs as a model for future manpower requirements is that they form a static reference point that does not provide for possible changes in the pattern of a dermatologist's services. If, for example, similar to the British experience, dermatology becomes a referral-based specialty, the needs for dermatologists would be substantially less than at present, whereas if dermatologists are called upon in any national scheme to render all primary care in dermatology, the manpower estimates based upon PGP experiences would far understate the need for additional dermatologists.

The manpower-analysis approach based on PGP experience (as well as most other planning methods) is also static in the sense that it embodies all other characteristics of dermatology practice unique to this point in time, such as the current state of scientific knowledge, existing therapeutic methods, and major population features that determine levels of demand. Although these structural characteristics are not expected to change dramatically in the near future, long-run projections may be greatly affected by such change.

The manpower study group is aware of the serious limitations of extrapolating the PGP data for national planning and this report is only presented as one of the many facets of analysis being undertaken by this group to better understand the need for dermatology manpower.

Treatment of Lip Keratoses (Actinic Cheilitis) With Topical Fluorouracil

Ernst Epstein, MD

• **Topical (5-fluorouracil [5-FU]) as a 5% solution was used to treat isolated actinic keratoses of the lips as well as diffuse actinic damage of the lower lip. Although producing considerable temporary discomfort, final results proved excellent, with recurrences in only two of 12 patients treated. Preliminary biopsy of suspicious infiltrated areas is mandatory, as is careful follow-up to ensure complete healing. Topical fluorouracil is an alternative to surgical excision of the vermilion border of the lip in those patients with severe diffuse actinic damage of the lips.**

(*Arch Dermatol* 113:906-908, 1977)

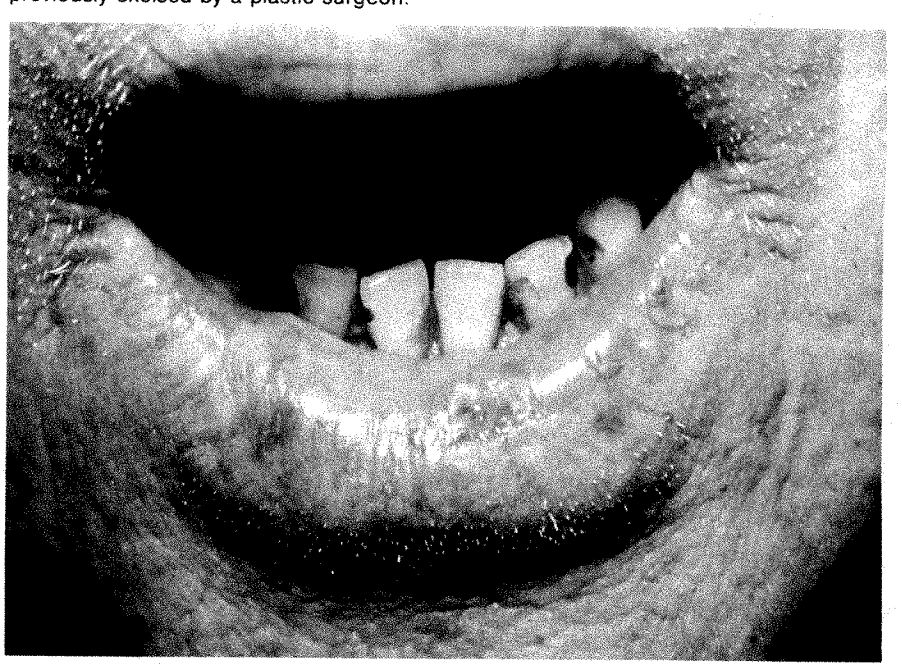
Topical administration of fluorouracil has proved to be an elegant method of destroying actinic keratoses of the face.[1-4] Since fluorouracil selectively destroys actinically damaged cells, it removes facial keratoses with cosmetic results generally superior to destructive modalities, such as surgery, liquid nitrogen, curettage, or electrodesiccation. When topical fluorouracil is used on the face, patients are usually instructed to avoid applying it to the lips because of the possibility of severe irritation. The manufacturers advise that fluorouracil be used "with care" about the mouth.

Actinic keratoses on the lips are fairly common; I have found that they are effectively destroyed by treatment with topical fluorouracil. Discussions with dermatologic colleagues showed that others have found fluorouracil effective in the treatment of isolated actinic keratoses of the lips, as well as the diffuse actinic lip damage known as chronic actinic cheilitis. While successful fluorouracil therapy of lip keratoses has received mention in some papers,[4,5] others have warned against using fluorouracil on the lips.[1,2] To my knowledge, there are no publications detailing the results of topical fluorouracil in keratoses of the lips. This report describes my four-year experience with topical fluorouracil in treating actinic lip keratoses.

MATERIALS AND METHODS

Fluorouracil was used as a commercially available 5% solution since preliminary studies suggested that it acted more rapidly than the 5% cream formulation. The patients were instructed to apply the 5% fluorouracil solution sparingly three (or sometimes four) times a day to the entire vermilion area of the lip with their fingertips, taking care to avoid the mucosa. Patients were seen after one week; based on the degree of reaction, they were instructed when to stop applying the fluorouracil. Photographs were taken before,

Fig. 1.—Case 9. Recurrent eroded actinic keratosis in a 56-year-old man that had been previously excised by a plastic surgeon.



Accepted for publication Oct 6, 1976.

during, and after treatment, using color transparencies and a one to two reproduction ratio.

The aim of treatment was to produce a thorough erosion of the affected area. With completion of treatment, patients were asked to use white petrolatum (petroleum jelly) as desired for its soothing and lubricating effect on the raw and fissured lips. In a few patients, 1% hydrocortisone ointment was used. No other medications were used.

REPORT OF CASES

A 55-year-old man (case 9) was examined in December 1974 with a 5-mm diameter superficial erosion of the mid lower lip present 18 months (Fig 1). Two years earlier, a histologically proved actinic keratosis had been excised at this site by a plastic surgeon, but it recurred six months after surgery. The patient was directed to apply a 5% fluorouracil solution four times daily to the eroded area and a surrounding small margin. Figure 2 shows the effect produced after eight days. The fluorouracil treatment was continued for a total of 13 days, after which there was prompt healing (Fig 3) without any recurrence in the 16-month follow-up period.

A 56-year-old man (case 7) was seen in December 1970 for an erosion on the right side of his lower lip at the site of a squamous cell carcinoma treated with X-ray therapy 20 years earlier. The erosion was excised, the pathology report describing "hyperkeratosis with premalignant cytologic alteration." After surgery, the lip healed uneventfully, but the patient returned one year later with a new area of superficial lip ulceration. This second erosion cleared with liquid nitrogen freezing. However, in October 1972, the patient had multiple new lip keratoses; these were treated with a 13-day course of 5% fluorouracil solution applied three times daily to the entire lower lip. A month later the lip had healed. For nearly one year after the fluorouracil treatment, the lip remained well, but the development of additional keratoses in October 1973 led to a second course of fluorouracil applied four times daily for 12 days. After this second treatment, the patient remained free of lip keratoses up to the present (29 months).

Fig 2.—Case 9. Appearance after eight days of treatment with 5% fluorouracil solution applied four times daily.

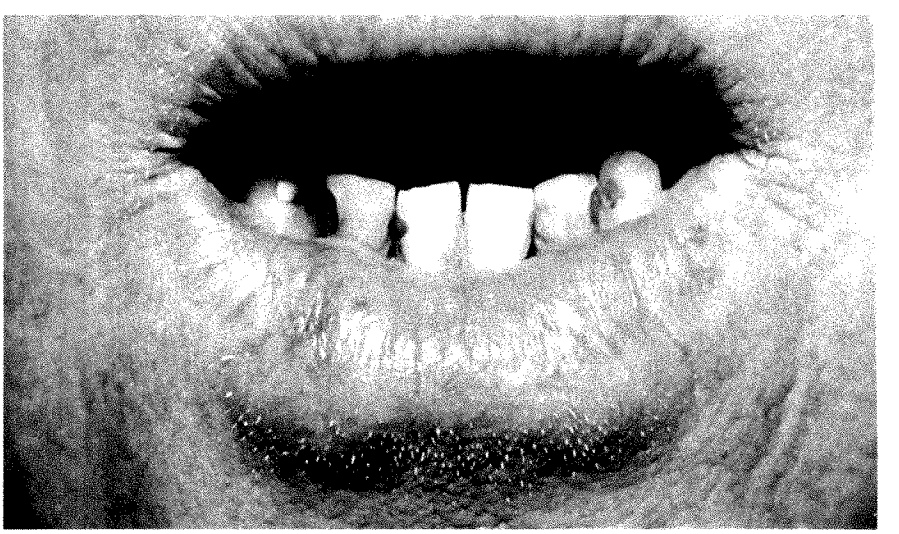

Fig 3.—Case 9. Result four weeks after completion of a 13-day course of treatment with topical fluorouracil.

RESULTS

The results in 12 patients (8 men, 4 women) treated during the years 1972 through 1975 are detailed in Table 1. Two patients had recurrences; one (case 1) had one small keratosis apparent 38 months after fluorouracil therapy. This lesion responded to liquid nitrogen destruction. The other patient with a recurrence (case 7 described previously) received a second course of topical fluorouracil. The mean age of these 12 patients was 56 years (range, 36 to 73 years). The lesion occurred on the lower lip of ten patients, and on the upper lip of two. Six patients underwent biopsies. Three had prior lip cancer while seven had prior skin cancers elsewhere. In four patients, isolated lesions were treated, while in eight the entire lip was treated. The mean length of therapy was 12 days (range, nine to 15 days), and the mean length of follow-up was 22 months (range, two to 48 months).

COMMENT

In view of the role of sunlight, it is not surprising that the lower lip was involved in the majority of cases. That men outnumbered women in these

†Patient 7 had two courses of treatment with fluorouracil applied to his lower lip.

series is probably a tribute to the protective effects of lipstick. Lip keratoses are the result of sun damage, and it is important that nine of the 12 patients had had skin cancers. Two patients had only had lip cancers, a third patient had a previous lip cancer plus skin cancers elsewhere, while an additional six patients had only had skin cancers at sites other than the lip.

The problem of lip carcinoma raises the issue of biopsies. Half of the patients had biopsies performed, and if there is a suspicion of malignancy in that the keratosis is infiltrated, deeply ulcerated, or persistent, preliminary biopsy is mandatory. Since squamous cell carcinoma of the lower lip has the potential of metastasizing, it requires surgery or radiation. Those patients treated without biopsy because of multiple or superficial lesions should be followed up carefully to ensure that healing is complete. If topical fluorouracil therapy is not successful in completely eradicating a lesion, it must be biopsied.

The only side effect encountered was lip discomfort. The effect of fluorouracil became evident three to four days after the start of treatment when tender erosions appeared, and after one week of treatment, the lip was usually sore. During the latter stages of treatment, some patients complained of considerable discomfort and required mild analgesics at bedtime. Usually ten to 13 days of treatment produced a brisk erosion. Healing was complete two or three weeks after stopping the fluorouracil treatment. Several patients had applied the fluorouracil too generously and had developed erosions of the adjacent lip mucosa. These mucosal ulcerations healed uneventfully. Although some patients complained bitterly of discomfort during treatment, all were delighted with the final results. In a few patients, hydrocortisone ointment was prescribed for treatment of erosions once fluorouracil therapy had been completed. However, plain white petrolatum seemed equally effective in providing symptomatic relief during healing.

No systemic side effects were observed, and none were expected, since even if the entire applied dose were absorbed, it would represent only a minute fraction of the therapeutic dose of intravenous fluorouracil. The safety of topical fluorouracil has been documented in many studies.[1-5] The mechanism of action, biochemistry, and cutaneous effects of fluorouracil are not discussed in this communication, since they have been thoroughly covered by others.[6-8]

While topical fluorouracil proved an effective way of destroying isolated lip keratoses, its greatest usefulness seemed to be in those patients with widespread actinic damage and multiple or recurrent keratoses. Conventional destructive methods, while capable of removing existing keratoses, do not prevent new ones, and the traditional approach to the problem of the severe, chronic actinically damaged lower lip has been excision of the entire vermilion border of the lip. While excision of the vermilion border is an effective treatment, it alters the sensory ability and the appearance of the lower lip. Topical fluorouracil not only removes existing keratoses, but also delays the formation of new lesions. It appears that topical fluorouracil therapy represents a medical alternative to surgical treatment of the diffusely actinically damaged lip.

Acute Panniculitis

A Clinical and Histopathologic Study of 34 Cases

Lars Förström, MD, R. K. Winkelmann, MD, PhD

• Thirty-four patients had histopathologic findings of acute panniculitis. 15 had clinical findings of erythema nodosum; 6 had infectious lesions; and 5 had Weber-Christian-like conditions with recurrent febrile suppurative or nonsuppurative nodular eruptions; 3 of the 5 had amylase and lipase enzyme abnormalities with or without pancreatic disease. Five additional patients had acute panniculitis that would be termed "erythema induratum" or "nodular vasculitis" by most clinicians, and the subsequent pathologic findings and courses were consistent with this view. Two patients had limited, traumatic panniculitis, forming a distinctive group but trauma was a factor in lesion formation in all groups, and one patient had vasculitis. Whereas acute panniculitis, with or without fat necrosis, may be associated with many inflammatory syndromes of the skin and subcutaneous tissue and may rarely occur in all, the most common relationship is with erythema nodosum in its most acute forms.

(*Arch Dermatol* 113:909-917, 1977)

Acute panniculitis describes the infiltration of fat lobules with masses of polymorphonuclear leukocytes, and it is often accompanied by necrosis of the white cells, as well as variable necrosis of the fat cells. The dermatopathologist occasionally can classify his findings only in terms of the descriptive diagnosis of acute panniculitis. The pathology report that suggests a severe disease may confuse the clinician, whose patient has short-lived inflammatory nodules of the skin and subcutaneous tissue. Experienced dermatologists can associate such reports with traumatic panniculitis, but most cases are not traumatic in origin. Some authors consider acute panniculitis as the first stage of Weber-Christian disease, but true Weber-Christian disease, if it exists, is a very rare and ill-defined syndrome. Our review of cases of acute panniculitis forms the basis of the present report and indicates that acute panniculitis is most often associated with erythema nodosum and that other causes such as infection and trauma are less common.

SERIES AND METHODS

A review of the biopsy specimen files of the Department of Dermatology at the Mayo Clinic revealed 34 cases with the histopathologic findings of acute panniculitis for which adequate clinical information and follow-up were available. When the biopsy specimen was taken, the ages of the patients averaged 46 years and ranged from 8 to 74 years. Of the 34 patients, 25 were women and nine were men. The mean duration of the disease was 3.5 years (range four days to 45 years), and the mean duration of the individual nodules was three weeks (range four days to four months).

The patients' records were reviewed, and the later course of the disease was analyzed on follow-up visits and by questionnaires. Hematoxylin-eosin and resorcin-fuchsin-Giemsa stained slides were available for study, and multiple sections were observed. When indicated, polaroscopy and ultraviolet fluorescent study of sections were done for the detection of foreign material.

All lesions showed infiltrates of predominantly polymorphonuclear cells involving fat lobules; in some lesions, the entire lobule was replaced by inflammatory cells. In some sections, this acute reaction was intermingled with lymphocytes and a few histiocytes. Fat necrosis sometimes occurred, and often there was necrosis of the cellular infiltrate itself.

RESULTS

According to history and clinical findings, the cases could be grouped into the following six categories: erythema nodosum (15 cases), skin infections (6 cases), erythema induratum (5 cases), traumatic panniculitis (2 cases), Weber-Christian-like syndromes (5 cases), and vasculitis (1 case).

aspects of the legs, often on the thighs, buttocks, and upper extremities, and occasionally on the trunk and abdominal skin (Table 1). Eleven of the patients were women, and the mean age of the group was 38 years. One of the patients, who had crops of nodules (five or six at a time), reported that several of the nodules had occurred after local trauma. Six patients had the disease less than three months. The cases that caused diagnostic problems were the six with recurrent episodes lasting two to seven years. Generally, the duration of the individual nodules was two to three weeks (range one week to eight weeks). In two patients, arthralgia developed, and only three were febrile. These signs and symptoms were unrelated to associated diseases. Two patients had the nodular eruption after having had a sore throat; one had ulcerative colitis; two had sarcoidosis; and one had chronic leukemia.

Laboratory and Reontgenographic Findings.—The erythrocyte sedimentation rate (ESR) was slightly elevated (21 to 40 mm/hr) in seven of the 15 patients, but in three, it was high (55, 69, and 120 mm/hr). Only two patients had leukocyte counts higher than 10,900/cu mm; one of these had chronic lymphatic leukemia. The antistreptolysin O titer (ASO) was moderately elevated (333 units) in one patient who had no history of sore throat. In another patient, a culture from the throat showed growth of streptococci of the viridans group. The chest roentgenograms were normal for all but the two patients with sarcoidosis, and these showed hilar adenopathy and nodular infiltrates. Cultures of nodules from six patients were negative for bacteria, acid-fast organisms, and fungi.

Histopathologic Findings.—Biopsy specimens showed acute panniculitis with a predominantly polymorphonuclear cell infiltrate (Fig 1). Often, there was necrosis of the cellular infiltrate itself and some secondary necro-

sis of the fat. The acute panniculitis was principally focal, occurring in the periphery of the fat lobules in relation to the vessels, but in some of the lesions, the whole fat lobule was replaced by masses of polymorphonuclear leukocytes. Hemorrhage was an almost constant feature, and in some of the patients, it was extensive. Phlebitis was not a significant feature in the multiple sections studied. One of the patients had a mixed cell infiltrate in some areas of the specimen with foci of necrosis and, adjacent to the necrotic area, large pseudomalignant mononuclear cells (Fig 2). One patient (case 15) with erythema nodosum and sarcoidosis had acute panniculitis with proliferative lipophagic cells similar to so-called second stage of Weber-Christian disease (Fig 3).

Skin Infections

Clinical Data.—This group consisted of six patients, two of whom had fever. Three patients, one with pericholangiolitic hepatitis, had infectious skin lesions secondary to pruritus and excoriation. One patient had abscesses on his right hand and thigh secondary to contact dermatitis due to neomycin sensitivity. One patient had infected varicose ulcers of the legs. The last patient in this group, a 13-year-old boy, had skin lesions of macules, papules, and pustules on his arms, legs, and trunk for one week, until he died of pneumonia and staphylococcal sepsis. Three of the patients were men, and three were women. If the 13-year-old boy were excluded from this group, the mean age would be 66 years (range 57 to 74 years). The disease lasted from one week to six months.

Laboratory and Roentgenographic Findings.—The patients had elevated ESR that exceeded 40 mm/hr in all but one case; the boy with staphylococcal sepsis had an ESR of 82 mm/hr. Only two patients had elevated leukocyte counts. Urinalysis showed no abnormalities except for the boy with pneumonia sepsis who had hematuria. Culture of biopsy specimens showed growth of pathogenic bacteria in the four patients in whom it was performed. Two patients had *Pseudomonas aeruginosa* cultured, and one patient had *Micrococcus pyogenes*. Culture of the biopsy specimen from the septic patient showed many *Staphylococcus aureus* organisms, as did blood cultures.

Histopathologic Findings.—Biopsy specimens showed acute panniculitis with focal or large areas of necrosis. One of the specimens showed marked vascular proliferation of granulation tissue in the fat lobules. Two of the patients had histopathologic features similar to those seen in a patient with sterile panniculitis in whom amylase and lipase were found in the skin.[1] In a biopsy specimen from a lesion secondary to pruritus and scratching, there was a marked pseudoepitheliomatous hyperplasia. The patient with sepsis had, in addition to acute panniculitis, a similar cellular infiltrate in the dermis, with small foci of necrosis.

Erythema Induratum (Nodular Vasculitis)

Erythema induratum is defined as a chronic and recurrent tuberculous delayed hypersensitivity reaction involving the vessels of the legs. The histologic feature is usually a tuberculoid granuloma with caseation necrosis. Nontuberculous erythema induratum is a convenient equivalent term for nodular vasculitis.

Clinical Data.—The five patients in this group had chronic red to bluish nodules on their lower legs, particularly on the calves (Table 2). Ulceration of one or several nodules occurred in two patients (cases 16 and 17); in another (case 18), the nodules showed fluctuation, and one patient (case 19) had lesions that left depressions on healing. One patient (case 20) with nodular vasculitis had no ulcerations or scars. One patient (case 19) had suffered from pleurisy on four different occasions and pericarditis on one occasion. The father of patient 17 had died of tuberculosis when the patient was 6 years old. In this diagnostic group, the disease had lasted from 1.5 to 45 years, the average being 11 years. The individual nodules lasted from four weeks to three months and healed with scarring. All the patients were women, and their ages averaged 52 years (range 33 to 63 years).

Patient 16 had isoniazid treatment for nine months without apparent improvement. Patient 17 was cured during 12 months of isoniazid treatment. Patient 18 developed new lesions in spite of treatment with isoniazid and para-aminosalicylic acid for seven months. Patient 19 was lost to follow-up. Patient 20 was not treated with antituberculous therapy.

Laboratory and Roentgenographic Findings.—All the patients had elevated ESR, the highest value being 96 mm/hr in one hour. All patients had normal leukocyte counts. Two (cases 16 and 19) were reactive to intra-

dermal testing with 1 tuberculin unit of purified protein derivative (PPD), and two (cases 17 and 20) were reactive to 5 tuberculin units; this test was not done in case 18. All five patients had normal urine. Chest roentgenograms showed evidence of disease only in case 19—the right apex showed thickening of the pleura. Culture of biopsy specimens from the nodules revealed no growth of bacteria, *Mycobacterium tuberculosis*, or *Brucella* organisms, or fungi. Culture of sputum for *M tuberculosis* was negative in the two cases in which it was performed.

Histopathologic Findings.—One patient (case 16) had acute panniculitis with masses of polymorphonuclear cells invading the fat lobules, as did two others (cases 17 and 20) in whom there was additionally extensive secondary fat necrosis. In case 18, although the predominant feature was that of acute panniculitis, careful search revealed small areas of granulomatous panniculitis. Subsequent biopsy specimens showed only granulomatous features, typical of erythema induratum with caseation necrosis. In case 19, the acute polymorphonuclear leukocyte infiltrate was intermingled with lymphocytes, and there was phlebitis similar to erythema nodosum.

Acute Weber-Christian-Like Syndromes With Enzyme and Nonenzyme Panniculitis

These five patients (two men and three women) had recurrent febrile, inflammatory, subcutaneous masses that sometimes were associated with suppuration.

Clinical Data.—Four of the five were febrile with the development of the nodules. Three patients (cases 21, 22, and 23) had generalized nodules. Although the syndrome of recurring nodules extended from eight months to four years, individual nodules lasted only two to six weeks (Table 3). Three patients (cases 21, 22, and 23) developed suppuration and ulceration, and two (cases 23 and 24) had depressed residual change in the subcutaneous tissue. Pancreatic disease or enzymes (lipase and amylase) in the blood, urine, and skin were found in a patient with pancreatic carcinoma (case 22), in a previously reported patient with amylase and lipase in the inflamed skin (case 21),[1] and in a patient with lipase in the drainage from the lesions (case 23). Two patients (cases 21 and 23) had normal pancreatic function and structure at autopsy and laparotomy, respectively.

Case 21 was of a 47-year-old man who had painful subcutaneous nodules scattered over the body for three years at two separate periods, with a free interval of nine months. Each time, the activation of the disease was preceded by a sore throat and fever. The onset of the nodules was accompanied by nausea and malaise. The individual nodules subsided within one to three weeks, without ulceration or scarring except for two nodules that ruptured spontaneously, draining liquified material. However, new lesions continued to develop, particularly on areas likely to suffer minor trauma, that is, over bony prominences. He died with pericarditis and infarction of the terminal ileum, as well as infarction of the right kidney. Autopsy showed a normal pancreas, both grossly and microscopically. This patient has been described in detail previously.[1]

Case 22 was a 63-year-old man whose chief complaint was gradual onset of gastric distress that had lasted for six months. When examined, he had had severe, generalized, abdominal pain for one hour, three to four times a day. He had lost 5.4 kg. Laparotomy revealed a hard, nodular lesion, approximately 5 cm in size, within the neck of the pancreas. Needle biopsy from the pancreas showed adenocarcinoma grade 2.

The day after laparotomy the patient developed chills and a temperature of 40 C (104 F), which were considered to be the result of urinary infection. One week later, there was sudden onset of dyspnea, circulatory collapse, and shock. A clinical and roentgenographic diagnosis of lobar pneumonia was made, and *S aureus* was isolated from sputum. Treatment with vancomycin hydrochloride and later with chloramphenicol resulted in improvement within five days. Forty days after admission, tender, red nodules suddenly appeared on his legs. The nodules occurred in linear distribution bilaterally over the inner and extensor aspects of both legs. The nodules became fluctuant and drained 160 ml of chocolate-colored purulent material. Culture of the material for organisms was negative. The skin lesions involuted with injections of adrenocortcotropin (40 units/day). The patient died after having been hospitalized for 56 days. Postmortem examination revealed pancreatic carcinoma and diffuse pancreatitis with extensive necrosis.

Case 23, a 55-year-old woman with chronic symptomatic cholecystitis, had a three-month history of tender, liquifying, and draining nodules of the thighs and buttocks. After the lesions had healed, a depression in the subcutaneous tissue was observed. Each crop of nodules occurred with fever and malaise. No history compatible with factitial panniculitis was obtained. On two occasions, fluid drainage from lesions showed lipase (36 units/ml). Two biopsied lesions were grossly hemorrhagic and necrotic, but lipase and amylase were not found. Histologically, acute panniculitis was observed. Cholecystectomy revealed a normal pancreas and mesenteric adenitis.

The two patients who were without abnormal enzyme values had localized inflammatory nodules of acute panniculitis.

Case 24, a 46-year-old woman, had nodules for 14 months after having had a sore throat. Lesions occurred both on the extremities and on the trunk, with predisposition for pressure sites. She had fever during the time that a new crop of nodules developed. The nodules were red and tender. There was no ulceration or suppuration, but when they healed, the lesions left depressions.

Case 25, a 43-year-old woman, had dermatitis of the hand for which she received a corticosteroid injection ten days before the onset of the nodules. She had also received intramuscular injections of pain relievers in her hips for severe headaches. The first red and tender nodules developed on her arms, where no injections had been given. These nodules healed after one month without ulceration or suppuration. For 4 years, nodules appeared on her buttocks, from which the biopsy specimens were taken, and these showed acute panniculitis.

Laboratory and Roentgenographic Findings.—The ESR was slightly elevated in cases 21, 22, 23, and 24, and in case 25, it was 81 mm/hr. None of the patients had leukocytosis. The serum amylase levels were normal in all four patients in whom the enzyme was measured, and the urinary amylase level was elevated fivefold in case 21. In case 22, there was an increase in serum amylase activity from 160 to 3,000 units/100 ml (normal up to 507

Fig 4.—Polymorphonuclear leukocytes with necrosis in acute panniculitis and pancreatic carcinoma. Small focus lipophagic proliferation is observed in left center (hematoxylin-eosin, original magnification ×160).

units/100 ml). Cultures of the lesions for bacteria, fungi, and acid-fast organisms were negative.

Histopathologic Findings.—Cases 21 and 22 showed focal acute panniculitis. Case 21 also showed fat necrosis, liquefaction, and microcysts. Case 22 showed mild lipoblastic proliferation also (Fig 4). In case 24 particularly, the septa were affected by masses of polymorphonuclear cells. There was extensive hemorrhage in case 23. The biopsy specimen from case 25 revealed acute panniculitis and fat necrosis.

Traumatic Panniculitis

We define this as a syndrome of erythematous nodules that occur on minor trauma and have the histologic features of acute panniculitis.

Clinical Data.—This group consisted of two patients. One was a 44-year-old woman who fell and lacerated her scalp, for which she was given a tetanus toxoid injection. One week later, a red, tender, hot infiltration developed at the injection site, and after another week, a similar lesion developed on the upper anterior aspect of her thigh, a site of unknown trauma. One month later, two similar but linear lesions developed over the right lumbar area after the patient had been horseback riding. Finally, she struck the medial aspect of her left arm on a cupboard door, a minor blow, and nine days later, a tender, red, hot area appeared at the site of the trauma. There was no fever or other constitutional symptoms with any of the lesions. She had had hives in the past at least once a year. Except for an eruption after taking a sulfa drug, no sensitivities were known.

Examination showed several inflammatory subcutaneous lesions. A red-violaceous macule, 5 by 4 cm in size, was present in the lower deltoid area of the left arm at the site of the original tetanus injection. There was a round, tender, subcutaneous nodule, about 3 cm in diameter, near the upper border of the lesion. The entire area was warmer than the surrounding skin. There was an indurated subcutaneous linear lesion, 6 × 2 cm in size; another similar lesion, 4 × 2 cm in size, was seen parallel and horizontally over the lumbar area. Both lesions showed hyperpigmentation. On the site of the trauma (from striking the cupboard door), the medial aspect of her upper right arm, she had a red, infiltrated, tender, subcutaneous mass that was 10 cm in diameter. The right upper anterior aspect of her thigh had an irregular 2-cm area of lipoatrophy, with a central subcutaneous induration. Otherwise, she was in good general health.

The other patient was a 36-year-old woman who had a five-year history of recurrent nodules on the extremities. The nodules occurred during the winter months only. The first episode of nodules appeared over the elbows and was accompanied by fever and malaise. She visited a physician, who treated her with cortisone. The lesions cleared without any residua over a period of two to three weeks. The next episode occurred two years later and consisted of three or four nodules, which were 3 to 8 cm in diameter and located on her thighs and arms. At first, the lesions were red and tender. Later, they diminished in size and lost their color. Again, she was treated with cortisone. Since then the lesions recurred

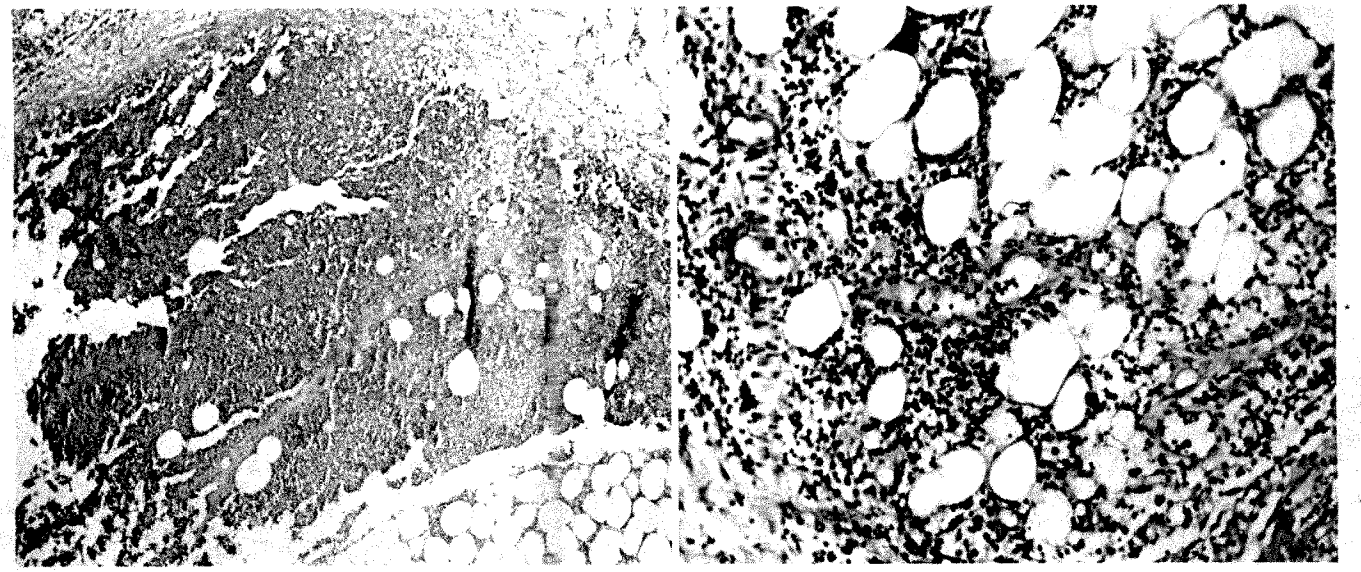

Fig 6.—Left, Acute panniculitis and necrosis in traumatic panniculitis. Right, Peripheral masses of polymorphonuclear leukocytes in fat lobule. Capillary vessels show secondary hyalinization (hematoxylin-eosin, left, original magnification ×64; right, original magnification ×160).

each winter, the episodes lasting weeks to several months. On three occasions, she had the lesions opened by a physician, and one drained spontaneously after trauma. Her local physician took a biopsy specimen, which he interpreted as being compatible with Weber-Christian disease. Thus, the patient was referred to our clinic. She left her home using crutches because a nodule on her left ankle was still draining purulent material after being incised. When she arrived at our clinic, there were hot, red, subcutaneous plaques at the circumference of the axillae due to the trauma of using the crutches.

Examination revealed a subcutaneous nodule that was 2 × 8 cm, along the medial aspect of her right arm, and several nodules at the circumference of the axillae. There was no color change of overlying skin. The posterior aspects of her thighs showed several red and tender nodules, 1 to 2 cm in diameter. Her general health was not changed. Marked improvement with healing or involution of all lesions occurred with bed rest.

Laboratory and Roentgenographic Findings.—The ESR was 45 mm/hr in one patient and 51 mm in the other. Both patients had normal leukocyte and differential counts. In the second patient, the hemoglobin value was 10.1 gm/100 ml; the lupus erythematosus clot test was negative; results of serum electrophoresis were normal; and the ASO titer was 250 Todd units. Both patients had normal serum amylase and lipase levels. Urinalysis revealed no abnormalities, and the chest roentgenograms revealed only slight cardiac enlargement in the first patient. Roentgenograms of the ankle were normal in the second patient. Culture of the pus from the incision site of the ankle showed growth of *P aeruginosa*. Cultures of biopsy specimens were negative for bacteria, *M tuberculosis*, *Brucella*, and fungi in both patients.

Histopathologic Findings.—The first patient had polymorphonuclear cells that were often arranged around cystic spaces in the fat (Fig 5); the lipophagic cells were few. The second patient had marked fat necrosis in addition to the polymorphonuclear leukocytes (Fig 6).

Vasculitis

A 46-year-old woman with regional enteritis (Crohn disease) had had lesions of cutaneous periarteritis nodosa on her lower extremities for four years. She had no signs or symptoms of infection. Focal or "starburst" livedo was prominent. Nodules on the livedo were suggestive of erythema nodosum. This patient was reported in detail in order to emphasize the vascular cutaneous lesions in Crohn's disease.[2] Biopsy specimens of the skin revealed acute panniculitis and no evidence of vascular inflammation until the entire lesion had been serially sectioned.

COMMENT

Erythema Nodosum

In many countries, erythema nodosum is not routinely studied by histopathologic examination. Furthermore, most studies of the histopathologic features of erythema nodosum have excluded cases in which the histologic findings have not fitted clearly defined limits accepted by the particular author. Probably for these reasons, the polymorphous nature of erythema nodosum histology, as described by us,[3] has not been fully recognized.

In most cases, erythema nodosum presents histopathologically as a vascular and septal inflammation characterized by a cellular infiltrate that is predominantly lymphocytic. Signs of thrombophlebitis are observed in 40% of cases.[4] Hemorrhage as a consequence of the phlebitis is common and should be recognized as a characteristic feature of erythema nodosum. Although emphasized by Miescher[5] in his classic description of the histologic features of erythema nodosum, the occurrence of hemorrhage has not gained much attention in more recent literature. It can occur as septal hemorrhage or as hemorrhage in the subcutaneous fat lobules.

In addition to the "typical" septal inflammation with phlebitis and hem-

orrhage, the spectrum of changes in erythema nodosum includes a true panniculitis of acute polymorphonuclear or subacute lymphocytic or rarely even chronic granulomatous type.[6] In our series of acute panniculitis, almost one half the cases were clinically typical examples of erythema nodosum, confirmed by follow-up. The necrosis sometimes seen apparently is not usually extensive enough to cause ulceration or scarring. Any individual feature may be predominant in a given area of a biopsy specimen so that multiple sections are necessary to recognize the variations in type and location of the pathologic process.

The observation of acute panniculitis in erythema nodosum has been made before, but it has not been emphasized in relation to clinical studies. Montgomery et al[7] stated in 1945 that erythema nodosum may show a relatively acute infiltration with atrophy and necrosis of the fat in the subcutaneous tissue. The case of acute benign panniculitis described by Turpin and Bocquet[8] probably was of erythema nodosum and is similar to many of our cases. More recently, Montgomery[9] described erythema nodosum in terms of an infiltration of polymorphonuclear leukocytes, although occasionally lymphocytes predominate. He found no constant findings, and he speculated whether there was a specific histologic picture for erythema nodosum. Likewise, Borrie and Stansfeld[10] concluded that, pathologically, erythema nodosum cannot be sharply separated from other examples of nodular vasculitis. Still later, Fine and Meltzer[11] observed foci of acute inflammation in one area and granulomatous inflammation in other areas of the same biopsy sections. They regarded this combination of acute and chronic inflammation as particularly characteristic of "chronic erythema nodosum."

Acute panniculitis is a descriptive histopathologic term whose features may be found at some time in most inflammation of the subcutaneous tissue. By simply expanding our range of diagnosis slightly to include cases with short-lived red nodules whether or not they are generalized, febrile, chronically recurrent, or suppurative, we find that two of the patients with Weber-Christian-type syndrome (cases 24 and 25), one with erythema induratum, and one with nodular vasculitis, and the two patients with traumatic panniculitis, could be considered to have acute panniculitis of erythema nodosum. Excluding the six patients with infection on the basis of clinical observation and culture, we find that 21 of the 28 patients with possible histopathologic acute panniculitis might be considered to have erythema nodosum.

Erythema Induratum

The typical histopathologic findings in erythema induratum include a granulomatous, tuberculoid infiltrate with vascular changes and areas of caseation necrosis. Although polymorphonuclear leukocytes have been reported to occur as components of the mixed cell infiltrate,[12] surprisingly five of our patients with acute panniculitis had clinical features generally known as being those of erythema induratum. We consider this diagnosis a distinct clinical entity, the cause of which sometimes can be tuberculous but generally is unknown (nodular vasculitis). The unresponsiveness of the disease to antituberculous treatment in two of three treated patients suggests a nontuberculous cause. In the future, more attention must be given to the age of the nodules biopsied because, in their evolution, even lesions of erythema induratum can develop a stage of acute panniculitis.

Acute Panniculitis With or Without Enzyme Changes (Weber-Christian-Like Panniculitis)

Since the classic description by Ungar,[13] histopathologists have associated acute panniculitis with the first stage of Weber-Christian disease.[14] However, the nosology of the Weber-Christian syndrome is at present very inexact[15,16]; several reports have included cases of erythema nodosum, acute traumatic panniculitis, and lupus panniculitis. Factitial panniculitis often presents histologically as acute panniculitis,[17-19] and several cases of Weber-Christian disease have on thorough examination seemed to have a factitial origin[17,20] or to be associated with enzyme abnormalities.[1,21-24] The demonstration of lipocyte proliferation in the second stage of Weber-Christian syndrome in some cases of erythema nodosum further emphasizes the lack of specificity of the histology of this entity. The further and final stage of fibrosis in Weber-Christian disease is nonspecific.

In our series, all of the cases of acute panniculitis and enzyme changes might earlier have been labeled Weber-Christian disease. Such cases may represent the only distinctive panniculitis syndrome that is equivalent to the description of Weber-Christian disease. Although the enzymes in serum, urine, and tissue may be related to the etiology of the process, they may only be markers of the tissue destruction. The destruction may be pancreatic or visceral as well as cutaneous, and the enzymes may be related to both visceral or cutaneous lesions.

Traumatic Panniculitis

The response of the subcutaneous tissues to mechanical trauma, insufficient in degree to cause immediate macroscopic injury, has been minimally studied. However, adipose tissue is extremely fragile, and even slight trauma may induce lesions.[25] Factitial panniculitis is one form of physically induced panniculitis. Jipp[26] reported traumatic fat necrosis, a necrotic inflammatory process occurring as nodules in the breasts following bleeding in the skin, after treatment with anticoagulants. Korting[18] found acute panniculitis with predominance of polymorphonuclear leukocytes and eosinophils to occur in nodules provoked by a "knock," a condition that he called nonfebrile suppurating Weber-Christian disease. Sarkany and Macmillan[27] proposed the name "recurrent, nonscarring, pressure panniculitis" for nodules appearing after local pressure and histologically showing acute panniculitis without vasculitis.

In two of the patients in the present series, we classified the panniculitis as traumatic because ordinary, minor trauma provoked the lesions. Probably other agents, so far unknown, may

have made the subcutaneous fat abnormally susceptible to "normal" trauma. In one of the patients, the seasonal appearance suggested a variant of erythema nodosum, and perhaps this is how the condition should be classified.

In our series of acute panniculitis, the role of trauma was not limited to the two patients classified as having traumatic panniculitis. Local trauma also preceded the development of several of the nodules in one patient with erythema nodosum and in one of the patients with the enzyme-panniculitis syndrome. Two additional patients with the enzyme-panniculitis syndrome and the patient with Crohn's disease and cutaneous periarteritis nodosa had predominance of lesions on locations likely to be traumatized, that is, bony prominences. In fact, the predisposition of the nodules for the anterior surface of the legs in erythema nodosum may be explained partly on the basis of the effect of minor trauma.

Vasculitis

The occurrence of vaculitis in the subcutaneous tissue is frequently associated with panniculitis. The panniculitis frequently is acute, angiocentric, and destructive, with infiltration of polymorphonuclear leukocytes and eosinophils. In all cases of acute inflammation, secondary hyalinization of the blood vessels can be observed, but in vasculitis, it is pervasive and also is found in the dermis where leukocytoclasia and vascular necrosis are more easily distinguished. In the spectrum of panniculitis associated with vascular inflammation, granulomas and lymphoproliferative features also may be found. The one case of vasculitis in our series illustrates that large, muscular, vessel inflammation also can be found with acute panniculitis.

CONCLUSIONS

This review of the special pathologic features of fat has revealed that most, if not all, inflammation of fat, whatever its cause, may have an acute inflammatory phase. All such lesions must be cultured and also studied for foreign materials and enzymes. The clinical pattern of the disease is most important in deciding the nature and prognosis of the nodular inflammatory process. Weber-Christian disease as an entity is rapidly being replaced by better described disease processes. Factitial panniculitis, traumatic panniculitis, panniculitis with enzyme changes, and connective tissue disease panniculitis are new syndromes that were once called "Weber-Christian disease." Erythema nodosum is the commonest form of clinical presentation of the histopathology of acute panniculitis, but even granulomatous erythema induratum may have a phase of acute panniculitis.

Intrauterine Herpes Simplex Infections

James M. Komorous, MD; Clayton E. Wheeler, MD;
Robert A. Briggaman, MD; Ivor Caro, MB, BCh, FF Derm

• Most dermatologists are familiar with the manifestations of neonatal herpes simplex infections. Few, however, are acquainted with the concept of intrauterine herpes simplex infections.

This article describes two additional cases of intrauterine herpes simplex infections with congenital malformations. Common features included intrauterine growth retardation, microcephaly, encephalitis, chorioretinitis, psychomotor retardation, and recurrent, grouped, cutaneous vesicles. Seven similar cases with congenital malformations are reviewed as well as cases of intrauterine herpes simplex infection without congenital malformations.

We propose that intrauterine herpes simplex infections be termed "early" when there is evidence of disturbed embryogenesis or "late" when congenital malformations are less specific or inapparent. We further suggest that the spectrum of intrauterine infections is similar to that of neonatally acquired infections.

(*Arch Dermatol* 113:918-922, 1977)

Herpes simplex infections in the newborn represent uncommon yet well-recognized entities that were first documented by Batignani in 1934[1] and Hass in 1935.[2] Since then, numerous reports and reviews on the topic have appeared, the most recent being those of Nahmias et al in 1970[3] and Hanshaw in 1973.[4] It is generally agreed that most neonatal infections may be acquired either by ascending infection from the mother's genital area to the in utero infant after premature rupture of the membranes or by transvaginal spread to the infant during delivery. It is much less well appreciated that intrauterine infections have also been reported. This article describes two additional cases of intrauterine herpes simplex infection with associated malformations and discusses the spectrum of in utero infections in terms of both time of acquisition and severity.

REPORT OF CASES

CASE 1.—A girl was born Jan 21, 1969, at North Carolina Memorial Hospital (NCMH) to a 19-year-old, gravida 2, para 2 woman at 36½ weeks' gestation. The pregnancy was unremarkable except for a history suggestive of herpes progenitalis in the first trimester. After an uneventful five-hour labor, the baby was delivered transvaginally. The two-minute Apgar score was 10. On physical examination the weight was 1,932 gm, length 43 cm, and head circumference 28.5 cm, all less than the tenth percentile for the gestational age. There was a good cry and suck reflex and normal neurologic function. Microcephaly was present with overlapping of the coronal sutures, along with an abnormal right macula and minimal, healed chorioretinitis of the left eye.

On the fourth hospital day, numerous flat, grouped pustules were noted over the trunk, arms, and legs (Fig 1). A Tzanck preparation from those lesions showed multinucleated giant cells and intranuclear inclusion bodies. A skin biopsy specimen of a pustule on the left forearm showed changes compatible with herpes simplex, and material from pustules on the chest, left thigh, foot, and arm induced a cytopathologic effect (CPE) in HeLa cell cultures characteristic of herpes simplex type 2. Attempts to isolate virus from the infant's mouth, throat, anus, vagina, and nares were unsuccessful. A sample of cord blood had a neutralizing antibody titer of 1:128 for herpes simplex type 2.

Results of complete blood count (CBC) and urinalysis were normal as was chest x-ray film. A skull x-ray film demonstrated a small calvaria with overriding sutures. Results of chemical analyses of the blood were within normal limits except for an elevated indirect bilirubin level compatible with neonatal jaundice. On Jan 29, the quantitative IgM was 17 mg/100 ml, and on Feb 13, it was 32 mg/100 ml. The cerebral spinal fluid (CSF) had an elevated protein level of 226 mg/100 ml, glucose of 54 mg/100 ml, and RBC count of 3/cu mm and no WBCs. The child had serum neutralizing antibody titers suggestive of a herpes simplex type 2 infection (Table 1). Other serologic studies showed nonreactive maternal and cord blood for syphilis, an infant rubella hemagglutination inhibition (HI) titer of 1:320 on Jan 29 and Feb 18, and a maternal rubella HI titer of 1:320 on Feb 17. On Jan 29, the infant cytomegalovirus titer was less than 1:8, and the toxoplasma titer was negative.

The child required tube feedings in the

premature nursery for the first week. New vesiculopustular herpetic skin lesions appeared throughout the hospital stay. Otherwise, she remained well, gaining to 2,310 gm without a change in head circumference, and was discharged on Feb 18.

She was observed closely thereafter in the pediatric and dermatology clinics where sequential sera were obtained for herpes simplex titers from the child and mother (Table 1). The maternal rubella HI titer on July 1, 1969, persisted at 1:320, whereas the infant's titer declined to 1:40 on May 6 and to 1:10 on July 1. On July 1, at 4 months of age, her weight, length, and head circumference were all less than the third percentile. She manifested severe psychomotor retardation, poor head control, opisthotonos, spastic quadriparesis, and bilateral nystagmus, but was able to blink her eyes in response to light and sound. On March 19, 1971, at 25 months of age, the child was admitted to NCMH because of dehydration. Vesicular lesions were noted on the neck, with a Tzanck preparation again showing multinucleated giant cells and intranuclear inclusion bodies. On April 13, at 27 months of age, she demonstrated marked microcephaly (head circumference 40.7 cm), growth retardation (weight 5,680 gm, length 69 cm), and psychomotor retardation. Ophthalmologic examination showed inability to follow light, bilateral healed chorioretinitis, and bilateral optic atrophy. Skull films showed microcephaly, a chest x-ray film showed diffuse bilateral infiltrates, and an electroencephalogram was grossly abnormal. The child was subsequently lost to follow-up.

*Neutralizing antibody titer is the reciprocal of the serum dilution that neutralized 50% of the herpes virus sample.

Case 2.—A boy was born at another hospital on July 21, 1975, to a 16-year-old, primigravida woman at 39 weeks' gestation. The birth weight was 2,450 gm (less than the tenth percentile). The pregnancy was uncomplicated except that the mother had an upper respiratory infection in the first trimester and noted her first episode of a perioral "fever blister" in the third trimester. No vaginal lesions were noted at the time of delivery. The mother's sister had recurrent herpes on one buttock; history pertaining to the father was unremarkable. At delivery oligohydramnios was noted, and the infant had an Apgar score of 6, poor suck, and a rash predominantly on the right side of the body. The child was transferred to NCMH on July 23 because of hypothermia and paroxysms of left-sided twitching and seizure-like activity. On admission he was lethargic, with a height of 49.5 cm (65th percentile) and head circumference of 32 cm (15th percentile). The fontanelles were flat with overlapping of the sutures, and there was positive transillumination over both frontal areas. He had a weak suck, weak cry, and was hypotonic with bilateral positive Babinski reflexes. His eyes were deeply recessed in the orbits, and microphthalmia was present. The pupils were normal and reacted to light, and "doll's eye" responses were intact. Ophthalmoscopic examination

Fig 2.—Anterior view of patient 2 at 48 hours after delivery. Erythematous, scaly, eroded, vesiculopustular eruption was confluent over the right side of the trunk and right upper extremity.

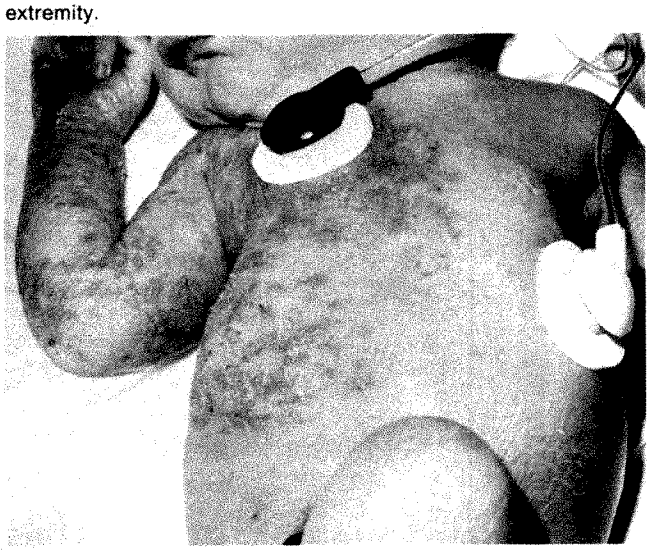

Fig 3.—Posterior view of patient 2 at 48 hours after delivery.

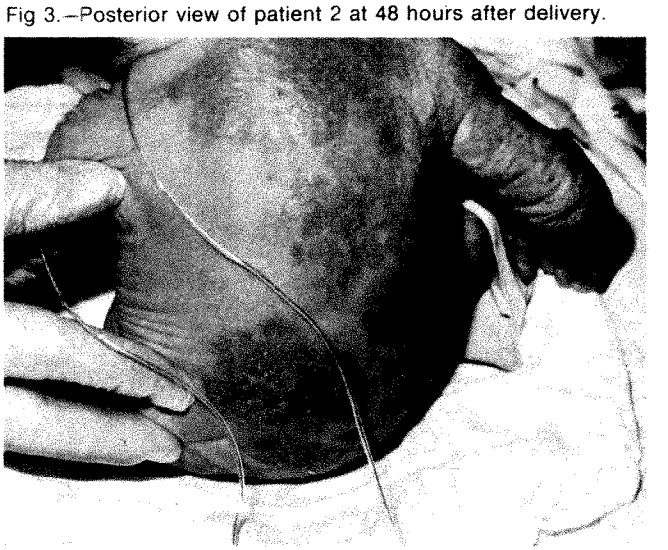

showed bilateral cobweb opacities at the plane of the posterior lens capsule and bilateral, white retinal masses thought to represent retinal dysplasia or scars. The liver edge was 1 cm below the right costal margin, but there was no splenomegaly. Skin examination revealed an ichthyotic appearance of the hands and feet and an erythematous, scaly, eroded, vesiculopustular eruption, which was confluent over the upper right arm and right side of the trunk with patches on the right shoulder, right axilla, right ear, nasolabial areas, cheeks, and both legs (Fig 2 and 3). A Tzanck preparation of blister fluid from the right axilla revealed acantholytic balloon cells, multinucleated giant cells, and intranuclear inclusion bodies. On the fifth hospital day blister fluid from vesicles in the right axilla and right upper back produced a CPE in HeLa cell cultures compatible with herpes simplex type 2. Viral cultures of the urine and CSF were negative. Serum obtained from the child on admission revealed neutralizing antibody titers consistent with a herpes simplex type 2 infection (Table 1). The mother's serum also demonstrated a herpes type 2 response. Rubella cytomegalovirus and toxoplasma titers were not elevated, and a serologic test for syphilis was nonreactive.

Results of CBC and platelet count were normal as was chest x-ray film. Chemical analyses of the blood gave normal results except for an SGOT of 99 IU and an elevated indirect bilirubin level compatible with physiologic, neonatal jaundice. Quantitative immunoglobulin determinations on admission demonstrated an elevated IgM of 34 mg/100 ml. The CSF had an elevated protein level of 210 mg/100 ml, glucose of 39 mg/100 ml, RBC count of 30/cu mm, and WBC count of 8/cu mm. Urine was unremarkable except for some unusual cells of possible embryonic connective tissue origin, but with no evidence of inclusion bodies. Skull films showed overriding of the sutures, and an EEG was abnormal with decreased voltage.

The child was treated with oxacillin sodium and kanamycin sulfate until the fourth day when all bacterial cultures were negative. The hospital stay was uneventful except for constant lethargy and temperature instability. He was transferred in an infant incubator to another hospital on Aug 4.

He was seen again on Sept 25, 1975, at 2 months of age, with recurrent, grouped vesicles on the trunk, possible deafness, and persistent temperature instability. The head circumference was 35 cm and he weighed 3,865 gm, below the third and tenth percentiles, respectively. He was lethargic and hypotonic and had hypopigmented areas with atrophy, scarring, and milia on the trunk, neck, and right arm. Skull films showed no calcifications. Ophthalmologic examination revealed inability to follow light and bilateral microcornea, microphthalmia, posterior synechias, posterior lenticular haziness, white vitreous masses, and chorioretinal scars.

The child was last seen on Jan 28, 1976, at 6 months of age. The head circumference was 39 cm (less than the third percentile), and he weighed 7,730 gm. The mother again described the intermittent appearance of grouped vesicles on the right side of his trunk, his inability to follow light or moving objects, and temperature instability. During the physical examination there were myoclonic jerking motions of his head and trunk as well as alternating flaccidity and rigidity of all of the extremities. Serum obtained from the infant and mother showed persistence of the herpes simplex type 2 titers, suggesting a chronic infection. The family was subsequently lost to follow-up.

VIRUS ISOLATION AND SEROLOGIC TESTS

In each case herpes simplex virus was isolated on HeLa cell cultures and identified as type 2 by the characteristic CPE produced by this virus. The virus in case 1 was also identified as type 2 by neutralization with anti-type 2 and anti-type 1 herpes simplex rabbit serum. Neutralization antibody tests were performed according to a previously described standard method.[5] The neutralization antibody titers were expressed as the reciprocal of the dilution of serum that neutralized 50% of the virus sample.

COMMENT

It is our opinion that these two infants represent the eighth and ninth documented cases of in utero herpes simplex infection with associated congenital malformations. Common features of their clinical presentations and subsequent courses are intrauterine growth retardation, microcephaly, encephalitis, chorioretinitis, psychomotor retardation, and recurrent, grouped, cutaneous vesicles. In addition, case 2 had seizures, microphthalmia, cloudy posterior lenses, persistent temperature instability, and immature connective tissue cells in the urine. The last two findings have not been previously described with intrauterine herpes infections, although urine sediment from the patient described by Florman and associates[6] contained cells with intranuclear "owl eye" inclusion bodies. In both of our cases, the diagnosis was made by the characteristic herpetic skin lesions, positive Tzanck preparations, induction of typical changes in HeLa cell cultures by material obtained from vesicular lesions, and elevated herpes simplex type 2 neutralizing antibodies in serum from the infant and mother soon after birth. Viral cultures from the infant's CSF, urine, mouth, nares, and anus were negative in each case. In case 1 the maternal and infant sera showed a notable rubella titer; however, the maternal titer remained elevated while the child's titer gradually decreased to within normal limits within five months, indicating only passive transfer of antibody. The infant's persistently elevated herpes simplex type 2 titers, however, indicated a chronic, ongoing viral infection. In case 2 the serum IgM was elevated, suggesting an in utero infection. Unfortunately, this finding is nonspecific, and the determination of specific IgM herpes virus antibodies, such as done by Nahmias et al[7] with the indirect immunofluorescent technique, was not performed.

Intrauterine Herpes Simplex Infections With Congenital Malformations

The first reports of possible in utero herpes simplex infections with congenital malformations were made by Schaffer and Avery in 1965[8] and South et al in 1969.[9] Florman and associates in 1973[6] reviewed four additional cases, including the first case of herpes simplex type 1 infection. They summarized the spectrum of anomalies, which included microcephaly, intracranial calcifications, diffuse brain damage, chorioretinitis, retinal dysplasia, microphthalmia, and a vesicular rash. Also in 1973, Montgomery and associates[10] reported a seventh case with the additional congenital anomalies of patent ductus arteriosus and short digits. The clinical and laboratory findings of those seven patients along with our two additional patients are summarized in Table 2. It is likely that there have been other cases of intrauterine herpes infection with congenital malformation that have not been recognized as such because of the lack of viral isolation, unavailability of serologic studies, or the similarity to congenital cytomegalovirus infections, as suggested by Florman and associates.[6] Hanshaw, for instance, knew of an infant with microcephaly, extensive cerebral calcifications, a vesicular rash, and a negative cytomegalovirus titer, but there was no viral isolation attempted (written communication, Oct 30, 1975).

*Schaffer and Avery[6]; South et al[9]; Murphy, cited in Nahmias and associates[3]; Rubio, cited in Nahmias and associates[3]; Alford, cited in Nahmias and associates[3]; Florman et al[8]; and Montgomery et al.[10]

Pathogenesis of Congenital Malformations

The time of infection is difficult to ascertain by the severity of the clinical findings alone and almost impossible without a well-documented episode of infection in the mother or the presence of specific congenital malformations. Although a history suggestive of first trimester herpes progenitalis was reported in five of the nine cases, there was no such history in the remaining four, including our second case. Unlike the rubella virus that infects the embryo during embryogenesis, ie, during the critical first eight weeks of pregnancy, with resultant nuclear cataracts, hearing loss, and cardiac anomalies,[11] the congenital anomalies associated with the intrauterine herpes infections have generally been less specific. Anomalies such as microphthalmia, chorioretinopathy, microcephaly, and intracranial calcifications are not due to primary disturbances of organogenesis, but rather are teratogenic sequelae to disturbances of normally formed organs that may occur anytime after the first eight weeks to late in the third trimester.[11] Except for the case reported by Montgomery and associates[10] with cardiac and digital anomalies, congenital malformations determined during embryogenesis have not been documented. Alford states that it takes four to six weeks for microcephaly to appear in extrauterine life after sufficient brain destruction. Extrapolating from this observation he estimated that his case of in utero infection occurred approximately five weeks before delivery (written communication, Sept 15, 1975).

Early and Late Intrauterine Herpes Simplex Infections

We propose, therefore, that intrauterine herpes simplex infections be termed "early" when there is substantial evidence of infection during the first eight weeks of gestation or "late" when congenital malformations are less specific or inapparent, suggesting infection between eight weeks of gestation and term. We consider our two cases examples of late intrauterine infection because there were no congenital malformations in these infants that would indicate herpetic infection during embryogenesis.

Evidence of early intrauterine herpes simplex infections in humans is quite limited. We have already discussed the case reported by Montgomery and associates.[10] Naib et al[12] have shown an apparent relationship between genital herpes infection during the first four months of pregnancy and an increased abortion rate. Boué and Loffredo[13] isolated herpes virus type 2 from a spontaneous abortion at five weeks' gestation, and Goldman[14] more recently reported herpetic inclusions in the endometrium after dilatation and curettage for a missed abortion. Nahmias recently stated,[15] however, that in his experience the virus was isolated from fetal membranes, rather than fetal tissue, and postulated that abortions are usually produced by indirect effects of the virus.

In addition to the nine cases of intrauterine herpes simplex infections with associated congenital malformations reported herein, there is other evidence of late intrauterine infections. Witzleben and Driscoll in 1965,[16] Sieber et al in 1966,[17] and Blanc in 1968[18] described the presence of placental lesions in four infected newborn infants. Recently, Altshuler[19] reported a case of neonatal herpes simplex with necrotizing chorioamnionitis and postulated ascending infection with transamniotic spread in the presence of intact fetal membranes. Further evidence of late intrauterine infection includes recovery of herpes virus from the placenta and/or cord blood,[20,21] the development of the disease in infants who had intact fetal membranes and were delivered by cesarean section,[20,22] and numerous cases with the presence of herpetic lesions at birth.[23-28] In almost all of these cases, there was no known maternal herpetic disease at delivery or well-documented history of herpetic infection during pregnancy; therefore, the time of intrauterine infection could not be determined.

Animal Models

Animal studies support the concept of intrauterine herpes simplex infections. Transplacental herpes infections have been demonstrated by Biegeleisen et al and again by Middel-

kamp et al in rabbit fetuses[29-31] and by Ferm and Low in hamster fetuses.[32] In none of these experimental models were congenital anomalies produced. However, Heath et al[33] demonstrated central nervous system damage, a small brain, growth retardation, and eye and auditory anomalies in chick embryos inoculated with herpes simplex virus.

Comparison of Intrauterine and Neonatal Herpes Simplex Infections

It is interesting to compare the spectrum of intrauterine herpes simplex infections to neonatal infections. It is most likely that intrauterine infections are secondary to maternal viremia and transplacental spread as with other viral infections. Most intrauterine infections reported have been due to herpes simplex type 2, similar to the findings in neonatal infections.[7] Congenital abnormalities such as microcephaly, chorioretinitis, intracranial calcifications, and psychomotor retardation as seen in late intrauterine infection have all been described after chronic herpes infections acquired in the neonatal period.[3,4,34,35] This would indicate simply an earlier onset of infection with the in utero cases, not necessarily a different pathogenesis. The spectrum of clinical disease seen in cases of late intrauterine herpes infection without malformations is also similar to that of neonatally acquired infections. This spectrum has ranged from fatal disseminated disease with hepatoadrenal necrosis, encephalitis, fever, pneumonia, and vesicular eruptions,[16,17,20-23,26] to recovery with recurrent vesicular eruptions, neurologic and ophthalmic sequelae,[23,24,27,28] to recurrent vesicular eruptions without detectable sequelae.[25,27,28]

Conclusion

Although there is evidence that the severity of the infection and the degree and number of congenital malformations is related to the time of onset and duration of the intrauterine disease in congenital rubella and cytomegalovirus infections,[11,36] evidence for this relationship with intrauterine herpes simplex infections is less clear. It is our impression that herpes simplex virus can infect the fetus at any time during pregnancy, as well as the neonatal period, with severity ranging from abortion, congenital malformations, severe infection without malformations, to mild disease with few sequelae, and perhaps even to subclinical infections. Perhaps the severity of intrauterine infections and the sequelae may well be related to as yet undetermined immune mechanisms[37] or other unknown factors, in addition to the time and duration of infection.

Cytomegalovirus, rubella virus, and toxoplasma titers were obtained at the North Carolina State Laboratory.

Pemphigus Antibody Action on Skin Explants

Kinetics of Acantholytic Changes and Stability of Antigens in Tissue Cultures of Normal Monkey Skin Explants

Jau-Shyong Deng, MD; Ernst H. Beutner, PhD; Suyu Shu, PhD; Tadeusz P. Chorzelski, MD

• The pathogenic effect of the intercellular antibodies of pemphigus was studied by using organ culture of monkey skin. Skin explants that were grown on sera with intercellular antibody titers of 320 or greater fixed these antibodies within one day as demonstrated by direct immunofluorescence for IgG. None of the control sera gave such staining patterns. Following the binding of intercellular antibodies, characteristic histologic changes appeared, notably separation of individual epidermal cells and acantholysis. These histologic changes became more marked in two to five days. During this period, the bound antibodies and the intercellular antigens decreased and disappeared. These temporal relationships of immunofluorescence and histologic findings suggest that pemphigus antibodies play a role in the induction of acantholysis.

Since the original description of the intercellular antibodies of pemphigus,[1] numerous studies have been reported concerning their clinical significance[2] and their role in the pathogenesis of the disease.[3] Specifically, pemphigus antibodies can passively transfer the disease[4-6] and appear to induce lesion formation after ultraviolet (UV) irradiation.[7] Using an organ culture system in which normal skin is incubated in sera containing pemphigus antibodies, Michel and Ko demonstrated acantholytic changes in the skin explants.[8] Our results confirm these findings and indicate that this system provides a good model with which to study the pathogenetic role of pemphigus antibodies in the development of pemphigus lesions. The purpose of this study is to detail findings on the kinetics of acantholytic changes and the stability of antigens in monkey skin explants.

SUBJECTS AND METHODS

Sera from five patients with pemphigus vulgaris were studied. These had titers of intercellular antibodies in the range of 320 to 1,280 on sections of fresh monkey esophagus. A normal serum and sera of 20 patients with various connective tissue diseases served as controls. The latter had high titers of antinuclear antibodies (ANA). (Details of findings with sera containing high titers of ANA will be reported elsewhere.)[9]

Methods of Organ Culture

Skin explants were taken from the abdominal wall of Asian *Macaca ira* monkeys immediately after they were killed. Before removal of skin, the hair was cut, and the skin was cleaned with 70% alcohol solution and dried with sterile cotton. The excised skin strips were then washed in a balanced salt solution that contained 100 μg/ml of neomycin hydrochloride. A keratotome was used to cut skin explants at a thickness of about 0.5 mm. Skin explants measuring 2 × 2 mm were grown at 31 C on 1 ml of pemphigus sera or control sera; each of these sera contained 100 μg/ml of neomycin, and a modified raft technique was used,[10,11] ie, explants were supported on wax-rimmed lens paper. Media were changed daily. Explants were removed after one to five days and processed for routine histologic study or immunofluorescence staining.

Immunofluorescence Staining

Explants were quick frozen in liquid nitrogen, cut 4 μ in a cryostat, and processed for immunofluorescence staining or stored at −80 C. Indirect immunofluorescence staining was performed with a conjugate that was prepared from a goat antiserum to human IgG with antibodies to both heavy and light chains and with the following characteristics: (1) total protein (P), 10.9 mg/ml; (2) fluorescein (F), 54.8 μg/ml; (3) antibody protein (AB), 2.85 mg/ml; and (4) molar F/P ratio 2.1.[12] To remove the anti-IgG antibodies, a portion of the conjugate was absorbed with 3.5 mg/

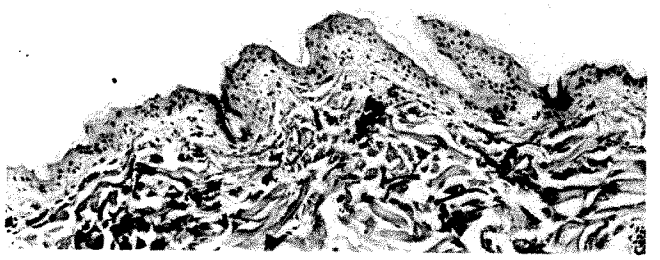

Fig 1.—Monkey skin on normal human serum after three days appears normal. There is little parakeratosis or thickening of horny cell layer. Epidermal cells seem to increase in size and stain more lightly (hematoxylin-eosin, ×100).

Fig 2.—Monkey skin in pemphigus serum after three days develops advanced suprabasal acantholysis involving both marginal and central portions of explant (hematoxylin-eosin, ×100).

Histologic Changes in Organ Culture of Skin in Pemphigus and Normal Human Sera

Time, Days	Histological Changes of Organ Culture	
	Pemphigus Serum	Normal Human Serum
1	Separation of individual epidermal cells and minimal acantholysis near margin of explant	Normal histologic structure
2	Acantholysis in marginal zone sometimes with separation of epidermis in central zone of skin	Essentially normal histologic structure
3	Advanced acantholysis, minimal parakeratosis, sometimes with separation of keratinized layers or vacuolation	Usually normal histologic structure, sometimes with separation of keratinized layers and vacuolation, also minimal parakeratosis
4	Advanced acantholysis, parakeratosis, and thickening of horny layers	Parakeratosis and thickening of horny layers
5	Advanced acantholysis and sloughing off of epidermis	Parakeratosis and thickening of horny layers
Special histologic changes	Acantholysis	Parakeratosis

ml of human IgG. Both unabsorbed and absorbed conjugate preparations were diluted 1:128 with phosphate-buffered saline that contained 4% bovine serum albumin for use in immunofluorescence. For the unabsorbed conjugate, this resulted in an AB concentration of 100 μg/ml. The degree of saturation of the intercellular antigen in organ culture was checked by indirect immunofluorescence with the same pemphigus serum in which explants were cultured.

RESULTS

Skin explants cultured with normal human sera or sera with ANA for one day underwent no detectable changes. By two days, only minimal histologic changes appeared, while after three days early parakeratotic changes could be seen (Fig 1). When the skin was maintained in organ culture for a longer period, thickening of the horny cell layers and parakeratosis became pronounced.

Skin explants maintained on pemphigus sera showed characteristic histologic changes. After one to two days, suprabasal separation developed in the epidermis, particularly at the periphery of the explants. Explants maintained on pemphigus sera for three to four days developed suprabasal acantholytic lesions (Fig 2). Pemphigus sera induced changes that resembled those seen in human pemphigus lesions prior to the appearance of inflammatory cells. The Table compares the histologic changes seen in explants grown on pemphigus and normal sera.

The binding of pemphigus antibodies to the intercellular areas of skin explants were shown by direct immunofluorescence for IgG deposits. While explants grown on normal sera had no intercellular deposits of IgG (Fig 3), those grown on pemphigus sera for one day gave positive direct immunofluorescence staining of the intercellular substance (Fig 4). Each of the five pemphigus sera produced positive direct immunofluorescence staining of the intercellular areas and suprabasal acantholytic lesions. In contrast, none of the 21 control sera produced either positive direct immunofluorescence staining patterns or histopathologic changes.

The time sequence of the appearance and disappearance of these reaction patterns is shown in the top of Fig 5. Direct immunofluorescence staining of the intercellular substance was the strongest on days 1 and 2, declined progressively on days 3 and 4, and disappeared thereafter. However, the titer of pemphigus antibodies in the medium remained constant since the medium was changed daily. The formation of intraepithelial lesions became more marked after maximal reactivity of the pemphigus antibodies had been reached, ie, in 48 to 72 hours.

Simultaneous indirect immunofluorescence for the disappearance of the intercellular antigens was performed on skin explants maintained on normal human sera for varying periods of time (Fig 5, bottom). These

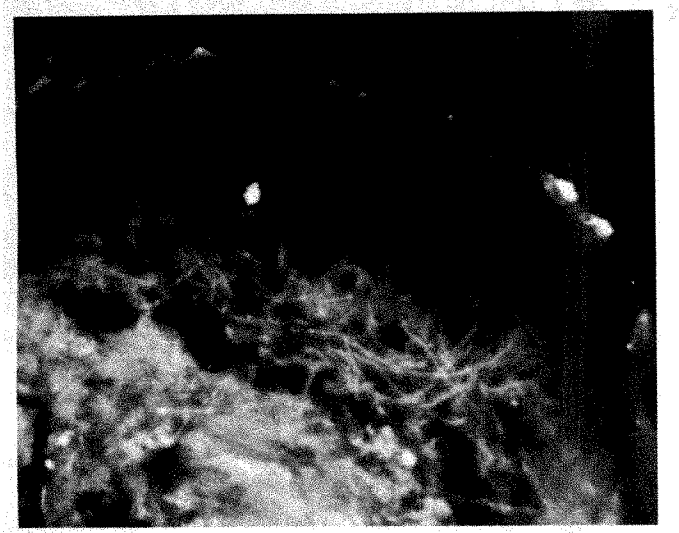

Fig 3.—Direct immunofluorescence staining for IgG deposition in epidermis of explant on normal human serum after one day reveals no staining in intercellular areas of epidermis. This serves as negative control (×400).

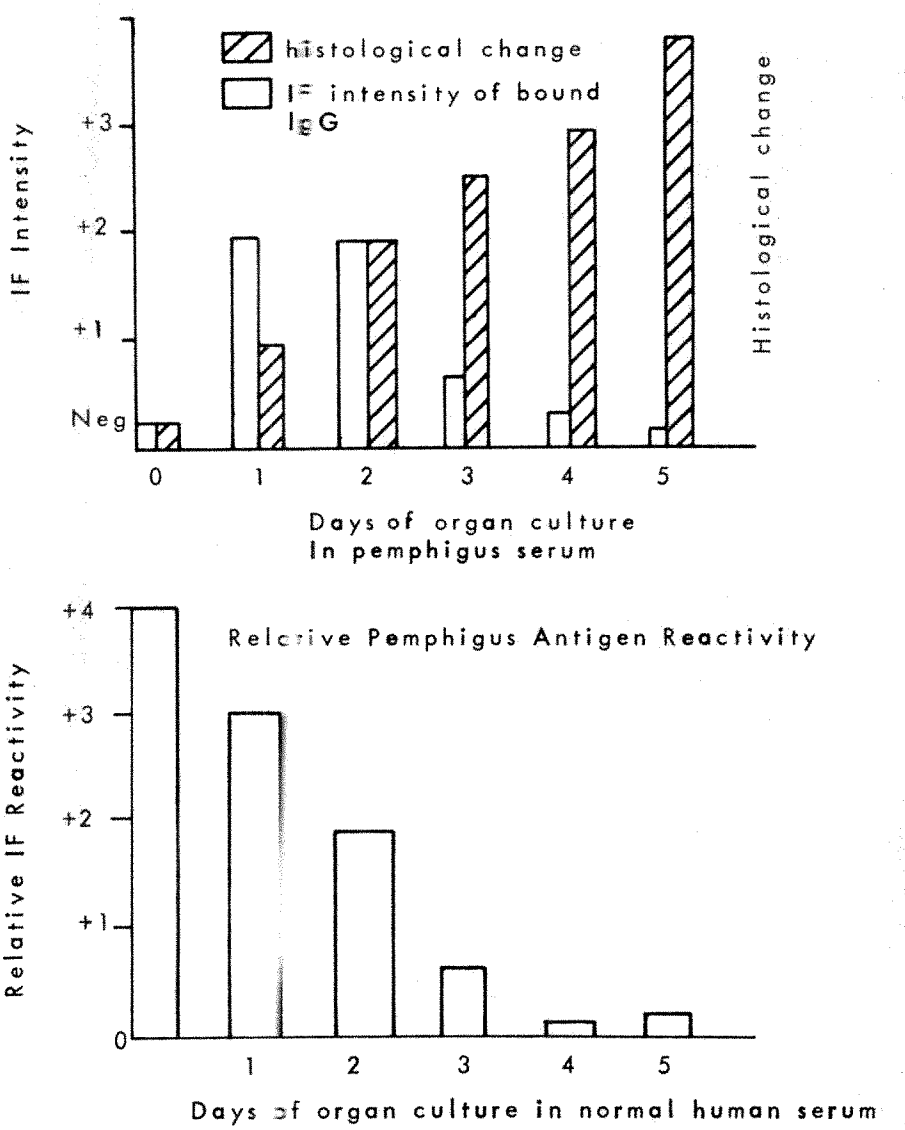
Fig 4.—Direct immunofluorescence staining of monkey skin in pemphigus serum for one day shows staining in intercellular spaces of epidermis. This indicates that pemphigus antibodies have diffused into tissue and reacted with intercellular antigens (×100).

Fig 5.—Interrelationship between histological change, intensity of immunofluorescent-bound (IF) pemphigus antibodies (top), relative pemphigus antigen reactivity (bottom), and time interval of organ culture.



tests, which were performed with a single dilution of a pemphigus serum that gave a 4+ reaction on uncultured skin, showed a progressive decrease in the intensity of indirect immunofluorescence staining from day 0 to day 3. By the fourth and fifth days in organ culture, the reaction was essentially negative, which indicated that the loss in pemphigus antigens occurred in skin explants maintained in culture. The loss in pemphigus antigen concentrations between days 2 and 4 paralleled the loss of organ culture-bound pemphigus antibodies in that time span and gave an explanation for the latter.

To gain a more quantitative measure of the rate of antigen loss in organ culture, separate studies were performed in which full titrations with three pemphigus sera were carried out on skin explants maintained on a normal serum for varying periods of time. Again skin explants cultured on normal serum for one to two days exhibited a progressive decrease in relative titers. After three days in culture, only one of the three sera still gave a measurable immunofluorescence staining titer, and on the fourth day, all three sera gave nega-

tive reactions.

While indirect immunofluorescence on explants grown on normal sera gave a measure of the rate of pemphigus antigen loss and direct immunofluorescence on explants grown on pemphigus sera gave a qualitative measure of the organ culture reactivity of pemphigus antibodies, indirect immunofluorescence on the latter explants was needed to determine the degree of antigen saturation. Since a comparable intensity of staining was obtained in indirect and direct immunofluorescence on days 1 through 4, it appears that the organ culture reactions of pemphigus antibodies with explants saturate the intercellular antigens.

Interestingly, an explant of clinically normal skin from a pemphigus patient with in vivo-bound pemphigus antibodies grown on normal serum developed acantholysis in organ culture; however, the patient from whom the explant was taken developed no lesions in the vicinity of the biopsy site or elsewhere on the skin. It may be that the failure to develop intercellular antigen in culture renders explants more susceptible to the effects of pemphigus antibodies and that the continued synthesis of intercellular antigen in vivo gives some protection against bulla formation.

COMMENT

Explants of monkey skin grown on sera containing pemphigus antibodies developed intraepidermal changes that appeared analogous to those seen in human pemphigus lesions. These findings confirm the report of Michel and Ko[8] on the cytopathic effect of pemphigus antibodies on human skin explants. Our data show the sequence of events, as follows: (1) The pemphigus antibodies saturate the intercellular antigen on the first day in culture. (2) While some early histologic changes appear in an occasional explant grown on pemphigus serum for 24 hours, the characteristic suprabasal acantholytic changes usually do not appear until the second or third day in culture. By that time, a marked decrease in the amount of intercellular antigen is evident in indirect immunofluorescence and the expected decrease in the corresponding fixation of pemphigus antibodies can be shown by direct immunofluorescence staining. (3) On days 4 and 5, the intercellular antigen is completely gone, and the explants grown on pemphigus sera exhibit fully developed lesions.

In principle, this organ culture system provides a remarkably simple experimental model for studies on the immunopathology of the human disease. Although skin explants are subject to various biological changes, including immunologic, biochemical, and histologic modifications,[10,11] that may cause questions in interpretation, the present study and previous reports[8,10,11,13] indicate that these changes are predictable when explants are maintained under appropriate conditions.

Schiltz and Michel[14] have recently shown that the IgG fraction of pooled pemphigus sera induced acantholytic changes in skin explants in the absence of complement, and that pemphigus antibodies effectively blocked the incorporation of RNA and protein by the suprabasal cells but did not affect the basal cells. The latter could explain the failure of explants grown on pemphigus sera to develop the parakeratosis seen in explants grown on normal sera.

While these organ culture studies together with the passive transfer studies[4-6] and the studies on UV induction by Cram[7] and by T.P. Chorzelski, MD (unpublished data, November 1973) point to a pathogenic role of pemphigus antibodies, it should be stressed that a model system based on the production in animals of the entire spectrum of immunologic phenomena seen in human pemphigus is still needed to obtain definite proof of the autoimmune cause of this disease. In effect, organ culture studies such as the ones considered in the present study should eventually be reproduced with sera from animals with pemphigus. Such sera would, naturally, be expected to have pemphigus antibodies that could bind in vivo and in organ culture.[15]

This study was supported by a grant from the Summerhill Foundation and by a postdoctoral fellowship of the China Medical Board of New York, Inc.

Tumor Cell Characterization of Histiocytic Medullary Reticulosis

Bernard N. Robinowitz, MD; Shiro Noguchi, PhD; Wilma F. Bergfeld, MD

• Tumor cells from a 10-year-old boy with suspected histiocytic medullary reticulosis were examined and were found to have receptor sites for complement, the ability to phagocytize latex beads, and the electron microscopical picture of immature histiocytes. These findings strongly support the diagnosis of histiocytic medullary reticulosis. This disorder and the method of examination of the tumor cells are discussed.

(*Arch Dermatol* 113:927-929, 1977)

In 1939, Scott and Robb-Smith[1] described four cases of a rapidly fatal malignancy of histiocytes they called histiocytic medullary reticulosis (HMR). They also included six cases from the literature. Since that time, approximately 84 cases have been reported.[2] The clinical features of the disease include hepatosplenomegaly, lymphadenopathy, anemia, fever, pancytopenia, or leukocytosis; the median survival is less than six months. The histiocytic infiltrate in the liver and lymphoid system is characterized by erythrophagocytic histiocytes with cytologic atypia. Cline and Golde[3] reported that these histiocytes most closely resemble the immature type A macrophage and that HMR is likely to be a variant of well-differentiated reticulum cell sarcoma.

In this communication, we describe the electron microscopy of this tumor as well as the presence of receptor sites for complement on the tumor cell surface, and we report that isolated tumor cells phagocytize latex beads and have no detectable IgG on their cell surface.

PATIENTS AND METHODS

A 10-year-old boy was examined (M.J. Freeman et al, unpublished data), and the diagnosis was established by his clinical course and by examining hematoxylin-eosin-stained sections of material from splenectomy, lymph nodes, liver, and skin biopsy specimens.

A biopsy specimen for electron microscopy and cell function studies was obtained from a skin tumor on the knee. A portion of the biopsy specimen was placed in 5% gluteraldehyde for 24 hours, was postfixed in osmium tetroxide, was dehydrated in ethyl alcohol, and was embedded in epoxy resin. A 1-μ section was cut with a glass knife and was stained with paragon multiple stain. Suitable areas were chosen for electron microscopy, and thin sections were made with a diamond knife. The sections were stained with uranyl acetate followed by lead citrate and were examined by electron microscopy.

The remainder of the biopsy specimen was shredded in Hanks balanced salt solution (HBSS) with a scalpel blade. The cell suspension and tissue debris were separated by gravity (15 minutes), and the cells were washed. From this, 3 million cells were obtained. The percentage of the isolated tumor cells forming erythrocyte

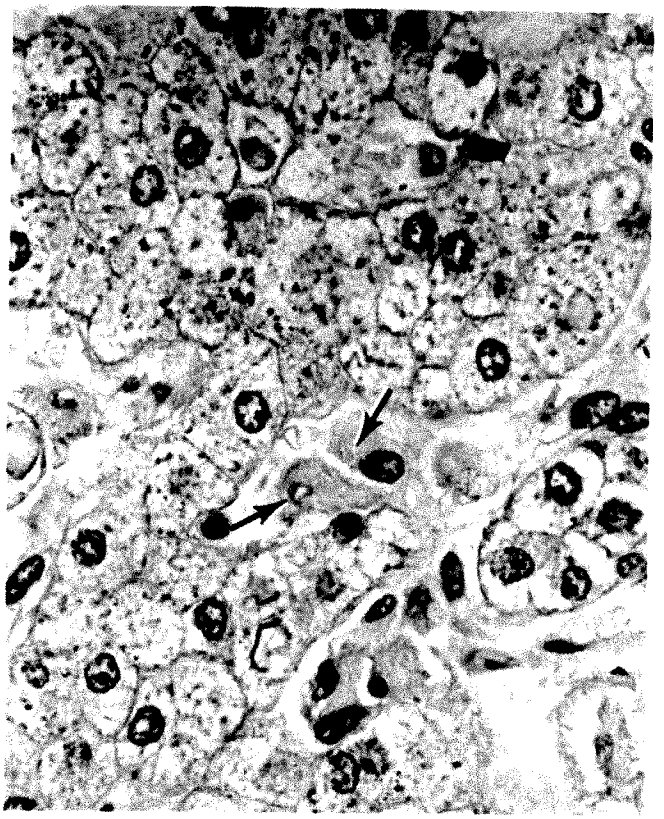

Fig 2.—Histiocytic erythrophagia, skin tumor histiocytic medullary reticulosis (arrows) (hematoxylin-eosin, ×200).

Fig 3.—Tumor cell and tissue (×21,200).

Fig 4.—Tumor cells forming erythrocyte antibody complement rosettes 30 minutes after incubation with latex beads. Note three ingested latex beads (×21,200).

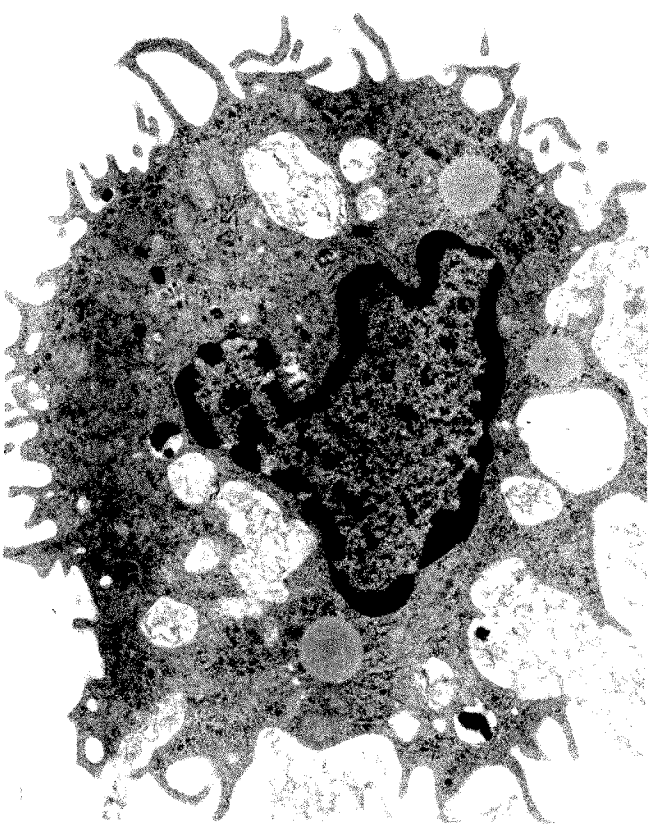

Fig 5.—Tumor cells forming erythrocyte antibody complement rosettes 30 minutes after incubation with latex beads. Note ingestion of tissue debris and latex beads (×14,300).

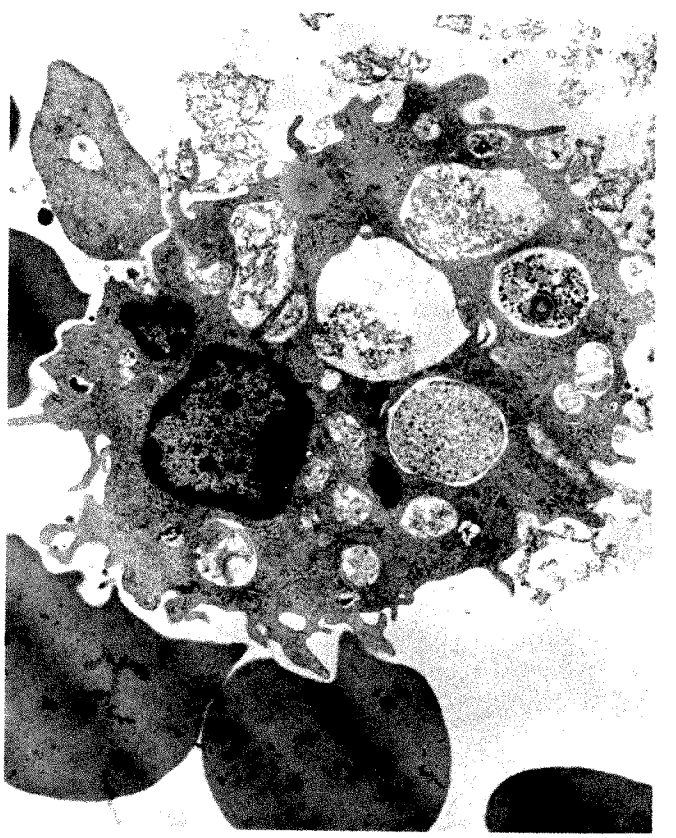

rosettes was determined by the method of Jondal et al,[4] and the percentage of tumor cells forming erythrocyte antibody complement (EAC) rosettes was determined by the method of Pincus et al.[5]

Phagocytosis was studied by adding 0.1 ml of a suspension of latex beads (0.81 μ) in HBSS to 1 ml (1 × 10 B cells per milliliter) tumor cells forming EAC rosettes, and then the mixture was incubated for 30 minutes at 37 C. After 30 minutes, these cells were placed in 5% gluteraldehyde for 24 hours. The cells were spun down to form a pellet and were stained, embedded, and examined as described for the tissue sections.

Tumor cell phagocytosis of latex beads (0.81 μ) was observed by adding a 0.1-ml suspension of the latex beads to 1 ml (1 × 10 B cells per milliliter) of tumor cells in HBSS, and the cells were observed under phase-contrast microscopy. The determination of tumor cells surface immunoglobulin was performed by staining with polyvalent antihuman immunoglobulins labeled with fluorescence.

RESULTS

By light microscopy, we noted that the ulcerated skin tumor (Fig 1) on the left knee was composed of large masses of normal and atypical histiocytes with focal areas of necrosis and acute and chronic inflammation. The atypical histiocytes displayed large pleomorphic vesicular nuclei with abnormal clamping of chromatin material. Within these nuclei were large nucleoli and an occasional mitotic figure. The nucleocytoplasmic ratio was approximately 1:1, and there were numerous large binucleated histiocytes. Serial sections of the tumor mass showed rare histiocytic erythrophagia within the skin tumor (Fig 2). This erythrophagia was also noted on multiple biopsy specimens of the visceral organs (M.T. Freeman et al, unpublished data).

By electron microscopy we noted that the tumor cells (Fig 3) were large histiocytes with a nucleocytoplasmic ratio of 1:1. The cytoplasm was that of an active cell with numerous ribosomes and polyribosomes and a variable amount of rough endoplasmic reticulum. The number of mitochondria within the cells also varied from few in some cells to many in others. The Golgi apparatus was well developed and was most commonly seen near the invaginated portion of the nucleus. Occasional vesicles, lysosomes, and vacuoles were noted in the cell's cytoplasm.

The shape of the nuclei varied from oval to half-moon. They commonly had one infolding and were without nuclear bridges or blebs. All nuclei had a large eccentrically placed nucleolus and a large amount of euchromatin with a rim of heterochromatin just beneath the nuclear membrane. Multiple nuclei were noted within some cells.

Sixty percent of the tumor cells formed spontaneous rosettes with EAC. No erythrocyte rosettes were formed. By electron microscopy, the tumor cells forming EAC rosettes were noted to have ingested latex beads (Fig 4 and 5), and large amounts of tissue debris were present in the tumor cell suspension. The tumor cells were filled with vacuoles, and lysosomes were filled with this tissue debris.

With the phase-contrast microscope, the isolated tumor cells were noted to be actively phagocytizing latex beads after 30 minutes of incubation at 37 C. No surface IgG was detected on the tumor cell surface.

COMMENT

The biopsy sections of the ulcerated skin tumor showed malignant histiocytosis with histiocytic erythrophagia. These findings were diagnostic of HMR. Again, similar findings of histiocytic erythrophagia were seen in the samples of tissue from lymph nodes, spleen, liver, and bone marrow.

On electron microscopy the HMR tumor cells appeared to be immature histiocytes. The nuclei appeared pleomorphic, and they had a large abnormal nucleolus that was suggestive of malignancy. The tumor cells appeared to be metabolically active, with numerous mitochondria, polyribosomes, and rough endoplasmic reticulum. These cells resembled the type 3 reticulum cell sarcoma described by Mori and Lennert,[6] differing only in having more lipid-filled vacuoles than reticulum cell sarcoma cells.

The description of erythrophagocytosis of the cells of HMR and the previous description of starch phagocytosis by giant peripheral blood histiocytes in a case of HMR prompted our study of tumor cell phagocytosis. The isolated tumor cells were noted to phagocytize latex beads actively and were shown to be actively phagocytizing tissue debris. The debris was surrounded by pseudopod projections of the histiocytes, forming a membrane-limited intracytoplasmic vacuole. The phagocytic ability of these tumor cells indicated that functionally HMR belongs to the macrophage line, and in accordance with the hypothesis of Cline and Golde,[3] the HMR appears to be a tumor of well-differentiated, tissue-fixed macrophagia (histiocyte).

Macrophages have a receptor on their surface membranes for complement.[7] We have demonstrated that the HMR cell has retained its complement receptor, thus, strengthening the view that HMR is a histiocytic tumor.

Finally, description of a complement receptor on the HMR cell surface suggests that in HMR, antibody-coated RBCs and complement are involved, possibly in erythrophagocytosis.

Mycophenolic Acid in the Treatment of Psoriasis

Long-Term Administration

Rosalie Marinari, MD; Raul Fleischmajer, MD; Alan H. Schragger, MD; Albert L. Rosenthal, MD

• **Thirty five patients with psoriasis (plaque type 26, guttate 3, pustular 4, and erythrodermic 2) were treated with oral mycophenolic acid for a period ranging from 52 to 104 weeks. The average follow-up was 89 weeks, and the dose schedule ranged from 2,400 to 7,200 mg daily. Excellent response was noted in 20 patients, good in 13 patients, and poor in 2. The most common clinical side effects were in the gastrointestinal tract, namely, diarrhea, nausea, abdominal cramps, and soft stools. A high incidence of herpes simplex, herpes zoster, and a flu-like syndrome was noted. Laboratory abnormalities consisted of mild blood hemoglobin reduction, one case of leukopenia (3,900 WBCs per cubic millimeter), two cases with thrombocytopenia and mild elevation of alkaline phosphatase. Mycophenolic acid appears as a promising drug for the treatment of severe psoriasis.**

(*Arch Dermatol* 113:930-932, 1977)

The use of antimetabolites in the treatment of severe, recalcitrant psoriasis or psoriasis associated with psoriatic arthritis is well documented in the literature. Since Gubner[1] described the use of aminopterin sodium in psoriasis in 1951, several new chemotherapeutic agents have been suggested or tried in the treatment of this disease. Methotrexate[2] gradually replaced aminopterin as the folic acid antagonist used in psoriasis. Azaribine[3] was tried as early as 1964 in psoriasis, but due to serious side effects, it was removed from the market in 1976. Hydroxyurea,[4,5] was introduced around 1970 and Stein et al[6] found it particularly effective for the treatment of pustular psoriasis.

The limiting factor in the use of any of the above drugs in psoriasis is their significant systemic toxicity. This includes adverse reactions on the gastrointestinal, hematologic, and central nervous systems. There have been reports of fatalities. Thus, the search for new antimetabolites where safety parallels efficacy has continued.

The rationale for the use of metabolic inhibitors in the hyperplastic state of psoriasis is well documented.[7] Mycophenolic acid is an antimetabolite that interfers with the synthesis of purine precursors of RNA and DNA. It probably blocks the reaction of inosine-5-monophosphate to xanthosine-5-monophosphate to guanosine-5-monophosphate.[8]

Mycophenolic acid is rapidly glucuronized in the liver after oral administration and is excreted by the kidney within 24 hours.[9] Only those cells that contain the enzyme glucuronidase appear to be susceptible to the inhibitory effects of the drug (Fig 1). Early tissue culture studies have shown that while free mycophenolic acid inhibits mitosis, glucuronized mycophenolic acid does not since it cannot penetrate cell membranes.[8] Thus, tissues such as the epidermis, the epithelial linings of the gastrointestinal and urinary tracts and certain tumors are susceptible to the antiproliferative effect of mycophenolic acid.[10]

Jones et al[11] have recently reported the results of their preliminary 12 week efficacy studies and double blind crossover studies are now in progress. The purpose of our report is to present toxicity and efficacy data on a two-year study with oral mycophenolic acid in the treatment of psoriasis.

SUBJECTS AND METHODS

Thirty-five patients, 13 females and 22 males, with severe psoriasis (Fig 2), resistent to conventional topical modalities were treated with oral mycophenolic acid after giving informed consent. The patients ranged in age from 15 to 75 with a mean age of 44 years. The average duration of their disease was 18½ years, and 21 patients had been treated previously with methotrexate; some for as long as nine years. All therapy given for systemic effect was stopped at least one month prior to treatment with mycophenolic acid. Twenty-six patients had the plaque type of psoriasis, three had guttate psoriasis, four

pustular psoriasis, and two, erythrodermas. Mycophenolic acid was dispensed in 400 mg capsules, and the dosage schedule varied from 2,400 to 7,200 mg daily, divided into equal amounts given every 8 or 12 hours. The dose was adjusted for every patient according to clinical response and toxicity. With high doses, almost all patients experienced adverse reactions, primarily diarrhea, but these side effects could be reversed by either stopping or lowering the dose of the drug. Many patients developed tolerance to the drug and were able to continue treatment at higher dosage schedules. The maintenance dose was about 4,000 mg daily.

The scoring of the severity of involvement was based on the percentage of body involved and on severity scores. Before treatment and at each successive visit, patients received a score on severity of erythema, scaling, and skin induration. Each of these factors were graded from 0 to 6 (0 indicates absent; 1, trace; 2, mild; 3, mild to moderate; 4, moderate; 5, moderate to severe; and 6, severe). The "total" severity score was the sum of the scores of three individual involved areas. Prior to treatment, the mean severity score was 62 (range 33 to 80), and the mean extent of body area involved was 36% (range 4 to 97).

These factors were followed and recorded for each patient at weekly intervals for eight weeks, biweekly for eight weeks, and monthly thereafter. Follow-up time ranged from 52 to 104 weeks, with an average of 89 weeks.

The following laboratory studies were performed on each patient visit: 12-factor automated blood chemical analysis (calcium, inorganic phosphorus, glucose, BUN, uric acid, cholesterol, total protein, albumin, total bilirubin, alkaline phosphatase, lactic dehydrogenase, SGOT), complete blood cell count, platelet count, and urinalysis. A complete eye examination was performed prior to treatment and at 28 and 52 weeks. Male subjects submitted semen analysis periodically during the first 16-week treatment period.

On each visit, patients were questioned about adverse reactions from a checklist, and the severity and duration of these adverse reactions were recorded.

RESULTS

The therapeutic response was as follows: complete clearing, 20; definite improvement except for mild residual erythema and/or small patches of activity, 13; and slight or no improvement, 2 (Fig 3). Symptomatic relief of pruritus was noted in the first two weeks of therapy, however, significant objective improvement of the lesions occurred at six to eight weeks with maximum effect usually by 12 weeks. Table 1 summarizes the data on response to therapy as measured by severity scores and percentage of body involved. The severity at 89 weeks is slightly higher than that at 52 weeks, which reflects some resistance to the drug following its prolonged administration.

The major clinical adverse reactions are listed in Table 2. Soft and frequent bowel movements, diarrhea sometimes associated with cramps, or rectal tenderness were the most common complaints. The frequency and severity of diarrhea was dose dependent and usually occurred in those patients receiving 3,600 to 4,800 mg daily. The onset of the diarrhea took place during the first through third week after initiation of treatment and usually consisted of four to five daily

*Mean of 35 cases.

bowel movements. All patients were advised that if diarrhea occurred and persisted for more than 24 hours, they should discontinue the drug for 48 hours, by which time the diarrhea usually was controlled. Then, they were placed on a lower dose schedule. We had one patient who developed diarrhea at a dosage of 3,600 mg/day. This patient continued mycophenolic acid therapy in spite of her diarrhea for five days at which time the diarrhea became bloody. The mycophenolic acid was discontinued. The patient was hospitalized and treated with fluid replacement, and no transfusions were found necessary. The sigmoidoscopy was interpreted as a "toxic colitis." At present, this patient is on mycophenolic acid therapy and doing well at a dose of 4,800 mg/day. At high dosage levels, some patients complained of a "weak, tired feeling," but as the drug was continued, these symptoms disappeared. Insomnia was not an infrequent complaint especially if a large dose was taken before retiring.

We had two cases with herpes zoster and nine patients with herpes simplex. In each patient, the viral infection ran a normal course, with complete recovery. Seventeen patients complained of a flu-like syndrome (about two episodes per patient) usually associated with a low grade fever, malaise, and myalgias, a nonproductive cough, and sometimes diarrhea that would last seven to ten days. The flu-like syndrome occurred after six months of therapy and only during the winter season. The high incidence of viral infections raises the question about the effect of mycophenolic acid on delayed hypersensitivity and immunity.

Routine laboratory studies performed revealed no significant abnormalities (Table 3). A reduction in hemoglobin of 1 to 2 gm/100 ml was noted in 13 patients, but none became frankly or symptomatically anemic. A mild leukopenia was seen in one patient (WBC, 3,900/cu mm), and two patients developed a thrombocytopenia (110,000 and 120,000 platelets/cu mm). A mild increase in alkaline phosphatase was noted in four patients. Jones et al[11] reported one case of leukopenia (WBC, 1,200/cu mm) and two cases of thrombocytopenia (66,000 and 90,000 platelets per cubic millimeter), in which all values promptly returned to normal when mycophenolic acid was discontinued and we had a similar experience.

COMMENT

Mycophenolic acid appears to be a safe and effective modality for the treatment of severe, recalcitrant psoriasis in its various clinical forms. The treatment regimen is a continuous one since once the drug is stopped, a relapse takes place within one to four weeks. The most common side effect is in the gastrointestinal tract and is dose related. Interestingly, many patients will develop a tolerance to this adverse reaction and then be able to maintain higher doses without problems.

Increased susceptibility to viral infections with mycophenolic acid is of interest since such a side effect was not reported with other antimetabolites used in the treatment of psoriasis. There does not appear to be any significant liver or kidney toxicity. However, studies are in progress where liver biopsies were performed before and during treatment.

This study suggests that because of its safety and efficacy, mycophenolic acid represents an encouraging alternative in the chemotherapy of severe, recalcitrant psoriasis.

Primary Cutaneous Coccidioidomycosis

A Review of the Literature and a Report of a New Case

Gary F. Carroll, MD; Leanor D. Haley, PhD; June M. Brown

• A 31-year-old woman working in the laboratory with the mycelial phase of *Coccidioides immitis* developed a firm, raised, erythematous lesion on the left index finger. A biopsy specimen of the lesion grew a white mold that proved to be *C immitis*.

A sinus tract communicating with the lesion and extending into the proximal phalanx developed. The expressed pus was positive for the tissue form of *C immitis* by potassium hydroxide and periodic acid-Schiff stains and fluorescent-antibody techniques. The sinus tract was irrigated with an aqueous solution of amphotericin B (Fungizone). The tract closed and the lesion decreased in size. Healing was completed in ten weeks.

Primary cutaneous disease must be distinguished from disseminated disease with cutaneous manifestations. In the majority of cases, primary disease heals spontaneously whereas disseminated disease usually requires systemic treatment with amphotericin B.

Before 1937 many authorities held that the majority of cases of systemic coccidioidomycosis resulted from direct inoculation of the skin with *Coccidioides immitis*, which produced localized cutaneous lesions and later spread via blood and lymph system to the viscera. This opinion was accepted because the first clinical lesion was frequently located on the skin, often at a site of recent trauma. In 1937 Dickerson,[1] and in 1938 Dickerson and Gifford,[2] outlined the natural history and pathogenesis of the disease. They demonstrated conclusively that the respiratory tract was the usual port of entry and that cutaneous lesions were, with few exceptions, the result of dissemination from a primary pulmonary focus. These authors also pointed out that most primary cases either escaped clinical recognition or were benign and associated with spontaneous recovery, permanent specific immunity, and lasting skin sensitivity.

Primary cutaneous coccidioidomycosis does occur, but it is rare. To our knowledge, only 17 authentic cases have been reported, all between 1926 and 1965.

Reports of the two earliest cases[3,4] were published before the work of Dickerson and Gifford and were not well documented in terms of present laboratory sophistication; nevertheless, the data seem to warrant the interpretation of the disease as cutaneous in origin.

In 1952 Curtis[5] briefly described a case that was later reported in considerable detail by Harrell and Honeycutt[6] in a review of 12 cases of coccidioidomycosis.

In 1953 Wilson et al[7] reviewed the clinical, pathologic, and serologic characteristics of primary cutaneous coccidioidomycosis and reported a new case of their own. To clearly distinguish primary cutaneous infection from disseminated disease with cutaneous manifestations, they formulated criteria that should be met before determining that the skin was the port of entry in a particular case. The most helpful of these criteria are listed as follows.

1. No history of significant pulmonary disease immediately preceding the appearance of the lesion.
2. History suggestive of inoculation through a break in the skin at the site of the first clinical lesion.
3. Short incubation period between inoculation and lesion—one to three weeks.
4. Lesion should resemble a chancre—a relatively painless, firmly indurated nodule with central ulceration—rather than an abscess.
5. Lymphangitis and lymphadenopathy should develop but only in the region of drainage.
6. Precipitins to coccidioidin should develop; complement-fixing antibodies

should be absent or present only in low titer.

7. Response to intracutaneous coccidioidin should convert from negative to positive and increase in reactivity.

Two cases of primary cutaneous disease in laboratory workers were reported in 1956 and 1959 by Trimble and Douchette[8] and Wright et al,[9] respectively. In 1961 Tiggert[10] described a case of laboratory infection in a previously immune individual, and in 1964 Sorensen and Cheu[11] reported a similar case. In 1964 Overholt and Hornick[12] reported three cases, all in laboratory workers, one of whom possessed previously acquired immunity.

In 1963 Goodman and Shabarum[13] reported a case of primary cutaneous disease in a black farm worker in Maricopa County, Ariz. Levan and Huntington[14] in 1965 described two cases in Filipino agricultural workers in the vineyards of the San Joaquin Valley, Calif. Also in 1965 Winn[15] reported primary cutaneous disease in three children, who were residents of the endemic California area.

Of these 17 cases of primary cutaneous coccidioidomycosis, 15 remained localized and 2 underwent dissemination.[3,15] The first of these dissemi-

nated infections occurred in 1926, long before the development of specific therapy. The second patient, reported in 1965, was treated with systemic amphotericin B. Both patients recovered. A third patient,[11] a Filipino farm worker, received intravenously given amphotericin B in the absence of dissemination because of the greater risk of this type of infection in Filipinos than in the general population.

In this article, we report a new case of primary cutaneous coccidioidomycosis acquired in the laboratory.

REPORT OF A CASE

A 31-year-old white woman, a graduate student, assisted in the inoculation of mice with a mycelial suspension of *C immitis* on Nov 15, 1974. On Nov 22, she performed autopsies on these mice, removing the liver and spleen, and made homogenates of these organs with Ten Broeck homogenizers. She does not recall any overt trauma either immediately preceding or during these procedures, and there was no contamination of the area by spillage.

She vaguely recalls acquiring a small splinter somewhere on her hands on or around Dec 16 while entering a cold room where media were stored. She does not recall the exact location of the splinter; she immediately removed it, and the lesion apparently healed without a trace.

On Dec 23 she first noted a raised lesion on the left index finger. It increased in size over a week's time, and she first sought medical advice on Dec 30.

There was no history of fever, malaise, or recent respiratory symptomatology. Past history was unremarkable. She had not lived or traveled in any of the southwestern states endemic for coccidioidomycosis or in Latin America. The coccidioidin skin test result had been negative in August 1974.

Examination on Dec 30 revealed a firm, raised, erythematous lesion on the lateral aspect of the left index finger overlying the proximal interphalangeal joint. There was mild erythema and edema of the proximal phalanx but no lymphangitis or lymphadenopathy.

On the following day, an excisional biopsy was performed, and tissue was submitted for histopathology and culture. Histopathologic examination demonstrated chronic inflammatory reaction; fungal cells were not noted with special stains. The homogenized specimen grew a pure culture of white mold that did not manifest the typical sporulation of *C immitis*. The tissues of the mice and guinea pigs inoculated with a suspension of this culture contained, at autopsy, spherules characteristic of *C immitis*.

On Jan 6, 1975 the proximal phalanx was noted to have increased in erythema, edema, and tenderness, and therefore, the eschar that had formed over the biopsy site was removed and pus was expressed from a sinus tract that extended into the proximal phalanx. This material was positive for the tissue form of *C immitis* by potassium hydroxide and periodic acid-Schiff stains and fluorescent-antibody techniques (Fig. 1 and 2).

A chest roentgenogram, complete blood count, and erythrocyte sedimentation rate were within normal limits. Roentgenograms of the left hand were unremarkable, except for soft tissue swelling of the index finger. Figure 3 shows the appearance of the lesion immediately after the eschar was removed. Results of skin tests and serologic evaluations throughout the course of illness are shown in Tables 1 and 2.

On Jan 9 the sinus tract was cannulated with a 21-gauge blunt needle through the opening at the proximal interphalangeal joint and irrigated with 10 ml of an aqueous solution of amphotericin B (Fungisone), containing 2 mg/ml.

The finger remained edematous, with minimal tenderness, for the next two to three weeks. At various times during this period, small (2 to 4 mm), erythematous, evanescent nodules of considerable tenderness suddenly appeared around the opening of the sinus tract. They persisted for a day or two, then disappeared as rapidly as they had appeared. At no time did the patient develop lymphangitis or lymphadenopathy, and repeated roentgenograms of the chest and left hand remained unremarkable.

With closure of the sinus tract, erythema and edema gradually subsided throughout the next four to six weeks. The finger appeared as shown in Fig 4 (taken ten weeks after the onset of illness).

COMMENT

In considering cutaneous lesions due to *C immitis*, the best policy is to assume that, unless there is convincing evidence to the contrary, such lesions are associated with disseminated disease. Extrapulmonic lesions are, in almost all cases, the result of dissemination from a primary pulmonary focus. This focus may be so insignificant that it is not detectable on roentgenographic examination, or it may have already healed by the time the disease had disseminated.

The ability to distinguish primary cutaneous disease from cutaneous lesions associated with disseminated disease is essential in management. The great majority of patients with primary disease note healing to be spontaneous without treatment, although local therapy is occasionally applied. However, even these local measurements are usually not necessary. Disseminated disease, on the other hand, usually requires immediate systemic treatment with amphotericin B.

As Wilson et al[7] and other authors[13] emphasized, primary cutaneous disease has similarities with primary pulmonary disease and differs from disease manifested by cutaneous lesions associated with dissemination in two important features: skin sensitivity and serologic response.

In primary disease (pulmonary or cutaneous), skin sensitivity to intracutaneous injection of coccidioidin usually converts from negative to

positive in the first few weeks after infection and should increase in reactivity unless immunity does not develop. On the other hand, disseminated cutaneous lesions are more often associated with decreasing or absent skin reactivity. Thus, a patient with cutaneous lesions due to *C immitis* and persistently negative skin test results is probably suffering from disseminated disease.

In general, serologic studies are most helpful in distinguishing primary disease from disseminated disease. The latex agglutination and precipitin tests[16] are useful in detecting IgM antibodies that appear early in the disease process.[17] Latex agglutination shows positive results one to two weeks after primary infection, persists two to four weeks, and becomes negative. Precipitins appear in the third to sixth week of illness, may remain positive in high titer for 6 to 8 weeks, and are absent by 12 to 16 weeks. On the other hand, complement-fixing antibodies are of the IgG type,[17] appearing in the eighth to tenth week of illness and increasing in titer as disease progresses. In general, the magnitude of the complement-fixation titer is related to the severity of the infection, the amount of tissue involved, and the gravity of the prognosis. With the exception of coccidioidal meningitis, serum complement-fixation titers greater than 1:16 often indicate extensively disseminated disease.

Thus, the serum of a patient in the early stages of primary disease (pulmonary or cutaneous) would be expected to be positive by latex agglutination and precipitin test results. The complement-fixation test usually demonstrates negative findings; occasionally they may be positive, but only in titers less than 1:16. In contrast, the serum of a patient with cutaneous lesions associated with disseminated disease would lack latex-agglutinating and precipitating antibodies but should demonstrate high-titered fixation of complement.

We believe that our patient represents an indisputable case of primary cutaneous coccidioidomycosis. This patient had direct contact with *C immitis*, and although no history of accidental self-inoculation can be obtained, there was ample opportunity, especially during autopsy of the mice, for this to occur. The incubation period is compatible with and the appearance of the lesion is typical of primary cutaneous disease. Results of serologic studies and intracutaneous tests are compatible with primary rather than disseminated disease. Failure to develop constitutional symptomatology and lymphangitis or localized lymphadenopathy, or both, and to demonstrate precipitins and increasing skin sensitivity is perhaps related to the immediate and aggressive surgical and local chemotherapeutic intervention.

Leo Kaufman, PhD, directed the serologic tests performed in this study.

Tropical Rat Mite Dermatitis

Maj Ernest N. Charlesworth, MC, USAF, Capt Robert W. Clegern, BSC, USAF

• We had a patient with dermatitis caused by the bite of *Ornithonyssus bacoti* (Hirst), commonly referred to as the tropical rat mite. The bite of this mite resulted in a severely pruritic papular dermatitis in our patient. Accurate identification of the mite indicated the presence of rat infestation.

(*Arch Dermatol* 113:937-938, 1977)

Dermatologists are keenly aware of problems associated with mites, particularly when the preferred host is man, as is the case with *Sarcoptes scabiei* of the hominis variety. Man is also vulnerable to less frequently recognized forms of dermatitis caused by mites parasitic on various animals. A case report of a patient with an annoying dermatitis caused by the bites of the tropical rat mite, *Ornithonyssus bacoti* (Hirst), is presented.

Accepted for publication April 27, 1976.

REPORT OF A CASE

A 69-year-old woman came to the dermatology clinic complaining of a pruritic dermatitis of four weeks' duration. This pruritic eruption was temporarily associated with her becoming aware of an infestation of small "bugs" throughout her house. She related that they seemed to be more numerous in the vicinity of her bedroom windowsill and in an adjacent bathroom. She first became aware of this infestation when placing bird food on an outer windowsill, sustaining an uncomfortable bite from a small "bug" on several occasions.

On physical examination, the patient showed discrete papules scattered over her breasts, shoulders, and arms (Fig 1 and 2). The primary lesion consisted of a 1- to 2-mm papule with a 2-mm halo of erythema. No central punctum, vesicle, pustule, or an associated urticarial component was noted in any of her lesions. There were neither excoriations nor burrows noted. The papules were more numerous in the area where the brassiere made tightest contact with the skin. The remainder of the physical examination was unremarkable.

Treatment of the patient was directed toward symptomatic relief with the application of 0.5% camphor in a hydrophilic lotion. In addition, she was given 10 mg of hydroxyzine hydrochloride every six hours as needed for pruritus. This treatment gave her good relief of the pruritus but did not prevent the development of new lesions.

Specimens the patient collected from her body two days prior to coming to the clinic were still motile. Preliminary microscopic examination disclosed a mite with morphologic characteristics similar to a bird mite, but similar also to other mites infesting other hosts. The mite was subsequently examined by the Agricultural Research Service, US Department of Agriculture; it was interpreted and identified as *O bacoti* or the tropical rat mite (Fig 3).

The patient was informed of the identification of the mite, and it was recommended that she have the house professionally exterminated for rats. She contracted a professional exterminator who confirmed the presence of rat nests in the attic. Within one month after the house was exterminated, she noted no further problem with either mites or a dermatitis.

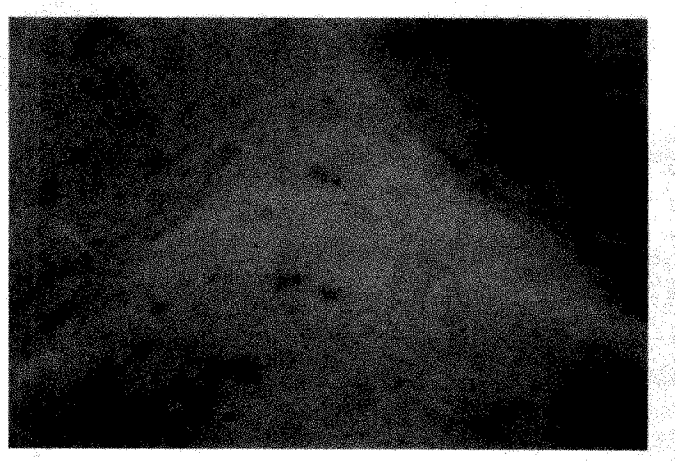
COMMENT

The tropical rat mite, *O bacoti*, has been found as an ectoparasite on many rodents, but the brown Norway (*Rattus norvegicus*) and the black roof rat (*R rattus*) are the primary host species.[1] Although the mite relies on the rat for its blood meal, under certain circumstances, man may become a victim of the mite's bite. The first case report of *O bacoti* as a cause of human dermatitis was in 1913 in Australia.[2] Since recognition of the mite in this country in 1923 as a cause of dermatitis, there have been many reports from various countries.[3-12]

The mites are yellow to dark red,

Fig 1.—Papular eruption over breasts and inframammary region.

Fig 2.—Close-up view of several papules on erythematous base.



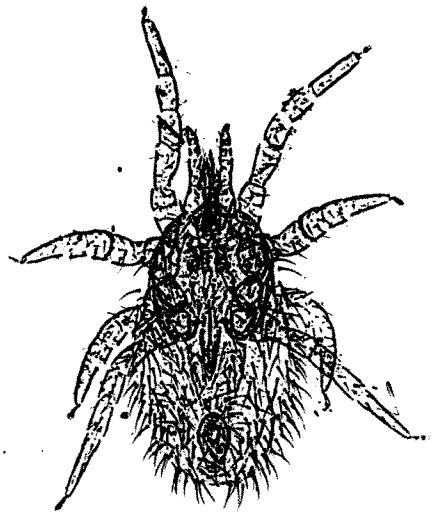


Fig 3.—Characteristic feature of tropical rat mite (×98).

depending on how recently the mite has fed. Both the male and female take their blood meals from the rodent as their preferred host. The female mite varies in size between 0.75 mm to 1.40 mm with the male somewhat smaller, and often they can be seen with the naked eye when crawling. The mite life cycle in the rat population has five stages: egg, larva, protonymph, deutonymph, and adult.[13-15] The larvae have three pairs of legs while the other stages have four pairs. The engorged female lays up to 100 eggs, which hatch into nonfeeding larvae. The larva then transforms into a protonymph, which requires a blood meal. The nonfeeding deutonymph follows, which subsequently develops into the adult form. The entire life cycle can take as little as 11 to 13 days under optimum conditions; however, the protonymph stage alone may survive to 43 days.[16] Engorged adult mites live an average of two weeks after feeding, but a few may survive eight or nine weeks.[17] It would thus appear that several weeks would have to elapse after rat extermination before the mite population would no longer pose a threat to humans.

Humans are usually bitten when the normal rat host is not available to the mite. This frequently occurs following rat extermination or some other cause of rat attrition. When the rat host is not available, *O bacoti* is capable of traveling several hundred feet in search of a blood meal. It is in this setting that man will most likely be bitten by the mite. The bite will induce a nonspecific dermatitis, usually consisting of small papules that tend to be more concentrated in areas covered by tight-fitting garments. The bite is frequently accompanied by mild pain at the site that precedes the pruritic dermatitis. Some patients may demonstrate an urticarial component to the dermatitis.[18] The lesions require no specific treatment and resolve when the rodent source of mites is eliminated. Because the character of the lesions is nonspecific, a differential diagnosis should include scabies, chigger bites, lice, bedbugs, grain, cheese, and fowl mites, dermatitis herpetiformis, and neurotic excoriations.

In addition to the discomfort of skin lesions, there is a possibility that *O bacoti* may be capable of transmitting disease. Although there is no documented report of human disease being contracted from this mite, there are experimental data that suggest it may be a potential disease vector. Murine typhus has been passed in the laboratory from rats to guinea pigs using *O bacoti* as the vector.[4,19] This mite has been shown to transmit rickettsial pox[20] and tularemia[21,22] from mouse to mouse. Plague, Coxsackie virus, and Q fever have also been shown to be transmissible to laboratory animals with *O bacoti* as the vector.[23-25] Despite the laboratory potential for disease transmission, *O bacoti* is currently of doubtful importance as a vector of human disease.

We believe that the proper identification of the mite causing this irritating dermatitis is important. The presence of mites are indicative of a rat-infested environment and proper identification allows the physician to advise the patient in eliminating the cause.

Westwood Pharmaceuticals, Inc, Buffalo, NY, provided assistance in the cost of reproduction of the color photographs used in this study.

Human Essential Fatty Acid Deficiency

Treatment by Topical Application of Linoleic Acid

Phyllis Skolnik, MD; William H. Eaglstein, MD; Vincent A. Ziboh, PhD

• An essential fatty acid (EFA) deficiency developed in a 19-year-old man who was being maintained on a long-term regimen of fat-free, intravenous hyperalimentation fluids. The EFA deficiency was reversed after 21 days by daily, topical application of linoleic acid to the patient's skin. The ratio of eicosatrienoic acid (20:3, n-9) to eicosatetraenoic acid (20:4, n-6) decreased to normal levels in the skin and serum with clinical improvement of the EFA deficiency syndrome. The cutaneous manifestations (scalp dermatitis, alopecia, and depigmentation of hair) were reversed with continued, topical application of safflower oil, which contains 60% to 70% linoleic acid.

(*Arch Dermatol* 113:939-941, 1977)

Essential fatty acid (EFA) deficiency has been described in rats, mice, dogs, swine, and humans.[1-3] The essentiality of a polyenoic acid is that the double bonds must have cis-configuration as in linoleic acid and arachidonic acid. Arachidonic acid is three to five times as effective as linoleic acid in promoting growth. However, linoleic acid is the essential fatty acid that can be most easily obtained from the diet in preventing EFA deficiency.

Rats, dogs, mice, and pigs that were fed EFA-deficient diets developed eczema, dry, scaling skin, tail necrosis, renal edema, and sterility.[1] Infants who were fed low-fat diets developed thrombocytopenia, dry, scaling skin, or dermatitis; they gained weight slowly, and their bodies had a poor ability to heal wounds.[2] In addition to these clinical signs, EFA-deficient animals and humans have an abnormally high serum concentration of the fatty acid eicosatrienoic acid (20:3, n-9) and a low serum concentration of arachidonic acid (eicosatetraenoic acid, 20:4, n-6). The increased 20:3/20:4 ratio is diagnostic of EFA deficiency.[4]

In a well-controlled study, Prottey and co-workers[5] demonstrated in three cases that the cutaneous application of sunflower-seed oil (rich in linoleic acid), but not olive oil, reversed the effects of EFA deficiency caused by chronic malabsorption and it increased the levels of epidermal linoleic acid.

With the increased use of long-term, parenteral nutrition, many patients may develop EFA deficiency. Supplementation of their diets with linoleic acid is, therefore, imperative. Since a previous study from our laboratory showed that topical prostaglandin E_2 (PGE_2) cleared scaly skin lesions of EFA-deficient rats,[6] we investigated the effect of topical applications of linoleic acid, which is an endogenous precursor of arachidonic acid, prostaglandin E_1 (PGE_1), and PGE_2 on the skin of a patient who was being fed fat-free fluids by intravenous hyperalimentation.

METHODS

The patient was a 19-year-old man with severe, inflammatory bowel disease, who had had a colectomy following a sudden perforation of his transverse colon. After receiving fat-free fluids by intravenous hyperalimentation for four months postoperatively, he developed dermatitis of the scalp and eyebrow areas, a diffuse scalp and eyebrow alopecia, and a lightening of his remaining scalp hair (Fig 1). He still required intravenous hyperalimentation because of an abdominal wall defect and bowel-to-skin fistulas.

The intravenous hyperalimentation fluids contained the essential and nonessential amino acids, dextrose, and water, all in varying concentrations. Multivitamins that were added to the intravenous fluids included ascorbic acid, vitamin A, vitamin D (ergocalciferol), thiamine hydrochloride, riboflavin (as 5-phosphate), pyridoxine, niacinamide, dexpanthenol, and vitamin E (dl-alpha tocopherol acetate). The patient had been receiving these substances prior to and after development of the cutaneous manifestations of EFA deficiency.

Five milliliters of venous blood and one 4-mm skin punch biopsy specimen were taken from the left thigh at each of three different times and analyzed for the determination of fatty acids. The blood and skin specimens were obtained before treatment and at seven and 14 days after treatment. The patient was treated topically with 150

mg of linoleic acid, which was carefully rubbed into the skin of his right thigh once a day for 21 days. Topical treatment with safflower oil (containing approximately 60% to 70% linoleic acid) replaced the linoleic acid applications to the right thigh after three weeks.

Analysis of Fatty Acids

The skin biopsy specimens were homogenized rapidly in chloroform:methanol, 2:1 (v/v) and the total lipids were extracted according to the procedure described by Folch et al.[7] The same method was used to extract the lipids from the serum. The total lipids from serum and skin were transesterified by refluxing under nitrogen for two hours with a 5% solution of hydrochloric acid in methanol. The methyl esters of the fatty acids were analyzed by gas-liquid-chromatography with a hydrogen flame ionization detector. The methyl esters were identified by internal standards of reference methyl esters of fatty acids (purity 95% to 99%). Quantification of fatty acid peaks was by triangulation.

Effects of Ultraviolet Light (UV-B) on Skin

The patient's response to ultraviolet light (UVL) irradiation was tested before and after topical linoleic acid therapy. Two sun tubes (major emission 290 to 320 nm; intensity, 2,000 $\mu W/cm^2$ at 10 cm) were used to irradiate 1 × 2-cm rectangular areas of the patient's left, volar forearm for various times at 30-second intervals. The minimal erythema dose (MErD), which is defined as: the minimum dose of UVL necessary to produce erythema 24 hours after irradiation, was determined.

RESULTS

After three weeks of topical therapy with linoleic acid, the scaling dermatitis of the patient's scalp resolved. Regrowth and repigmentation of his scalp and eyebrow hair occurred after three months of topical therapy (Fig 2). The topical safflower oil therapy was continued for the period during which the patient was maintained on intravenous hyperalimentation fluids, because his fistulous bowel disease prevented oral intake of solid foods and fluids.

The ratios of eicosatrienoic acid (20:3, n-9) to eicosatetraenoic acid (20:4, n-6) in the sera and skin specimens are shown in the Table. The ratio of the 20:3/20:4 fatty acids in the serum and the skin on admission into the hospital was increased greatly, demonstrating a clear case of EFA deficiency. After two weeks of topical treatment with linoleic acid, the ratio of these fatty acids was decreased to normal level in the skin. Although the ratio was still high in the serum, a notable drop had occurred from the pretreatment value. The MErD was the same and within normal range both before and after three months of linoleic acid therapy.

Cutaneous Application of Linoleic Acid

	20:3 to 20:4 Fatty Acid Ratio*	
Day	Serum	Skin
0	2.0	1.6
7	1.5	1.0
14	0.8	0.4

*Ratio of 20:3/20:4 > 0.4 denotes essential fatty acid deficiency syndrome.[4]

COMMENT

Our findings showed that a 19-year-old man who had been maintained on a long-term regimen of fat-free, intravenous hyperalimentation fluids developed signs of EFA deficiency. In addition to the cutaneous lesions, we found a marked increase in the ratio of 20:3/20:4 fatty acids in the patient's skin and serum. After three weeks of topical treatment with linoleic acid, the improvement of the dermatitis was parallel with a return to normal level of the 20:3/20:4 fatty acid ratio in the skin. A prominent decrease in this ratio also occurred in the serum (Table). These results indicate that linoleic acid was absorbed percutaneously and metabolized systemically to arachidonic acid (20:4, n-6). Percutaneous absorption of linoleic acid by EFA-deficient patients in whom correction of the cutaneous signs and the serum fatty acid ratio levels has taken place has been reported.[5-8] Correction of the skin 20:3/20:4 fatty acid ratio at sites distant from the linoleic acid applications has not been previously reported. The mechanism of action of

linoleic acid in reversing the skin signs of EFA deficiency is unknown. It is interesting, however, that Ziboh and Hsia[6] reported the clearing of scaly lesions in the skin of EFA-deficient rats with topical PGE_2. Since linoleic acid is an endogenous precursor of PGE_2, the possibility that the prostaglandins or their intermediates are involved in the reversal of the cutaneous signs associated with EFA deficiency is likely and deserves further study.

Of particular interest in this study is the repigmentation and growth of new scalp and eyebrow hair by the patient after several months of daily topical treatment with safflower oil. An analogous "browning" of normally black hair has been reported in EFA-deficient hooded rats.[9] These observations suggest that a relationship might exist between pigmentation, hair growth, linoleic acid, and its metabolites. Prostaglandins have been reported to disperse melanosomes in black goldfish[10] and to darken frog skin.[11] Further studies are necessary to elucidate possible relationships.

Since the E series prostaglandins are reported to be important mediators of UVL-induced redness,[12-15] it is surprising that the patient's MErD was normal before correction of his EFA deficiency. While EFA-deficient, the patient had reduced EFA precursors of PGE and an elevated skin concentration of eicosatrienoic acid (20:3, n-9), which is an inhibitor of prostaglandin synthesis.[16]

Our findings illustrate the need to supply linoleic acid to patients whose sole source of nutrition is fat-free fluids by intravenous hyperalimentation. Linoleic acid supplementation may also be necessary for patients suffering from fat malabsorption. Topical application of safflower oil is an effective and inexpensive method of dietary supplementation.

Pemphigus Vegetans of Hallopeau

Immunofluorescent Studies

Christopher G. Nelson, MD; Prapand Apisarnthanarax, MD; Samuel F. Bean, MD; J. Fred Mullins, MD

• Immunofluorescent techniques were used in the study of tissue from a patient with pemphigus vegetans of Hallopeau. The findings were typical of pemphigus, confirming the propriety of classifying this entity as a benign variant of pemphigus, rather than a disease of purely microbial etiology. The question is raised whether other types of vegetating pyodermas actually are separate diseases or represent a spectrum of pemphigus with the clinical appearance dependent on the patient's immunity to his disease. Immunofluorescent studies are proposed as a basis for classification.

(*Arch Dermatol* 113:942-945, 1977)

In 1889, Henri Hallopeau, MD, described a new skin disease characterized by polycyclic eruptions of pustules that gave way to eruptive firm pink papillomas which in turn progressively flattened and changed to dark brown patches which later faded.[1] His patient had involvement of widespread areas of skin and mucous membrane; the disease ran a benign course without pyrexia or systemic manifestations. He gave it the name "dermatitis pustulous chronic in foyers (centers) with eccentric progression."

Almost since the first report of this disease, its etiology has been subject to controversy. In 1898, Hallopeau[2] reported five more cases and shortened the name to pyodermite vegetante. A few months later, because of the development of bullae and a fatal outcome in one case, he became convinced that his disease was nothing more than a variant of pemphigus vegetans of Neumann.[3] He was followed in this opinion by many others.

Shortly after the turn of the century, Gaucher[4] postulated an infectious etiology for this disorder, and this opinion, too, gained a large following.

Today, much confusion still exists as to proper classification of the Hallopeau disorder—is it a relatively benign type of pemphigus (pemphigus vegetans of Hallopeau) or an idiosyncratic reaction to a cutaneous infection (pyoderma vegetans of Hallopeau) or are there perhaps two (or more) separate diseases?

In the last ten years, immunofluorescent techniques have been used to demonstrate circulating antibodies against epidermal components in pemphigus, and new insight has been gained into the pathophysiology of this group of diseases.

We had the opportunity to use immunofluorescent techniques in the study of a case of the Hallopeau rare disorder.

REPORT OF A CASE

A 70-year-old man was admitted to the University of Texas Medical Branch Dermatology service for evaluation of papillomatous lesions that had been waxing and waning in various flexural areas for the past year. Initially, the lesions involved only the inguinal areas, but later spread to the axillae, umbilicus, and nape of the neck. The primary lesions were reportedly papules and pustules; he denied the presence of bullae at any time. Over the same time period, the patient had developed extensive erosions inside the mouth, with a resultant 18-kg weight loss due to inability to eat because of pain. The patient had been treating his lesions by

Accepted for publication March 26, 1976.

frequent washing with soap and water, followed by dusting with an antibiotic powder. The past medical and family histories were noncontributory, as was the social history and review of systems.

Physical examination revealed a thin, chronically ill-appearing man with pertinent findings confined to the skin and oral mucosa. There were numerous verrucous papules, nodules, and tumors varying in size from a few millimeters to several centimeters in the inguinal folds, perineum, umbilicus, both axillae, and nape of the neck (Fig 1 and 2) There were two similar lesions, 5 mm in diameter, in the right antecubital fossa. The lesions varied in hue from flesh colored to erythematous, and some were crusted and purulent. The oral mucous membranes showed extensive erosions with some white plaque-like areas on the tongue, buccal mucosa, and gingivae.

On admission, CBC was normal except for an eosinophil count of 15%. Serum albumin was at the lower limits of normal, and there was a slight polyclonal increase of gamma globulin. The serologic test for syphilis was nonreactive, and the antinuclear antibody test was negative. Erythrocyte sedimentation rate was 32, and values for serum calcium, phosphorus, cholesterol, glucose, BUN, uric acid, creatinine, bilirubin, alkaline phosphatase, lactic dehydrogenase (LDH), SGPT, chloride, SGOT, carbon dioxide, potassium, and sodium were all normal.

Chest x-ray film, intravenous pyelogram, and upper gastrointestinal series were all normal. Barium enema showed diverticulosis without evidence of diverticulitis. Proctoscopic examination results were normal.

On admission, therapy with systemic and topical antibiotics was initiated. Several days later, when the skin biopsy was found to be typical of pemphigus vegetans, the entire regimen was discontinued, and a regimen of oral prednisone, 40 mg daily, and triamcinolone acetonide spray to the cutaneous lesions was started. His oral lesions were treated symptomatically with viscous lidocaine.

Almost immediately after the institution of this regimen, the vegetating lesions took on a dark violaceous color and began to regress. The oral lesions likewise showed dramatic response, and the eosinophil count returned to normal. The dose of prednisone was gradually tapered as the lesions continued to improve until the dose reached 15 mg/day, when there was a reappearance of the oral erosions. These promptly resolved when the steroid dose was adjusted upwards to 20 mg/day.

The patient was discharged on 20 mg of prednisone daily and thrice-daily application of triamcinolone acetonide spray to the small number of regressing lesions that remained.

In eight months of follow-up care, the vegetating cutaneous lesions have disappeared completely, leaving hyperpigmentation that is fading slowly. The patient is being maintained on prednisone, alternating 5 mg and 10 mg daily. At one point, he discontinued this medication and had a subsequent prompt return of his oral erosions. Reinstitution of the therapy was followed by their regression. Likewise, attempts to further lower his maintenance dose have resulted in reappearance of oral erosions.

MATERIALS AND METHODS

A verrucous nodule was excised for light microscopic examination, fixed in 10% formaldehyde solution (formalin), and stained with hematoxylin and eosin.

A similar verrucous nodule was excised for direct immunofluorescent studies. Biopsies were repeated one month after beginning treatment for both light microscopic and immunofluorescent study.

Tissue for indirect immunofluorescent studies was monkey esophagus.

The tissue obtained was quick frozen in liquid nitrogen and stored at a temperature of −20 C. Sections were cut in a cryostat at 4μ to 6μ and used within one week.

Commercially prepared fluorescein conjugated goat antihuman IgG, IgA, IgM, and BIC-globulin (C3) were used (Hyland Laboratories, Costa Mesa Calif). The molar fluorescein to protein ratio (F/P) and antibody concentration of the conjugates and dilutions used were as follows: IgG, F/P ratio, 3.5, 1.9 mg Ab/ml, diluted to a concentration of 50 μg/ml; IgA, F/P ratio 2.8, 0.8 mg Ab/ml diluted to a concentration of 100 μg/ml; IgM, F/P ratio 2.5, 0.3 mg Ab/ml diluted to a concentration of 100 μg/ml; and BIC globulin, F/P ratio 3.1, 1.2 gm Ab/ml, diluted to 50 μg/ml.

Standard direct and indirect immunofluorescent staining procedures were used as described by Beutner et al.[5] The control sera consisted of pemphigus vulgaris serum, bullous pemphigoid serum, normal human serum, and normal saline.

All studies were repeated one month after beginning treatment with prednisone.

RESULTS

Light Microscopic Studies

Hyperkeratosis, parakeratosis, and keratotic plugging of the hair follicles were present. There were marked acanthosis, papillomatosis, and considerable downward proliferation of the epidermis. Intraepidermal abscesses composed almost entirely of eosinophils were present in the acanthotic epidermis (Fig 3). Numerous acantholytic cells, appearing as single as well as clusters of rounded epidermal cells, were also seen within the abscesses (Fig 4). The dermis revealed a pronounced inflammatory infiltrate composed of an admixture of lymphoid cells, histiocytes, eosinophils, and a few neutrophils. The upper dermis showed moderate edema.

One month after initiation of the steroid regimen, a marked reduction in the amount of hyperkeratosis, acanthosis, and papillomatosis was seen, as well as the disappearance of the intraepidermal abscesses.

Direct Immunofluorescent Studies

Deposits of IgG were demonstrated in the intercellular substance throughout the epidermis. No IgA, IgM, or C3 was demonstrated. In addition, a striking picture was produced by fluorescence of the intraepidermal abscesses, which because of staining of the eosinophils and borders of the acantholytic cells, appeared to "light up" in comparison to the surrounding tissue (Fig 5). This staining was observed with anti IgG, but not with anti IgA, IgM, or C3.

One month after starting systemic steroids, direct immunofluorescence could no longer be demonstrated.

Indirect Immunofluorescent Studies

Using fluorescein conjugated antihuman IgG, intercellular antibodies to a titer of 1:20 were demonstrated on monkey esophagus. One month after initiation of steroids, this titer had dropped to zero.

COMMENT

Almost immediately after its introduction late in the 19th century, controversy began to develop around Hallopeau's new disease entity. Hudelo, Wickham, Brocq and Laredde still considered the disease a simple variant of dermatitis herpetiformis.[3] Kaposi and Herxheimer[3] argued that this was a deviation of pemphigus,

while Neumann, Neisser and Köbner[3] still regarded it as a separate entity because of the proliferative character (often with large vegetations), the localization, the peripheral progression, and the favorable prognosis. After one of his patients developed bullae and died, Hallopeau himself finally admitted in 1898[3] that his dermatosis was nothing more than a pustular variant of pemphigus vegetans that had been reported by Neumann in 1876. Neumann's disease was characterized by the formation of bullae that extended and coalesced, and on the floor of which papillomatous growths appeared. The disease often involved the mouth, and the course was fulminant and fatal.[6]

In a clinical lecture in 1906, Gaucher[4] affirmed a microbial etiology for what he called the "disease of Hallopeau," and the reports of several new cases with characteristic clinical and laboratory findings again gave the disease status as a separate entity. Later, other authorities[7-10] reaffirmed that cutaneous infections could give rise to papillomatous proliferations and the term "pyoderma vegetans" came into common usage.

Many authors,[11-14] including Hallopeau himself, continued to consider Hallopeau's original entity related to pemphigus vegetans of Neumann, or at least hypothesizing it as a type of pemphigus.

Brunsting and Underwood,[15] in 1949, reported five cases of pyoderma vegetans associated with ulcerative colitis and found some correlation between control of the colitis and control of the skin lesions. In addition, each of their patients was noted to have oral or nasal mucous membrane involvement. McCarthy[16] applied the term pyostomatitis vegetans to three cases reported by him which involved primarily the oral cavity. Current authorities[17] state that mucous membrane involvement is common in pyoderma vegetans.

In 1966, Stone and Mullins[18] described two patients with pemphigus vulgaris who developed lesions clinically and histologically typical of pemphigus vegetans at the site of chronic *Candida albicans* infections. They suggested pemphigus vegetans

may be the method by which patients with pemphigus respond to chronic infectious processes.

Our patient presents a clinical picture typical of Hallopeau's original description of his disease—the progressive multiple eruptions of pustules, later giving way to eruptive papillomatous lesions. Oral lesions were likewise present. The benign course of the disease in our patient, as well as his eosinophilia and skin biopsy findings, leave no doubt that this is, indeed, an example of Hallopeau's rare disorder.

Our findings of direct and indirect immunofluorescent studies typical of pemphigus confirm the findings of Ouimet et al[19] in a similar case. We believe our case is only the second to be so studied.

These findings confirm the opinion of those who believe pyoderma vegetans of Hallopeau belongs nosologically with pemphigus. Because the disease has a benign course and fails to produce bullae, we believe that it should be separated from pemphigus vegetans of Neumann and be recognized as a distinct entity—pemphigus vegetans of Hallopeau.

Whether pemphigus vegetans of Hallopeau is also separate and distinct from pyoderma vegetans remains unanswered. Both diseases share similar clinical features, including vegetating cutaneous lesions and mucous membrane involvement. In addition, common histopathologic features include hyperkeratosis, acanthosis with intraepidermal abscess formation, and a chronic dermal inflammatory infiltrate. It has been written[17-20] that the two entities may be separated on the basis that pyoderma vegetans may show fewer eosinophils and acantholytic cells in the intraepidermal abscesses than pemphigus vegetans.

Since eosinophils and acantholytic cells may be seen within the intraepidermal abscesses in both diseases, we propose that any differentiation must be made by immunofluorescent studies. Pemphigus vegetans of Hallopeau will have immunofluorescent findings typical of pemphigus; pyoderma vegetans should not. It is possible that many or all cases reported in the past as pyoderma vegetans actually were pemphigus vegetans, and the clinical appearance and course depended on the patient's immunity to his disease. Thus, a spectrum could exist from frank pemphigus vulgaris through pemphigus vegetans of Neumann, pemphigus vegetans of Hallopeau and on to the benign vegetating pyodermas.

The immunofluorescent techniques needed to properly categorize these diseases are now at hand. Future studies should be done to put this diverse group of disorders in the proper perspective.

Pigmented Basal Cell Cancer Masquerading as Superficial Spreading Malignant Melanoma

Michael J. Fellner, MD, James M. Katz, MD

• A 49-year-old woman of Spanish descent had a pigmented lesion on the thigh present for many years, which enlarged recently. The lesion showed notching and black, brown, and blue colors that led to the initial diagnosis of superficial spreading malignant melanoma. Results of skin biopsy disclosed the lesion was a basal cell epithelioma with large amounts of melanin in the dermis. This report illustrates the importance of considering pigmented basal cell epithelioma in the differential diagnosis of superficial spreading malignant melanoma.

(*Arch Dermatol* 113:946-947, 1977)

The differential diagnosis of deeply pigmented lesions includes malignant melanoma. In addition to the multiplicity of colors, which has been well described,[1] notching has been cited as a feature of both lentigo malignant melanoma and superficial spreading malignant melanoma. Pigmented basal cell cancer is distinguished from melanoma by the presence of a round, raised, pearly border. The following describes a differential diagnosis in which these two entities, which usually are easily differentiated clinically, posed a difficult problem.

REPORT OF A CASE

A 49-year-old Spanish woman who had a long history of a mole on the right medial aspect of the right thigh complained of an enlargement of the lesion during the past six months. The patient's previous medical history was unremarkable and she denied any symptomatology other than enlargement of the lesion.

On physical examination, the lesion (Fig 1) measured 2.5 × 2 cm, and it appeared as an irregularly shaped, hyperpigmented lesion with variation in color, ranging from black to brown to blue, with a serpiginous raised border. Pigment spillage was apparent and the lesion was notched. There was no enlargement of femoral or popliteal lymph nodes. The patient had an olive to tan complexion, dark black hair, and brown eyes.

The clinical impression was superficial spreading melanoma. Basal cell epithe-

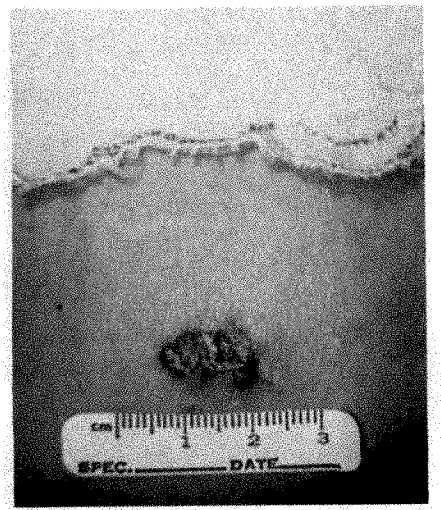

Fig 1.—Lesion showing gray irregular marking, notching, surrounding erythema, pigment spillage, ulcerative crusting, and subtle raised border extending beyond black lesion.

Fig 2.—Massive deposits of pigment within cells in papillary dermis and epidermis.

lioma of the pigmented variety was also considered as part of the differential diagnosis but was considered less likely. An excisional biopsy was done.

Results of the histologic examination showed hyperkeratosis with extension of melanin pigment into the horny layer of the epidermis. The stratum germinativum was heavily pigmented with irregular basalioma cells extending into the dermis. At low-power magnification (Fig 2), large amounts of pigment and basalioma cells showed some resemblance to superficial spreading melanoma. At high-power magnification (Fig 3), basalioma cells were

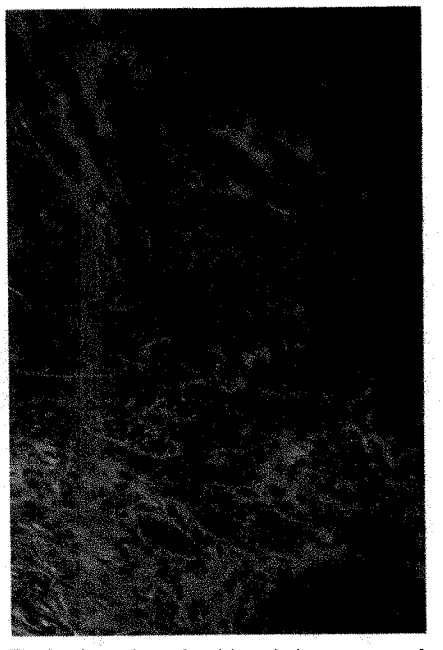

Fig 3.—Invasion of epidermis by masses of amorphous material with dark pigment and basalioma cells in dermis.

Fig 4.—Hyperkeratosis and "church spire" appearance in epidermis with massive deposition of pigment within epidermal cells.

seen clearly, and the diagnosis was pigmented basal cell epithelioma.

COMMENT

In 1975 a total of 5,538 tumor specimens that had been obtained from biopsies were studied histologically and reviewed for diagnostic accuracy in malignant melanoma. In this group three cases of basal cell cancers were found by histologic examination that had been diagnosed clinically as malignant melanoma, an incidence of less than 0.1%, indicating the rarity of this situation. The diagnosis of malignant melanoma in these three patients finally proved to be pigmented basal cell cancer, similar to the findings in our case. The reverse, diagnosing pigmented basal cell cancer and subsequently finding malignant melanoma, occurred in six patients.

An unusual aspect of this lesion was the striking clinical resemblance to superficial spreading melanoma, as described by Mihm et al,[1] with the variation in color, especially the gray intermixed with black and brown, as well as the notching. In addition, this occurred on the thigh of a Spanish woman with relatively dark skin, eyes, and hair, and was on a covered area of the body, the upper thigh. The location favored superficial spreading melanoma rather than basal cell epithelioma. The histology showed similarities to superficial spreading melanoma. The massive amount of pigment deposition were unusual for basal cell cancer.

The clinical diagnosis of basal cell cancer has been reported with an accuracy that ranges to a 25% error in diagnosis.[2,3] Pigmented basal cell cancer should be included in the differential diagnosis of malignant melanoma.

Follicular Atrophoderma and Basal Cell Carcinomas

The Bazex Syndrome

Peter Viksnins, MD, Alan Berlin, DO

• **Seven members of one family had a rare, inherited syndrome of follicular atrophoderma, basal cell carcinomas, and localized anhidrosis. Associated findings in some subjects were generalized hypohidrosis and "eczema" involving the face shortly after birth. This syndrome shows dominant inheritance, possibly x-linked. Follicular atrophoderma is an important skin manifestation, as it has been associated in all reported cases with other systemic or cutaneous abnormalities.**

(*Arch Dermatol* 113:948-951, 1977)

The syndrome we are describing consists of the following four components: (1) follicular atrophoderma; (2) basal cell carcinomas; (3) localized anhidrosis and/or generalized hypohidrosis; and (4) hypotrichosis. This syndrome was initially presented by Bazex et al, in 1964,[1] and subsequently published under the title of "Follicular Atrophoderma, Basal Cell Carcinomas and Hypotrichosis."[2] He and associates described six affected members of one family. All of these patients had hypotrichosis, although this was not seen in any of our patients. Some of these patients also had a generalized hypohidrosis and anhidrosis of the face. To our knowledge, no other reports of patients with this syndrome have appeared in the literature.

Detailed case histories of our two initial cases are presented. The pertinent findings in the additional cases are summarized in tabular form (Table). Their relationships are shown in the pedigree (Fig 1). Information regarding the grandfather (I 1) of the probands was obtained from his three daughters (II 3, 5, and 6) and one of his sons (II 1). The father of the probands was not examined.

Accepted for publication March 2, 1976.

REPORT OF CASES

Case 1 (III 5).—A 22-year-old male college student came to use for treatment of multiple lesions on the face (Fig 2 through 4). He gave a history of having had eight or nine previous facial lesions diagnosed as "skin cancers" after surgical excision. One lesion had been treated with x-irradiation and one more recently with fluorouracil. He found that the fluorouracil caused considerable inflammation but did not result in complete resolution of the lesion. Multiple new lesions had developed on his face during the past year. He was aware of an unusual skin pattern present on the dorsum of the hands and feet as well as the elbows. According to his mother, this type of skin was common in the family and was present at birth. He stated that he sweated normally in all body areas except on the cheeks and chin. He found that even when working out in the gym, he did not develop any drops of sweat on the cheeks or chin. He felt that he burned easily on exposure to sunlight, and for this reason, he frequently had used a sunscreen preparation.

Past Medical History.—The patient's mother stated that immediately after birth, he had developed an erythematous, scaling eruption on the ears and the skin behind the ear. This had been diagnosed as "eczema" and cleared spontaneously in a matter of months. There was no history of any other skin disorder, in particular, no history of pigmentary abnormalities. He had the usual childhood diseases and had not been treated for any significant illness. Three years previously, he had normal lumbosacral x-ray films after an examination for low back pain. History was negative for any musculoskeletal disorders, swelling or cysts along the mandible, soft tissue tumors, seizure disorders, or any psychological problems. Review of systems was entirely negative except for myopia.

Examination.—No abnormalities were noted except for the skin findings. The patient had medium to dark brown hair with a fair complexion and numerous freckles. Atrophic white scars marked the sites of previous basal cell carcinoma surgery. Eight suspicious lesions on the face were noted. These papular lesions ranged in size from 2 to 5 mm. Four were lightly pigmented with fine overlying telangiectasias; two were flesh-colored, and two showed slight erythema and scaling.

The skin on the dorsum of both hands extending to the proximal phalanges showed a "multiple ice-pick mark" pattern. An identical pattern was noted on the dorsum of both feet and both elbows. The skin in the affected areas, when picked up between the fingers, showed a considerable accentuation of the normal skin creases. The individual lesions had the appearance of exaggerated follicular funnels. Only a few terminal hairs were noted in the involved areas but multiple scattered fine vellus hairs were present. Hair growth and distribution appeared normal in all other areas. There were no nail abnormalities, palmo-plantar pits, or keratoderma. Albright sign (dimpling of a knuckle due to a shortened metacarpal bone) was absent.

Laboratory Results.—Roentgenograms of the skull, mandible, and chest showed no abnormalities. Values for the following were within the normal range: CBC, urinalysis, BUN, creatinine, uric acid, phosphorus, calcium, glucose, cholesterol, total protein, total bilirubin, SGOT, lactic dehydrogenase, and alkaline phosphatase. Chromosome studies on leukocytes (25 cells counted) showed no structural or numerical abnormalities.

Treatment.—Eight facial lesions were removed under local anesthesia by parallel excision and curettage. A 4-mm punch biopsy was taken from a follicular lesion on the left elbow.

Case 2. (III 6).—A 24-year-old man (brother of case 1) developed multiple facial lesions at age 19 (Fig 5). Initially, he noted two lesions, one in the right infraorbital area and one on the right side of the nose. The former was surgically excised, and he was told that it was a skin cancer. The latter lesion had been clinically successfully treated with fluorouracil. Four new lesions had developed on his face over the last one to two years. He stated that the skin pattern on his hands, feet, and elbows was identical to that of his brother. According to his mother, the skin pattern was present at birth. He stated that he sweated normally in all areas including the face. He was able to tolerate sunlight well and frequently worked out-of-doors for longer periods.

Past Medical History.—The patient's mother stated that immediately after birth, he developed a severe eczema involv-

Summary of Findings and Past Medical History

Case No.	Age/Sex	Basal Cell Carcinomas of the Face, Approximate Number of Total Lesions	Age at Onset, yr	Follicular Atrophoderma, Location	Hypohidrosis Generalized	Anhidrosis Above Neck	Facial Eczema Soon After Birth	Other Medical Conditions
1 (III5)	22/M	16	15	Dorsum hands, dorsum feet, elbows	—	+ (Face, except forehead	(Mild—ears only)	None
2 (III6)	24/M	5	19	Dorsum hands, dorsum feet, elbows	—	—	Severe	Hay fever
3 (II 3)	57/F	15	16	Dorsum hands, dorsum feet, elbows	—	+	Severe	Scoliosis
4 (II 5)	55/F	8	22 or 23	Dorsum hands, dorsum feet, elbows	—	+	Uncertain	Diabetes mellitus

7 (III8)	21/M	None to date	. . .	Dorsum hands, elbows	+	+	None	Hay fever and acne vulgaris

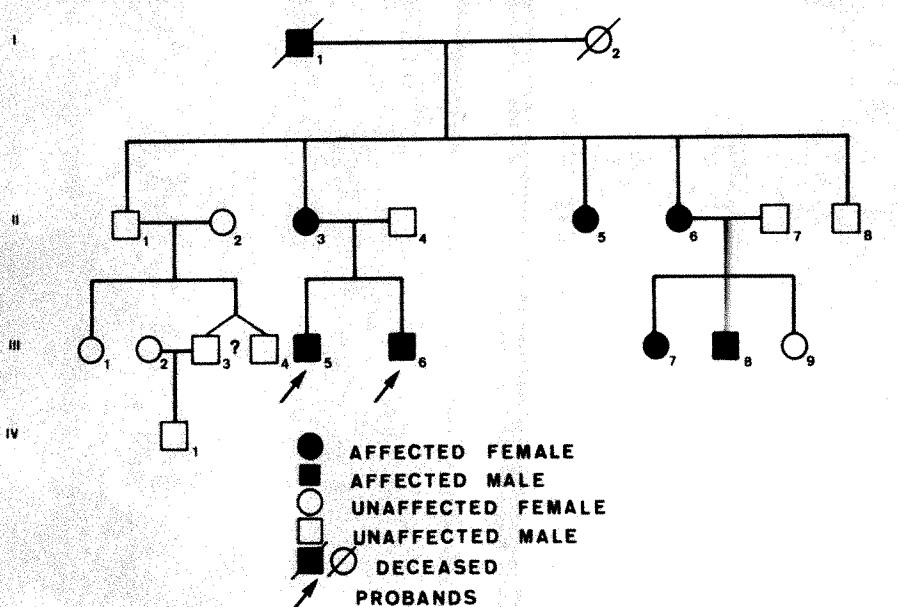

Fig 1.—Pedigree.

ing only the face. This eruption cleared during the first year of life. He had the usual childhood diseases and had not been treated for any significant illnesses. He gave a history of hay fever manifested by seasonal rhinorrhea, conjunctivitis, and sneezing. He also had multiple episodes of poison ivy. There was no history of pigmentary abnormalities, musculoskeletal problems, swelling or cysts along the mandible, soft tissue tumors, seizure disorders, or psychological problems. Review of systems was entirely negative.

Examination.—No abnormalities were noted except for the skin findings. The patient had light-to-medium brown hair, a moderately fair complexion, and multiple freckles. Scattered milia were noted on the face, especially on the right side of the nose in the area of previous fluorouracil therapy. Four lesions in the central facial area warranted surgical removal. These were all 2 to 4 mm, lightly-pigmented papules without telangiectasias. The skin changes on the dorsum of both hands, both feet, and both elbows were identical to those in case 1. Hair growth and distribution were normal in all areas. There were no nail abnormalities, palmar or plantar pits, or keratoderma. Albright sign was absent.

Laboratory Results.—Chromosome studies on leukocytes (25 cells counted) showed no structural or numerical abnormalities.

Treatment.—The four lesions were removed from the face under local anesthesia by parallel excision and curettage. A 4-mm, punch biopsy was taken from a follicular lesion on the dorsum of the left hand.

HISTOPATHOLOGICAL FINDINGS

Case 1.—Seven of the eight lesions removed from the face proved to be basal cell carcinomas. Islands of basaloid cells showing prominent peripheral palisading were seen in the dermis as well as budding from the epidermis. Biopsy of a follicular lesion from the left elbow did not show any abnormalities. The epidermis and dermis were normal. In multiple sections through the block, two small hair-containing follicles of the vellus type were seen. Sebaceous glands were present and normal in structure. Elastic fibers (Verhoeff stain) were normal in structure and quantity on light microscopy.

Case 2.—Three of the four lesions removed from the face proved to be basal cell carcinomas. One of these lesions showed considerable differentiation towards hair follicles and could not be histologically distinguished from a trichoepithelioma. The fourth lesion was an intradermal nevus. The biopsy of a follicular lesion from the dorsum of the left hand showed no abnormalities of the epidermis or dermis. One small, hair-containing follicle of the vellus type was seen. The sebaceous gland associated with this follicle was normal in structure. Elastic fibers (Verhoeff stain) were normal in structure and quantity on light microscopy.

COMMENT

The distinctive clinical picture of

Fig 2.—Hands (case 1). Multiple "ice-pick mark" pattern with exaggerated follicular funnels.

Fig 3.—Elbows (case 1).

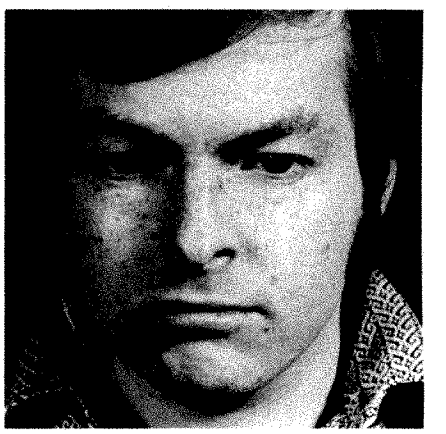

Fig 4.—Face (case 1). Multiple pigmented papules that are histologically basal cell carcinomas.

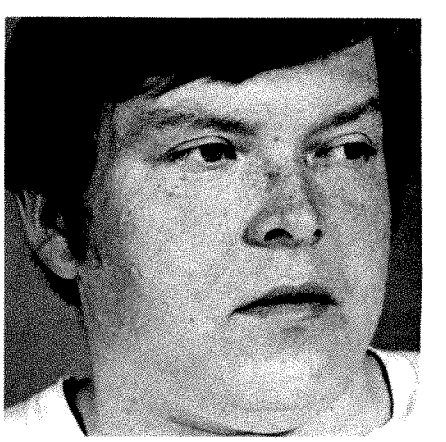

Fig 5.—Face (case 2). Pigmented papules and milia.

follicular atrophoderma should not be confused with any other entity. The skin lesions (Fig 2, 3, and 6) have been variously described as ice-pick marks,[3] dimples, which make the skin look vermiculate,[4] and depressions in the skin in a funnel shape around the pilosebaceous orifices.[2] We suggest the term "multiple ice-pick marks" to describe multiple lesions in one area, and the term "exaggerated follicular funnels" to describe individual lesions. In all seven of our patients, these follicular lesions were confined with remarkable regularity to the dorsum of the hands and the elbows. Bazex et al[2] described lesions not only on the hands, feet, and elbows, but also on the face. In the cases presented by Bazex et al[2] and in our current series, there was no history of preceding inflammatory skin disease involving any of the affected areas. The mother of patients 1 and 2 gave emphatic support to her observation of the skin changes in her newborn sons. Our other five subjects and those of Bazex et al[2] have had the lesions of follicular atrophoderma recognized early in life, but there is no certainty about the congenital nature of these lesions.

Despite the striking clinical appearance of the follicular lesions, no consistent histologic picture of follicular atrophoderma has emerged. Although no definite histologic abnormalities were noted in our biopsies, previous reports have mentioned absence of the hair follicle below the sebaceous gland level,[1] a normal pilosebaceous structure with flattening of the epidermis at the base of the pit,[2] and questionable edema and atrophy of the hair follicle with focal epidermal atrophy.[5]

As noted by Bazex et al,[2] the term "follicular atrophoderma" is not appropriate since there is neither clinical nor histologic evidence of definite atrophy of either the dermis or epidermis. Rather, the follicular ostium seems deeper and more lax than is usually seen; however, this term has become established in the literature. We also did not find any evidence of atrophy of either the epidermis or dermis. We found small superficial vellus type hair follicles that appeared normal in structure on light microscopy. No abnormalities of the elastic fibers were noted.

Basal cell carcinomas developed on the face between the ages of 15 and 26 in five of our seven subjects. The lesions are clinically indistinguishable from nevocellular nevi (Fig 4 and 5). Most common on the central facial area and eyelids, these basal cell carcinomas are morphologically and histologically identical to the lesions seen in the nevoid basal cell carcinoma syndrome (Gorlin syndrome).[3] Cases 6 and 7, ages 20 and 21, have not yet developed any basal cell carcinomas. The number of new lesions seems to decrease after age 30. None of the abnormalities associated with the nevoid basal cell carcinoma were seen in our cases except for scoliosis in case 3 and multiple milia in case 2. Skeletal abnormalities were sought but not

Fig 6.—Hands (case 2).

found. None of our patients had palmar or plantar pits or a positive Albright sign.

Anhidrosis involving the entire face and head was present in five subjects. Even after considerable physical exertion, these patients have not observed sweat formation above the neck. One patient had anhidrosis localized to the face with sparing of the forehead. In only one subject was sweating normal in all areas of the body. Generalized hypohidrosis of moderate degree was reported in three patients. Unfortunately, we did not have the opportunity to verify this finding by objective testing.

The fourth component of this syndrome, hypotrichosis, was not observed in any of our patients. We did find that the areas involved by follicular atrophoderma showed scattered fine vellus hairs and very few terminal hairs. Bazex et al[2] found hypotrichosis in all six of his subjects with varying degrees of alopecia in the scalp and eyebrow areas. The hair shafts were thin, lusterless, and chestnut colored. Body hair was thin and replaced by a down.

The lesions of follicular atrophoderma are of particular significance in that there has been only one case reported in the literature of follicular atrophoderma as an apparently isolated defect.[4] However, this patient also had keratosis pilaris and punctate keratoderma of the palms and soles. Other reported cases excluding those described by Bazex et al and our present series have been associated with the cutaneous and systemic abnormalities of Conradi disease. This rare multisystem syndrome is thought to be inherited as an autosomal recessive. According to Tasker et al,[5] the constant signs of this syndrome are saddle nose deformity, hypertelorism, frontal bossing, high-arched palate, short neck, and short stature with a diagnostic, radiologic hallmark of epiphyseal stippling seen during the first year of life. In fact, the term follicular atrophoderma was coined by Miescher[6] to describe the characteristic skin lesions seen in a 7-year-old girl with Conradi disease. In Conradi disease, the lesions of follicular atrophoderma seem to follow an inflammatory skin eruption present at birth. In the case reported by Bodian,[7] the follicular lesions appeared at about the age of 7 months. It is interesting that in our subjects, a skin eruption diagnosed as eczema was also present at birth or within the first few days of life. Although its exact nature is unclear, this dermatitis was definitely limited to the face and did not involve the areas of follicular atrophoderma. It is also likely that the lesions of follicular atrophoderma were present at birth in our subjects.

Nevoid basal cell carcinoma syndrome, Conradi disease, and the Bazex syndrome are separate entities; however, similarities among these entities exist. It is interesting to note that frontal bossing, hypertelorism, and a broad nasal root are constant signs in Conradi disease.[8] These same abnormalities have also been associated with the nevoid basal cell carcinoma syndrome.[9] Follicular atrophoderma, hypotrichosis, and areas of alopecia are associated with Conradi disease as well as the Bazex syndrome.

Analysis of the pedigree (Fig 1) of the Bazex syndrome clearly shows a pattern of dominant inheritance. Our findings would be compatible with an x-linked dominant pattern in that all daughters of the affected male subject were affected and none of his sons. The fact that no male-to-male transmission was seen in the pedigree published by Bazex et al[2] would also support an x-linked dominant pattern. However, in view of the small number of reported cases, the more common autosomal dominant pattern cannot be excluded. Future follow up of the affected male progeny would help clarify this point.

We have described seven additional cases of a rare, dominantly inherited syndrome consisting of follicular atrophoderma, basal cell carcinomas, localized anhidrosis and/or generalized hypohidrosis, and hypotrichosis. This syndrome may be related to both Conradi disease and the nevoid basal cell carcinoma syndrome.

Pseudomonal Balanitis

John W. Petrozzi, MD, Alexander Erlich, MD

• **Significant ecologic changes in the cutaneous flora during treatment may present a challenge both diagnostically and therapeutically. The development of an erosive balanitis due to *Pseudomonas aeruginosa* presented an example of such a microbiologic shift in the case reported. The eruption developed during treatment with topical antibacterial, antifungal, and corticosteroid agents. The sudden exacerbation of any balanitis while under treatment should alert the physician to the possibility of superinfection.**

(*Arch Dermatol* 113:952-953, 1977)

The following case discloses an infrequently reported cause of balanitis—*Pseudomonas aeruginosa*. The development of this potentially threatening infection during the course of treatment with various topical antibacterial, antifungal, and corticosteroid agents emphasizes the need to keep ecological principles in mind when dealing with cutaneous infections.

REPORT OF A CASE

A sexually active, 29-year-old man reported to the Philadelphia Veterans Administration (VA) Hospital on repeated occasions because of various penile eruptions, initially with scabies. Except for a few persistent nodules on the scrotum, he responded well to gamma benzene hexachloride lotion. Thereafter, several mollusca contagiosa appeared on the penile shaft. These were curetted without difficulty.

While using betamethasone valerate cream to the scabetic nodules he developed a few condylomata acuminata on the penile shaft. These responded to full-strength trichloroacetic acid with complete healing.

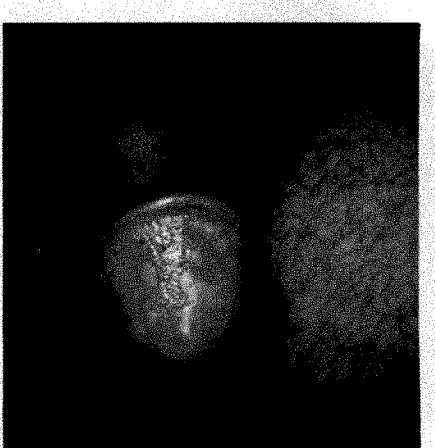
A few weeks later he was seen by his doctor, with pruritic superficial erosions on the glans penis. No preceding vesicles were recounted. A cream containing triamcinolone acetonide, neomycin sulfate, gramicidin, and nystatin (Mycolog) was used over a two-week period without benefit. He was then given amphotericin B lotion, again without response. Finally, idochlorhydroxyquin 3% hydrocortisone 1% cream was administered. However, while using the cream he suddenly developed the explosive onset of a painful, deep erosive balanitis (Figure). He continued to be treated with numerous topical steroid creams, with progression of the balanitis. Finally, cultures were taken at the Philadelphia VA Hospital, which revealed a heavy growth of *P aeruginosa* sensitive to gentamicin. Cool saline compresses and gentamicin sulfate cream afforded 50% improvement within a week. At that time a circumcision was performed at the patient's request, and further healing was completed over the following week. The patient was never febrile and did not manifest any systemic symptoms during the course of his disease.

Laboratory tests showed the following to be normal: complete and differential blood cell counts, urinalysis results, six- and 12-factor automated blood chemistry studies, two-hour postprandial blood glucose levels, chest roentgenogram, and VDRL test results.

COMMENT

This case discloses a diverse group of penile lesions that are frequently encountered in the sexually active male, ie, scabies, mollusca contagiosa, condylomata acuminata, and a balanitis.

The common causes of balanitis are trauma, contact irritant, or allergic dermatitis and infection. Other diseases that must be considered include plasma cell balanitis, Reiter syn-



Erythema, maceration, and erosive changes on glans penis.

drome, Behçet syndrome, erythema multiforme, cicatricial pemphigoid, fixed drug reactions, erythroplasia of Queyrat, and other malignant disorders.

Of the infectious agents, *Candida albicans* and herpes simplex are the most commonly encountered sources. However, syphilis, chancroid, and tuberculosis as well as amebic, trichomonal, staphylococcal, fusospirochetal, streptococcal, and gonococcal organisms can produce a balanitis. Surprisingly, a review of the literature revealed little mention of *Pseudomonas* as a cause of balanitis.

Our patient was under treatment for several weeks, with little improvement in his balanitis. However, the sudden, explosive exacerbation of the balanitis signaled a notable change in the course of his disease. Important was the fact that it occurred while he was being treated with topical steroids, antibacterial agents, and anticandida preparations. This is similar to the experience with several dermatologic entities.

In Gram-negative folliculitis, acne patients undergoing long-term treatment with systemic antibiotics suddenly develop recalcitrant pustules and deep nodules due to resistant *Proteus* and *Aerobacter-Klebsiella* organisms that have replaced the previous bacterial flora.[1] Not infrequently in these cases, there are explosive eruptions when antibiotics are changed or administered.

In the treatment of Hailey-Hailey disease, similar problems develop. Prolonged antibacterial treatment leads to superinfection with *Candida*, and vice versa. Hidradenitis suppurativa and "athlete's foot" yield the same problems.[2]

We think that the use of topical steroid, antibacterial, and anticandida agents in this case led to colonization with *P aeruginosa*, which subsequently became invasive, leading to a severe erosive balanitis. The enhanced colonization of *Pseudomonas* after removal of the Gram-positive flora has been well demonstrated by Taplin et al.[3] Since *Pseudomonas* may be an occupant of the lower bowel in 1% of the nonhospitalized population, fecal contamination is the likely source of infection in this case.

The severity of the balanitis reflects the ability of *Pseudomonas* to produce potent exotoxin as well as proteolytic, elastolytic, lipolytic, and collagenolytic enzymes.[5] The destructive cutaneous effect of chronic *Pseudomonas* infection was evident in the case of severe otitis externa recently described in the dermatology literature by Petrozzi and Warthan.[6] Fortunately, since we were dealing with a healthy patient and the eruption was still of recent onset, a beneficial response could be obtained with topical measures.

The lack of prior communications dealing with pseudomonal balanitis may reflect the rarity of such an occurrence, inadequate diagnosis, or simply a failure of reporting it. We describe our case to increase clinical awareness of this entity, particularly since early diagnosis is essential in light of the potential destructiveness of this organism. In view of the many genital diseases being encountered today by dermatologists and the frequent use of topical steroids, antibiotics, and anticandida agents, any case of severe unresponsive balanitis should receive proper microbiologic study to eliminate *Pseudomonas* as the source of infection.

Congenital Sensory Neuropathy

Report of an Atypical Case

John R. Person, MD; Roy S. Rogers III, MD; K. Hable Rhodes, MD

• **An otherwise normal 11-year-old boy had greatly reduced acral pain and temperature sensation with associated trophic damage. The disorder was present at birth, and there was no family history of similar problems. The patient also exhibited complete anhidrosis. The case may be an "overlap" between what has been termed as hereditary sensory neuropathy (HSN) type 2 and type 4.**

(*Arch Dermatol* 113:954-957, 1977)

The onset of an acquired peripheral neuropathy is usually obvious to the adult patient who can perceive the change and verbalize his problem. The onset of many of the hereditary sensory neuropathies (HSNs), however, is at birth. The patient usually has recurrent acral skin ulcers and a history of repeated injuries that may progress to substantial deformity before the correct diagnosis is made. When the trophic damage is mild and largely cutaneous, it is common for these patients to be examined by a dermatologist.

We report a case of congenital sensory neuropathy, which was encountered recently at the Mayo Clinic. Although typical in presentation, the case differs in some respects from previously reported cases.

REPORT OF A CASE

A healthy-appearing, 11-year-old boy was seen initially in this clinic in August 1975 with a history of hyperkeratotic fingers and toes, and intermittent, nonpainful, and poorly healing ulcers of the same areas. He had been the product of a normal spontaneous vaginal delivery and had seemed to be normal at birth. He had been entirely healthy otherwise, but was described by his mother as unathletic and clumsy. His intelligence and progress in school were normal. Numerous evaluations had centered previously on an infectious or immunologic cause for the recurrent ulcerations, but none had been found. The patient had received various systemic antibiotics and topical preparations for the recurrent, infected ulcers. In summer 1975, a dermatologist in the patient's hometown detected a probable neurologic deficit in pain perception in the acral extremities and suggested that the patient's hands and feet be vigorously protected. Three months later the patient came to this clinic.

Initial examination showed a well-developed and well-nourished boy in no distress. His weight was 39.5 kg, his height was 147 cm, and his blood pressure was 90/50 mm Hg. The fingers and toes were hyperkeratotic and slightly fissured, and a healing 1-cm ulcer was noted on one finger (Fig 1 and 2). Decreased acral pain perception but normal touch perception was found.

The patient was examined in the Department of Dermatology, where the ulcer and hyperkeratosis were thought to be entirely consistent with neurotrophic damage. Results of a potassium hydroxide test of scales were negative for the presence of superficial fungi.

The patient was seen in the Department of Neurology, where examination demonstrated loss of superficial pain and, to a lesser extent, temperature in an acral distribution, including the hands, wrists, feet, and ankles. Pain sensation was minimal in the digits, but gradually increased as testing proceeded proximally, becoming normal at the levels of the midthighs and antecubital fossae. Results of the neurologic examination were otherwise noncontributory.

A detailed family history did not reveal any Jewish ancestry or consanguinity; a dubious revelation indicated that a maternal great-grandfather had been "sickly" and "had to protect his hard hands." The patient had one normal brother.

The following laboratory tests gave results within the normal ranges: ESR (Westergren method), cholesterol, triglycerides, serum protein electrophoresis, complete blood cell count, platelet count, SGOT, total hemolytic complement, serum IgE, and urinalysis. Values for serum alkaline phosphatase and serum phosphate were elevated but were consistent with normal bone growth. A 24-hour specimen of urine tested for amino acids was largely within normal limits. Results of a CSF examination showed normal values for glucose, protein, and cell counts; the VDRL test for syphilis on the CSF was negative.

Fig 1.—The patient's hands.

A roentgenogram of the chest showed a congenital dysplastic first left rib, and a roentgenogram of the cervical portion of the spinal column did not show any evidence of abnormality. Destruction of the left second middle and all distal phalanges, with soft tissue swelling of the right third digit, was evident on roentgenograms of the hands, and those of the feet showed resorption of the distal phalanges of the right foot, with soft tissue swelling of the first three digits.

Electromyography showed normal motor conduction in the right arm and leg, but sensory studies showed small amplitude-evoked responses to orthodromic and antidromic stimulation of the ulnar and median nerves. Response latency and conduction velocity were normal. Sural nerve responses were minute distally. Results of a needle examination of two distal muscles were normal. The interpretation was "consistent with a sensory peripheral neuropathy. The fact that sensory conduction velocity and distal latencies are normal would favor axonal involvement rather than demyelination."

Sweat testing showed complete anhidrosis. Results of audiometric testing were within the normal range. A sural nerve biopsy specimen showed depletion of fibers on which regeneration could not be ruled out, but no obvious qualitative abnormalities were present.

Quantitative sensory testing was performed and showed the affected areas to be borderline-normal in touch discrimination, in the second percentile in temperature discrimination, and below the second percentile in pain discrimination. Pain perception, however, was present in all areas tested. Compound action-potential testing showed a small but well-developed A-alpha and a reduced C-fiber potential; no A-gamma potential was present.

Testing of the patient's brother and parents showed normal pain, temperature, and touch discrimination normal electromyograms; and normal results of sweat tests. The patient's paternal aunt showed mild abnormalities in thermal discrimination, which were thought to be the result of the hurried nature of that particular examination; the other sensory modalities were within the normal ranges.

The patient and his parents were counseled at length in the necessity for scrupulous local care, avoidance of trauma, and aggressive treatment of infections of the hands and feet. The techniques suggested have been recommended by the Public Health Service Hospital in Carville, La, for use in the treatment of lepromatous neuropathy.[1]

Fig 2.—The patient's feet.

COMMENT

The congenital sensory radiculopathies and neuropathies are a diverse and confusing group of disorders (Table). The first cases probably were reported in 1852 by Nélaton,[2] who noted the occurrence of perforating foot ulcers in several members of one family. Many cases have been re-

Congenital and Hereditary Sensory Neuropathies

Type	Hereditary Sensory Radicular Neuropathy[6-13]	Nonprogressive Sensory Radicular Neuropathy[19]	Congenital Sensory Neuropathy[14-18]	Familial Dysautonomia[20]	Congenital Sensory Neuropathy with Anhidrosis[23-26]	Present Case

ported[3-5] since that time, but most have lacked the pathologic and physiologic studies now considered appropriate. Hicks[6] reported one of the most extensive series of cases in 1922. He described ten members in a family of 34 members, spanning four generations, who had shooting pains in the legs, deafness, and perforating ulcers on the feet, which progressed to foot deformity. In affected areas, loss of temperature sensation exceeded loss of pain, and touch was least affected. Involvement of the lower extremities was more extensive than that of the upper extremities. The disorder became evident in the second decade or later and was inherited as an autosomal dominant.

A family with similar disorders was described by Thévenard[7] in 1942, and the disorder has occasionally been referred to as Thévenard syndrome. In 1951, Denny-Brown[8] studied, at autopsy, an affected member of the family reported by Hicks. He found primary degeneration of the dorsal root ganglia with unmyelinated fibers more seriously affected than myelinated fibers. He termed the disorder "hereditary sensory radicular neuropathy."

Although the disorder is a radiculopathy, clinical differentiation of it and of a peripheral neuropathy may be impossible. Motor involvement is variable but usually is mild; the peroneal muscles are affected most commonly. Deafness has not been a feature[7-13] except in the cases reported by Hicks.[6] Ohta and his associates[14] referred to this disorder as HSN type 1 to distinguish it from the recessively inherited sensory neuropathy that they studied in a large Quebec kinship and termed HSN type 2. In the latter cases the onset was a birth, lancinating pains were absent, and sensory loss was generalized but accentuated acrally. Loss of touch was greater than that of pain and temperature, and there was no motor involvement. A peripheral nerve biopsy specimen showed an almost total absence of myelinated fibers in the affected areas. The cases of Winkelmann et al,[15] of Johnson and Spalding,[16] of Heller and Robb,[17] and of Schoene et al[18] probably were of this type.

Other authors have described a recessively inherited sensory loss, present from birth, associated with generalized anhidrosis. Fever may be a prominent symptom. The patients usually are retarded and, at autopsy, have shown an absence of primary sensory nerves in Lissauer's tract and dorsal root ganglia. Pain perception is absent, temperature perception is reduced, and touch is normal. Skin biopsy specimens show normal-appearing sweat glands, and sural nerve biopsy specimens show normal myelination. Ohta et al[14] refer to this disorder as HSN type 4.

Ogden and his colleagues[19] have described a recessive or perhaps nonfamilial radicular neuropathy, which differs from HSN type 1 in its inheritance, its presence at birth, and its lack of progression. It is also the

only one of the hereditary neuropathies to show a normal "flare" response to intradermal histamine administration. Biopsy specimen of an affected nerve shows a loss of myelinated fibers.

Familial dysautonomia, first described by Riley and his associates,[20] is a recessively inherited disorder, which is present at birth, and occurs with increased incidence among Jews. The patients are usually retarded and they exhibit drooling, defective lacrimation, and acrocyanosis. Erythematous mottling usually occurs with heat or emotional stress. A generalized reduction in pain perception is often reported and temperature sensation may be reduced; with time, these sensations may become more normal. Sweating is increased. Fungiform and circumvallate papillae are absent from the tongue. At autopsy, demyelination of the posterior columns and dorsal root fibers is found.[21] Ohta et al[14] refer to dysautonomia as HSN type 3.

These neuropathic disorders are to be distinguished from various other conditions.[8,13,15] In congenital indifference to pain, the patient from birth can perceive painful stimuli but does not interpret them as unpleasurable. Autopsy studies, in such cases, have not shown any obvious anatomic defects.[22] In asymbolia, a lesion of the parietal lobe is responsible for an acquired indifference. Hysteria or psychic states can occur similarly. In syringomyelia, the arms and hands are unresponsive to pain and temperature, but other sensations are intact, muscle atrophy is present, and the lower extremities are spared. The onset is in young adulthood. The disorder is caused by a fluid-filled cavity in the central gray matter of the spinal cord, which interferes with discussating fibers in the cord. The cause of syringomelia is unknown and it is rarely familial. Also to be differentiated are the hereditary chronic interstitial neuritis of Déjérine-Sottas disease, which involves both motor and sensory function and results in palpably enlarged nerves, and the various acquired peripheral neuropathies of toxic, infectious, or metabolic origin.

Our case does not fit readily into any of the described syndromes, but it probably is best classified as an "overlap" between congenital sensory neuropathy (HSN type 2) and congenital sensory neuropathy with anhidrosis (HSN type 4).

Quantitative sensory testing was performed in the laboratory of Dr Peter James Dyck.

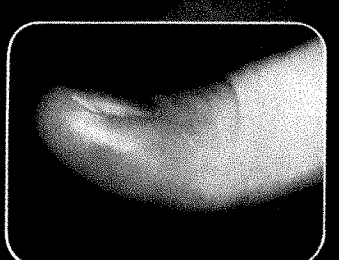
NOCIN Minocycline HCl
al and Intravenous Brief Summary
ntraindications: Hypersensitivity to any tetracycline.
arnings: Intravenous use, particularly in pregnancy, in daily ıses exceeding 2 grams has been associated with deaths rough liver failure. When need for intensive treatment outeighs potential dangers, perform renal and liver function tests ıfore and during therapy; also follow serum concentrations. In nal impairment, usual doses may lead to excessive accumulaon and liver toxicity. Under such conditions, use lower total ıses, and, in prolonged therapy, determine serum levels. This ızard is of particular importance in I.V. use in pregnant or ıstpartum patients with pyelonephritis. In such cases, the blood vel should not exceed 15 mcgm/ml, and liver function tests ıould be made at frequent intervals. Do not prescribe other cyclines during tooth development (last half of pregnancy, infancy and childhood to the age of 8 years) may cause permanent discoloration of the teeth (yellow-gray-brown). This is more common during long-term use but has been observed following repeated short-term courses. Enamel hypoplasia has also been reported. Tetracyclines, therefore, should not be used in this age group unless other drugs are not likely to be effective or are contraindicated. Photosensitivity manifested by an exaggerated sunburn reaction has been observed in some individuals taking tetracyclines. Advise patients apt to be exposed to direct sunlight or ultraviolet light that such reaction can occur, and discontinue treatment at first evidence of skin erythema. Studies to date indicate that photosensitivity is rarely reported with MINOCIN *Minocycline HCl*. In patients with significantly impaired renal function, the antianabolic action of tetracycline may cause an acidosis. CNS side effects (lightheadedness, dizziness, vertigo) have been reported, may disappear during therapy, and always disappear rapidly when drug is discontinued. Caution patients who experience these symptoms about driving vehicles or using hazardous machinery while taking this drug. **Pregnancy:** In animal studies, tetracyclines cross the placenta, are found in fetal tissues, and can have toxic effects on the developing fetus (often related to retardation of skeletal development). Embryotoxicity has been noted in animals treated early in pregnancy. **Newborns, infants and children:** All tetracyclines form a stable calcium complex in any bone-forming tissue. Prematures, given oral doses of 25 mg./kg. every 6 hours, demonstrated a decrease in fibula growth rate, reversible when drug was discontinued. Tetracyclines are present in the milk of lactating women who are taking a drug in this class

Staph infection: Skin deeper

When the patient is penicillin-hypersensitive, when bacteriologic testing shows *Staph. aureus* to be resistant or the infection has proved unresponsive, MINOCIN *Minocycline HCl* may be an effective alternative.* Clinical studies have demonstrated satisfactory response in 156 of 173 simple or mixed skin and soft tissue infections due to staphylococci.



Actual patient photograph after 7 days of MINOCIN.

MINOCIN®
MINOCYCLINE HCl

CAPSULES 50 mg and 100 mg
SYRUP 50 mg/5 cc
INTRAVENOUS 100 mg/vial

100 or 200 mg initially, 50 mg *q.i.d.* or 200 mg initially, 100 mg *b.i.d.*

*Tetracyclines are not the drugs of choice in the treatment of any type of staphylococcal infection. MINOCIN is indicated for treatment of *Staphylococcus aureus* skin and soft tissue infections only when bacteriologic tests indicate appropriate susceptibility to the drug.

MINOCIN Minocycline HCl
Oral and Intravenous Brief Summary (continued)
organisms, including fungi. If superinfection occurs, institute appropriate therapy. In venereal diseases when coexistent syphilis is suspected, darkfield examination should be done before treatment is started and blood serology repeated monthly for at least four months. Patients on anticoagulant therapy may require downward adjustment of such dosage. Test for organ system dysfunction (*e.g.*, renal, hepatic and hemopoietic) in long-term use. Treat all group A beta-hemolytic streptococcal infections for at least 10 days. Avoid giving tetracycline in conjunction with penicillin.
Adverse Reactions: GI: (with both oral and parenteral use) anorexia, nausea, vomiting, diarrhea, glossitis, dysphagia, enterocolitis, inflammatory lesions (with monilial overgrowth) in anogenital dermatitis (uncommon). Photosensitivity is discussed above ("Warnings"). **Renal toxicity:** rise in BUN, dose-related (see "Warnings"). **Hypersensitivity reactions:** urticaria, angioneurotic edema, anaphylaxis, anaphylactoid purpura, pericarditis, exacerbation of systemic lupus erythematosus. In young infants, bulging fontanels have been reported following full therapeutic dosage, disappearing rapidly when drug was discontinued. **Blood:** hemolytic anemia, thrombocytopenia, neutropenia, eosinophilia. **CNS:** (see "Warnings"). When given in high doses, tetracyclines may produce brown-black microscopic discoloration of thyroid glands; no abnormalities of thyroid function studies are known to occur. **NOTE: Concomitant therapy:** Antacids containing aluminum, calcium, or magnesium impair absorption; do not give to patients taking oral minocycline. Studies to date indicate that absorption of MINOCIN *Minocycline HCl* is not notably influenced by

CNS side effects including lightheadedness, dizziness, or vertigo have been reported with MINOCIN. Patients who experience these symptoms should be cautioned about driving vehicles or using hazardous machinery while on minocycline therapy.

Historical Review

Hutchinson's *Archives of Surgery* Revisited

Robert Jackson, MD, FRCP(C)

• **I present a brief review of Hutchinson's *Archives of Surgery*. I have listed most of his well-known and not-so-well-known early clinical descriptions. To this list can be added descriptions of Peutz-Jegher syndrome, lipomelanic reticulosis, telangiectatic lupus erythematosus, temporal arteritis, and recurrent herpes simplex on the thigh and buttocks.**

The characteristics of Hutchinson's writing are the use of catchy, descriptive terms, his use of patients' names for diseases, his belief in the effectiveness of illustrations, superb clinical observation but faulty conclusions, and a lack of humor. Seventy-two years after his death, there is still much that can be learned about clinical disease from Hutchinson.

(*Arch Dermatol* 113:961-964, 1977)

Jonathan Hutchinson
Born at Selby July 23rd 1828
Died at Haslemere June 23rd 1913
A Man of Hope and Forward Looking Mind
Tombstone, Sir Jonathan Hutchinson
St Bartholomew Churchyard
Haslemere, England

One may wonder why another paper is needed on Sir Jonathan Hutchinson (Fig 1). His medical bibliography totals almost 1,200 items, and there have been numerous personal and scientific articles published on his life and scientific reports.[1-3] However, the writings of this most amazing man are a gold mine of clinical information, and, like any mine, have to be continually worked in order that one may extract everything of value from them.

The source for the content of this paper is mainly the 11 volumes of Hutchinson's *Archives of Surgery*, published between 1889 and 1900.[4] I use the possessive Hutchinson's correctly—he wrote every word himself. These volumes form the heart of his medical bibliography.

The purpose of this article is to point out several early descriptions of clinical disease that can be found in these 11 volumes. These early descriptions have not generally been accredited to Hutchinson. Identification of priority in medicine is usually a difficult and not too profitable pursuit. However, Hutchinson's technique of observation and description of these conditions is so neat that it needs to be repeatedly held up as an example in this very complex medical world of what can be learned by simple clinical observation and clear, lucid, short description. In addition to a reproduction of some of his probable "firsts," some general comments are made on his technique of observing and recording, and on his personal life and accomplishments.

DESCRIPTIONS OF CLINICAL CONDITIONS

Many descriptions of clinical conditions have been found in Hutchinson's writings. Some of these are probably firsts, but even if they are not, his excellent writing and drawings and prominence in medical circles of the time have made these descriptions worthy of note.

Well Known

Arsenical keratoses and cancer
Atrophic balanitis (balanitis xerotica obliterans)
Chiropomphylx
Dermatitis gangrenosa infantum (gangrenous varicella or vaccinia)
Hilliard lupus (verrucous lupus erythematosus)
Hutchinson triad of congenital syphilis:
- Screwdriver-shaped notched upper central incisors
- Interstitial keratitis
- Eighth nerve deafness

Hutchinson freckle (lentigo maligna)
Hutchinson recurrent summer eruptions (prurigo aestivalis, hydroa vacciniforme)
Idiopathic calcinosis of the scrotum

Accepted for publication May 21, 1975.

PROBABLE FIRSTS

More recently, keratoacanthoma[7] and toxic epidermal necrolysis[8] have been found in his writings. I wish now to illustrate a few more probable "firsts" of Hutchinson.

In many of these, the "first" clinical description has been assigned to other investigators. References to these publications are included in the subtitles.

Peutz-Jegher Syndrome (1921,[10] 1949[11])

Hutchinson clearly illustrated the pigmentation of and about the lips and on the buccal mucosa in twin 9-year old sisters (Fig 2). McKusick[9] and Ingram[8] report that one of the twins was later proved to have polyposis of the small intestine.

Lipomelanotic Reticulosis (Dermatopathic Lymphadenitis, 1932[12])

Under the title of "Hebra's Bubo: the Bubo of Prurigo," Hutchinson describes "soft, flabby enlargement of the glands in Scarpa's triangle, which is met with in chronic cases of prurigo nous eruptions in the legs"[13] (Fig 3).

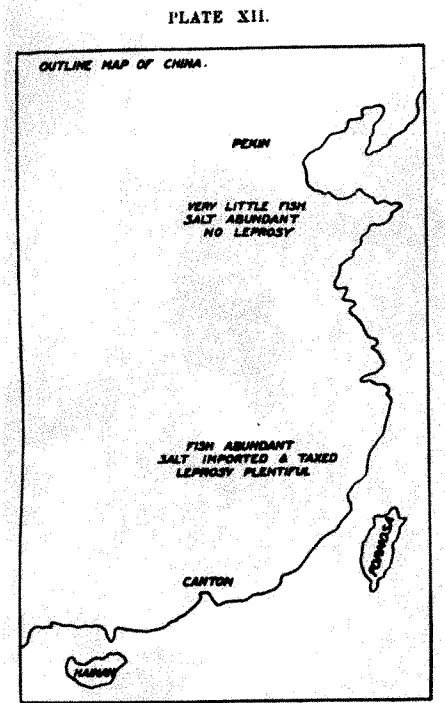

Fig 5.—Outline map of China to show suggested relationship of fish, salt, and taxes. (From *On Leprosy and Fish Eating: A Statement of Facts and Explanations*)

Fig 6.—Physician's dress when visiting plaque patients. "The figure represented is that of a physician equipped for visiting patients ill with the plague. He is enwrapped in a habit which completely protects his body and he wears a mask for his face. The mask has a nose of enormous length destined to contain oderiferous substances supposed to be disinfectant." Hutchinson obtained this from a Venetian physician. It came from a manuscript dating about 1750. (From *Archives of Surgery*, vol X, 380, 1899)

EDUCATIONAL MUSEUM, HASLEMERE,
1947

Fig 7.—Title page of text *A Country Museum*. Museum was founded and built by Hutchinson in 1895.

"As is well known, common eczema but rarely causes gland enlargements. I suspect that the scratching which pruriginous eruptions provoke has much to do in causing lymphatic irritation."

Telangiectatic Lupus Erythematosus (1903[14])

This unusual variety of discoid lupus erythematosus is not adequately described in present-day textbooks. There is no marked change in the epidermis, except for a persistent circumscribed redness, which close inspection shows to be due to telangiectatic blood vessels (Fig 4). The forehead, flush areas of face, upper part of the chest, and upper part of the back are the sites commonly affected. The eruption may remain for years without change. Evidence of systemic disease is lacking. Rarely, a fine epidermal atrophy may be present.

Temporal Arteritis (1934[15])

The subject of this case was an old man named Rumbold, the father is a well-remembered beadle at the London Hospital College thirty years ago. He was a tall, fine-looking man, rather thin, and quite bald. He had been a gentleman's servant, having lived in the family of the Earl of Dundonald, and he had, I believe, suffered from gout. At the time that I saw him he was living with his son near to the London Hospital College. He was upwards of eighty, and almost in his dotage. I was asked to see him because, as I was told, he had had red "streaks on his head" which were painful and prevented his wearing his hat. As I have said, he was bald, and his scalp was thin. The "red streaks" proved on examination to be his temporal arteries, which on both sides were found to be inflamed and swollen. The streaks extended from the temporal region almost to the middle of the scalp, and several branches of each artery could be distinctly traced. The condition was nearly symmetrical. During the first week that he was under my observation pulsation could be feebly detected in the affected vessels, but it finally ceased; the redness then subsided, and the vessels were left impervious cords. At no time was any gangrene of the skin of the scalp threatened. The old gentleman lived, I believe, several years after this without any other manifestation of arterial disease.[16]

Recurrent Herpes on the Thigh and Buttock

Of this patient, Mr. F—, my notes under date March 1880, record: He has had four attacks of herpes on the right buttock. He now shows me his fourth eruption, three long oval groups of abortive vesicles sloping down the buttock. He thinks that he feels rather ill whenever it comes, and the right leg feels weak and there is some tenderness in the inguinal region of right side. He never had herpes on the penis, and he never had ordinary shingles. His first attack of herpes was a year or more ago, and he has had three since last Christmas. He had syphilis two years ago.[17]

Sir Jonathan Hutchinson and His Writings

Hutchinson's writings have several characteristics. First was his ability to pick descriptive terms that were accurate and would be remembered. Examples are the "apple jelly" nodule of lupus vulgaris, the "screwdriver" central incisor peg teeth, and the "ground glass" cornea of congenital syphilis.

Second was his tendency to use the name of a patient for a condition that he did not understand. Examples are Mabey malady (terminal phalanx arthritis [acroarthritis] in association with recurring attacks of iritis), Penmann disease (hydroa aestivale), Mortimer malady (sarcoidosis), and Branford legs (erythema induratum). He believed that by doing so he would not prejudice subsequent thought and investigation of a newly recognized condition.

Third was his belief in the effectiveness of illustrations. All were hand drawn, mostly by Edwin Burgess and Mabel Green. They admirably supplemented his short, lucid clinical descriptions.

Fourth, there is the general summation that his clinical observations were valid but that his conclusions were often faulty. The best example of this is his long-standing and rigid belief that "the cause of the malady known as true leprosy is the eating of fish in a state of commencing decomposition".[17] How this idea got into his head, and why it stayed there, would be a most interesting story.

In his text *On Leprosy and Fish Eating*,[18] he gives the following three reasons as to why he did not look for the Hansen bacillus in the decomposing fish. First, he had the "assured conviction that the general facts were overwhelmingly conclusive and that they needed only to be clearly set forth." Second, he assumed that others would look for the bacillus in fish. "A third and perhaps the most influential reason for my individual neglect of microscopic search in the incriminated fish, has been a deep distrust of the negative conclusion." He even tied in the availability of salt used in curing fish (and hence preventing decomposition) as being related to the incidence of leprosy (Fig 5). He traveled to many parts of the world to get supporting information on fish-eating habits. However, as the contemporary American dermatologist William Pusey said (cited by Ingram[6]), all he ever proved was that rotting fish was eaten all over the world.

Another example of his incorrect conclusions was his belief that alopecia areata was a modified ringworm, or at any rate, a sequela of that disease.[19] He keeps stating and looking for evidence of its parasitic origin, despite the fact that all his microscopic examinations for fungal products were negative.

Finally, it must be said that he was a prim, humorless man. Nowhere in his most extensive writings (including letters and the opinions of those who knew him) was there ever any indication that he had a sense of humor. His lectures and writings were fascinating, dramatic, and informative—but not funny. He had an interest in the odd, unusual, and bizarre (Fig 6).

It is not surprising that with his able inquisitive mind he had many other interests. One of his favorites was the Medical Graduates College and Polyclinic. This was a series of 50 lectures and demonstrations that he gave in the 1890s and early 1900s for an annual fee of one guinea. Any medical man could attend. With the current resurgence of postgraduate or continuing medical education, it is humbling to realize that Hutchinson was doing this three quarters of a century ago. His other interest was the Haslemere Educational Museum, which he built and set up himself (Fig 7). Its purpose was to show general scientific information of all sorts with a special orientation to children. Work with this museum occupied many of his final years.

An excellent blend of clinical efficacy and cosmetic acceptance. Now indicated for seborrheic dermatitis.

Obviously, efficacy is foremost in your mind when you recommend a therapeutic shampoo. And efficacy, coupled with cosmetic acceptability, usually guarantees a successful therapeutic course.

That's why Head & Shoulders is so highly regarded in the treatment of dandruff.

Clinically effective

For years, Head & Shoulders has proved effective in the treatment of dandruff—whether for initial therapy or long-term control. And now, research shows that Head & Shoulders is effective in the treatment of seborrheic dermatitis.*

Cosmetically pleasing

Head & Shoulders lathers well, has a pleasant odor and appearance, and need not be left on the scalp for an extended period of time. Also, it leaves hair clean, manageable, and attractive.

Head & Shoulders®

You'll like it for its therapeutic benefits. Your patients will like it for its cosmetic appeal.

Solar Simulator Tests Demonstrate Superior Substantivity

SUPER SHADE LOTION [5% PABA] for SUN SENSITIVE PATIENTS

Superior in "Wash Off" Resistance and Cosmetic Elegance to The Leading "PABA" Formula

Super Shade Sun Blocking Lotion by COPPERTONE gives maximum sunburn protection for patients who enjoy the sun yet need the maximum filtering of the sun's ultraviolet rays. Super Shade has these advantages:

- WASH OFF RESISTANCE. The superior substantivity of Super Shade enables it to resist removal by perspiration and swimming. Reapplied as directed, it gives all day protection. Super Shade lets your patient stay in the sun 10 times longer without burning than with no protection.
- COSMETIC ELEGANCE: Super Shade is a white, creamy, non-greasy lotion. Unlike clear products, users can see where Super Shade has been applied. It permits an even uniform coverage with no gaps or unprotected areas.
- HELPS PREVENT SUN DAMAGE that may cause premature wrinkling, aging of the skin and skin cancer when used regularly as directed.

Active Ingredient: Para-Aminobenzoic Acid 5%. Alcohol 60%.

Sun Sensitive Patients Will Appreciate Your Recommendation of Super Shade.

Bullous Pemphigoid

Clinical and Serologic Evaluation for Associated Malignant Neoplasms

A. Razzaque Ahmed, MD; T. Ming Chu, PhD; Thomas T. Provost, MD

Bullous pemphigoid (BP) has been reported in association with malignant neoplasms of the urinary tract, lung, genitalia, breast, pancreas, gastrointestinal (GI) tract, skin, and lymphoreticular system.[1] The course of BP usually does not parallel the course of the malignant neoplasm. The malignant neoplasm may be evident at the onset of BP or present as an incidental finding at postmortem examination.[2]

Carcinoembryonic antigen (CEA) levels greater than 2.5 ng/ml have been reported in serum samples from patients with pancreatic, colonic, rectal, gastric, mammary, and cervical malignant neoplasms, and in some leukemias.[3] The presence of CEA correlates with a high incidence of proved malignant neoplasms and is an early indicator of clinically unrecognized recurrence.[4]

The purpose of this study was to determine the incidence of a malignant neoplasm in a large number of patients with BP using clinical as well as serologic evaluation.

Subjects and Methods

Thirty-three patients with BP were studied. All of the patients had the typical clinical disease, subepidermal bullae on routine histopathologic features, and demonstrated the presence of immunoglobulins and/or the third component of complement at the dermal-epidermal junction of peribullous skin. These 33 patients (15 women, 18 men) ranged in age from 45 to 93 years (mean, 72.3 years). These patients have been followed up by routine physical examination every six months for a period ranging from one to five years (mean, 3.2 years). Initial examination included the following laboratory studies; CBC, differential, urinalysis, SMA-12, stool for occult blood, and chest roentgenograms. Carcinoembryonic antigen assay was performed using a radioimmunoassay using a zirconyl phosphate gel.[5] A total of 76 serum samples consisting of the initial as well as the most recent sample, were analyzed.

Results

No gross evidence of malignant neoplasms was observed in these 33 patients. Eleven of these patients have died, and three autopsies have been performed. In one patient, a microscopic adenocarcinoma of the colon was detected. The serum of this patient was negative for CEA. No malignant neoplasm was observed at autopsy in the other two patients.

A level of 2.5 ng/ml or greater is considered a positive CEA determination. One of our patients had a level of 4.4 ng/ml. This patient, however, had a detailed examination in the hospital including upper GI series, barium enema, and repeated stool examination for occult blood. No evidence of malignant neoplasms was detected, and he remained asymptomatic 18 months later. The rest of the 75 serum samples were negative for CEA.

Comment

The incidence of proved malignant neoplasm in our bullous pemphigoid patient population is one of 33 (3.0%). The incidence of malignancy in New York, excluding New York City, for 33 persons with a mean age of 72 years, observed for three years as determined by extrapolating the International Union Against Cancer (UICC) tables[6] is 4.2%. If we assume the elevated CEA represents an unrecognized cancer, this would give two malignant neoplasms in 33 patients. The 95% confidence level for an annual incidence of malignancy is 0% to 5%. The incidence rate in our series is, at most, 2.0% per year. Therefore, we conclude that in our patients with bullous pemphigoid there is no increase in the incidence of malignant neoplasms. Recently, Stone and Schroeter[1] failed to demonstrate that patients with bullous pemphigoid compared with age-matched controls have a substantial increased incidence of malignant disease. The results of our study support their conclusions.

Permanent Anonychia After Stevens-Johnson Syndrome

Birgitte Wanscher, MD, Jens Thormann, MD

Loss of nails with scarring that leads to anonychia may occur on a congenital basis, as in the nail-patella syndrome and the dystrophic epidermolysis bullosa, or on an acquired basis, as seen after severe trauma, as well as in the case of impaired peripheral circulation, in lichen planus, and in bullous drug eruptions.[1] Any drugs that induce bullae can cause nail changes or nail loss due to destruction of the nail matrix.[1]

To our knowledge, hitherto nothing has been written about the nail changes in Stevens-Johnson syndrome. Therefore, we will present such a case report of a patient with permanent nail loss.

Report of a Case

A 29-year-old man was admitted to the dermatology department April through July 1971 with a fulminant attack of Stevens-Johnson syndrome.

Physical examination results showed suppurative conjunctivitis on both eyes and edema and redness of the eyelids. On the lips and around the nostrils, severe crusting and oozing was found. In the mouth, denuded, edematous, and red areas were seen. All over the body and the extremities, erythema multiforme lesions appeared, some of them with bullae. The skin of the hands showed confluent bullae and small bullae immediately proximal to the nails of some of the fingers and on the fingertips. The patient was treated systemically with betamethasone (Celestone) for 2½ months, cyproheptadine hydrochloride (Periactin), tetracycline hydrochloride, erythromycin stearate (Abboticine), and various topical preparations. The cause of the disease was considered to be tablets that contained 0.1 mg of belladonna alkaloid malates, 0.3 mg of ergotamine tartrate, and 20 mg of phenobarbital (Bellergal) which, for two months, had been the treatment of hyperhidrosis.

In November 1975, the patient was readmitted to the hospital to clarify the cause of his Stevens-Johnson syndrome. On this admission, the patient reported that, after discharge, all the nails of his fingers and toes were shed, and that no regrowth had occurred. The absence of nails had caused little trouble.

Results of physical examination of the nails showed cicatricial anonychia and pterygium. On the proximal halves of some of the nail beds, slightly keratinized epithelium was found. Only the fifth left toenail showed an almost normal nail plate. The peripheral circulation was unimpaired. No treatment was given, because the nails remained unchanged for four years. No biopsy specimen was taken.

Comment

The nail anomaly found in our case has been reported as a consequence of lichen planus of the nails.[1-4] Lichen planus may even be confined only to the nails without involvement of skin and mucous membranes, but it rarely involves all the nails.[3,4] The immediate course in the present case with shedding of all nails indicates that the patient's cicatricial anonychia was due to the Stevens-Johnson syndrome.

Zaias and Alvarez[5] have shown that the nail plate is solely produced by the nail matrix and receives no contribution from the proximal nail fold and the nail bed. The scarring is, therefore, caused by destruction of the matrix. In our patient, we found pterygium formation, which is also due to destruction of the nail matrix and fusion of the epithelium of the dorsal nail fold with the nail bed.[5]

Several recent reports concerning the treatment of nail dystrophy with intralesional administration of triamcinolone acetonide using a needleless injector (Port-O-Jet or Dermojet) have appeared,[6] and promising results have been obtained in the treatment of lichen planus.[6] However, when the nail changes, especially the pterygium formation, have lasted for more than a year or when the nails show severe destructive dystrophy, no response has been found. Apart from the systemic corticosteroid treatment that this patient received in the immediate phase, no treatment of the nails was attempted because the condition had been present for four years. However, perhaps injections of a corticosteroid suspension through the posterior nail fold to the matrix ought to be tried early to prevent the permanent anonychia.

IN SKIN INFECTIONS, WHERE CLEANLINESS REQUIRES MORE THAN SOAP

BETADINE® Skin Cleanser

Degerms as it cleanses

ıtients can use BETADINE Skin Cleanser to degerm and cleanse face, hands and body, gently and thoroughly—ırticularly when it is essential to prevent autoinoculation of new sites, as may be the case in infected acne pimples.

BETADINE Skin Cleanser, with its rich, golden lather, provides these advantages:

- Prompt, broad-spectrum microbicidal action—kills both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts.
- Maintains microbicidal activity in the presence of blood, pus and serum.
- Virtually nonirritating to skin and mucosa.*
- Nonstaining to skin and natural fabrics.

Supplied: 4 fl. oz. plastic bottles.

*In the rare instance of local irritation or sensitivity, discontinue use by the individual.

Clear choice

When dermatoses become infected with bacteria or fungi, plain topical steroids are generally not the recommended therapeutic choice.

A clear choice, however, is Vioform®-Hydrocortisone. With its unique four-way action, it supplies the kind of comprehensive treatment many common dermatoses* require.

*This drug has been evaluated as possibly effective for these indications. See brief prescribing information.

Vioform®-Hydrocortisone
(iodochlorhydroxyquin and hydrocortisone)

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: Contact or atopic dermatitis; impetiginized eczema; nummular eczema; infantile eczema; endogenous chronic infectious dermatitis; stasis dermatitis; pyoderma; nuchal eczema and chronic eczematoid otitis externa; acne urticata; localized or disseminated neurodermatitis; lichen simplex chronicus; anogenital pruritus (vulvae, scroti, ani); folliculitis; bacterial dermatoses; mycotic dermatoses such as tinea (capitis, cruris, corporis, pedis); moniliasis; intertrigo. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Hypersensitivity to Vioform-Hydrocortisone, or any of its ingredients or related compounds; lesions of the eye; tuberculosis of the skin; most viral skin lesions (including herpes simplex, vaccinia, and varicella).

WARNINGS
This product is not for ophthalmic use.
In the presence of systemic infections, appropriate systemic antibiotics should be used.

Usage in Pregnancy
Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been established. Therefore, they should not be used extensively on pregnant patients in large amounts or for prolonged periods of time.

PRECAUTIONS
May prove irritating to sensitized skin in rare cases. If this occurs, discontinue therapy. May stain.
If used under occlusive dressings or for a prolonged period, watch for signs of pituitary-adrenal axis suppression.
May interfere with thyroid function tests. Wait at least one month after discontinuance of therapy before performing these tests. The ferric chloride test for phenylketonuria (PKU) can yield a false-positive result if Vioform is present in the diaper or urine.
Prolonged use may result in overgrowth of nonsusceptible organisms requiring appropriate therapy.

ADVERSE REACTIONS
Few reports include: Hypersensitivity, local burning, irritation, pruritus. Discontinue if untoward reaction occurs. Rarely, topical corticosteroids may cause striae at site of application when used for long periods in intertriginous areas.

DOSAGE
Apply a thin layer to affected areas 3 or 4 times daily.

HOW SUPPLIED
Cream, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of 5 and 20 Gm. *Ointment*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a petrolatum base; tubes of 20 Gm. *Lotion*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearic acid, cetyl alcohol, lanolin, propylene glycol, sorbitan trioleate, polysorbate 60, triethanolamine, methylparaben, propylparaben, and perfume Flora in water; plastic squeeze bottles of 15 ml. *Mild Cream*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of ½ and 1 ounce. *Mild Ointment*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a petrolatum base; tubes of 1 ounce.

½
Therapeutic effectiveness with half the dose

Schering

Once-a-day dosage

NEW Fulvicin® P/G*

brand of griseofulvin [ultramicrosize], USP

(specially processed) **125 mg. tablets**

*"P/G" means a new polyethylene glycol system for enhanced absorption –

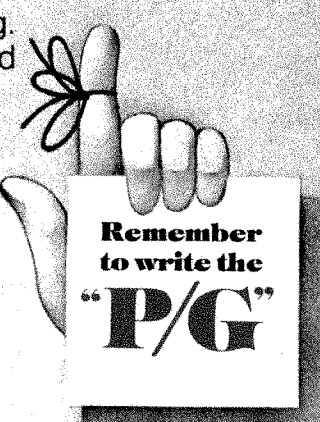
A 250 mg. daily dose (two 125 mg. tablets) of new FULVICIN P/G can replace 500 mg. of griseofulvin (microsize), USP. This is made possible by a special process in which the ultramicrosize griseofulvin crystals are partly dissolved in polyethylene glycol and dispersed through the tablet matrix for enhanced absorption.

Patient convenience –

FULVICIN P/G can be prescribed as two 125 mg. tablets once a day. Compliance is further assured by the easy-to-swallow size of the tablets.

Patient savings –

FULVICIN P/G is up to 35 per cent less expensive per dose than all microsize griseofulvin formulations.**



**Based on list-price comparison.

See Clinical Considerations section on following page...

Schering

NEW P/G
Fulvicin®
griseofulvin [ultramicrosize], USP
(specially processed) 125 mg. tablets

Clinical Considerations: INDICATIONS FULVICIN P/G Tablets are indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: tinea corporis, tinea pedis, tinea cruris, tinea barbae, tinea capitis, tinea unguium (onychomycosis); when caused by one or more of the following genera of fungi: *Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes, Trichophyton interdigitalis, Trichophyton verrucosum, Trichophyton megnini, Trichophyton gallinae, Trichophyton crateriform, Trichophyton sulphureum, Trichophyton schoenleini, Microsporum audouini, Microsporum canis, Microsporum gypseum,* and *Epidermophyton floccosum*. Note: Prior to therapy, the type of fungi responsible for the infection should be identified. The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone. Griseofulvin is not effective in the following: Bacterial infections, Candidiasis (Moniliasis), Histoplasmosis, Actinomycosis, Sporotrichosis, Chromoblastomycosis, Coccidioidomycosis, North American Blastomycosis, Cryptococcosis (Torulosis), Tinea versicolor, and Nocardiosis. **CONTRAINDICATIONS** This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of hypersensitivity to griseofulvin. **WARNINGS** *Prophylactic Usage*: Safety and efficacy of griseofulvin for prophylaxis of fungal infections have not been established. *Animal Toxicology*: Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin once a week during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorogenicity, these studies were not of adequate design to form a basis for conclusions in this regard. In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals. *Usage in Pregnancy*: The safety of this drug during pregnancy has not been established. *Animal Reproduction Studies*: It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress. Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this. **PRECAUTIONS** Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic, and hematopoietic, should be done. Since griseofulvin is derived from species of penicillin, the possibility of cross-sensitivity with penicillin exists, however, known penicillin-sensitive patients have been treated without difficulty. Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated. Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy. Barbiturates usually depress griseofulvin activity, and concomitant administration may require a dosage adjustment of the antifungal agent. **ADVERSE REACTIONS** When adverse reactions occur, they are most commonly of the hypersensitivity type, such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities. Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs. When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

Wilson's Disease and Penicillamine-Induced Anetoderma. Presented by Lt Comdr WILLIAM DAVIS, MC, USN.

A 15-year-old boy and his 13-year-old brother are presented. The 15-year-old patient had a diagnosis of Wilson's disease established after an episode of hepatitis in the spring of 1970. Laboratory screening of the family revealed the brother to have decreased ceruloplasm and increased copper levels. Both patients have been treated with penicillamine, 1.0 to 1.5 gm daily, since the summer of 1970. Both patients for the past two years have shown circumscribed plaques of hemorrhagic milia and scarring of the skin of the elbows and knees. The younger patient has had atrophic lesions of the axillae and neck for about one year. Both patients appear somewhat pale but do not show organomegaly or Kaiser-Fleischer rings. Both have scarred, hemorrhagic areas with numerous 1- to 5-mm milia located over the elbows and knees. The younger patient has central confluent and peripherally sharply demarcated 5- to 15-mm light blue, atrophic macules involving the axillae and sides of the neck. A liver biopsy specimen from the younger patient showed copper 157 μg/gm, and that from the older patient showed 210 μg/gm (normal range, <100 μg/gm). A 24-hour urine specimen on the older patient showed copper, 1,123 μg/liter (normal value, 20 to 50 μg/liter). A skin biopsy specimen from the knee of the younger boy showed milia and scarring. A biopsy specimen from his right axilla revealed an absence of elastic tissue by special staining with the Hart's elastic tissue stain; a biopsy specimen from the axilla of the 15-year-old showed normal skin.

Discussion

COMDR C ROBERT CHARLES, MC USN: The effects of penicillamine therapy are varied; those described in the literature include allergic eruptions, desquamation, hemorrhagic or pemphigus-like bullae, friability, discoloration, epidermal inclusion cysts, cutis hyperelastica, cheilosis, glossitis, stomatitis, vulvar ulcerations, and elastosis perforans serpiginosa. The younger of the two siblings presented today has yet another complication of penicillamine therapy, that of anetoderma. To our knowledge, this complication has yet to have been described in the literature although it is my understanding that Dr Margaret Wood of the University of Pennsylvania saw an almost identical case of penicillamine-induced anetoderma at the Cleveland Clinic several years ago.

The pathogenesis of the anetoderma in this case could be related to copper deficiency resulting from penicillamine chelation or to direct penicillamine effects on elastin. Copper is required for the formation of stable cross-links between lysine residues, and severe copper deficiency may be associated with structural abnormalities of elastic tissue. In Wilson's disease, which is characterized by chronic toxic reaction to copper, however, a direct effect of penicillamine on elastic tissue seems more likely. Elastic tissue, like collagen, involves the participation of aldehydes to form stable cross-links. Penicillamine can react nonenzymatically with aldehydes to form thiazolidine compounds, thus impairing the formation of such stable cross-links. In a similar fashion, penicillamine also has profound effects on collagen, producing an accumulation of soluble collagen via a block in the formation of insoluble collagen and an accelerated turnover of preformed insoluble collagen. These changes in collagen are no doubt responsible for many of the other cutaneous effects of penicillamine therapy, including inclusion cyst, friability and delay in wound healing.

Nonproprietary Name and Trade Name of Drug

Penicillamine—*Cuprimine.*

Parapsoriasis en Plaques. Presented by MATTHEW OLIVO, MD, LT STEPHEN DAMM, MC, USN.

A 53-year-old man was initially seen in 1968 with a one-year history of an asymptomatic eruption about the waist and on the buttocks. Physical examination at this time revealed scaling erythematous patches, with areas of telangiectasia involving the hips, lower abdomen, and back. He was treated with fluocinolone acetonide cream 0.1% with some improvement.

Discussion

DONALD BAXTER, MD: I think the patient now has mycosis fungoides. Patients of this type initially have scaly, yellowish to red lesions that may show mild atrophy or slight infiltration. When you follow-up with serial biopsy specimens over several years, you begin to get a picture that histologically is fairly typical of mycosis fungoides. The recent biopsy specimen does not show significantly atypical cells, but there are lymphocytes within the epidermis and an occasional small collection of these is present. These would be acceptable as Pautrier microabscesses.

EUGENE J VAN SCOTT, MD: The lesions are clinically compatible with the cases in which mycosis fungoides evolves. Our problem frequently is in obtaining confirmation histologically of a diagnosis of mycosis fungoides. Early diagnosis and treatment is, in my opinion, important in mycosis fungoides as it is in cancer in general.

HARRY J HURLEY, MD: I believe the emphasis on the telangiectatic element or the poikilodermatous change as a clinical feature strongly suggesting mycosis fungoides is important. Once the lesions of parapsoriasis have acquired this additional poikilodermatous feature, clinically we can consider the disease to be mycosis fungoides.

SAMUEL L. MOSCHELLA, MD: The lesions are clinically and histologically consistent with early mycosis fungoides. Since the patient is asymptomatic, the question of whether or not to treat him arises. Does one cure early mycosis fungoides by intensive topical treatment with mechlorethamine hydrochloride or by intensive therapy with the electron beam? From our experience so far, I am not optimistic and think that our therapy for mycosis fungoides is still palliative. We are probably capable of reducing the morbidity of the disease, but I question our capacity to affect its final prognosis or duration. Although mechlorethamine is an excellent form of therapy, we have the problem of sensitization in our patients despite following the recommended initial course of therapy to induce tolerance.

DR VAN SCOTT: We now have data on about 100 cases. At least 50% of the patients in these cases are free of disease and a number of these, after five years, have had their therapy discontinued with no recurrence, so we can begin to think in terms of cure. It is easier to effect a cure in the early stages. It is a rule in treating neoplasms to treat them while they are a small problem.

DONALD PIROZZI, MD: I would like to ask Dr Van Scott the incidence of sensitization in patients given weekly injections to induce tolerance.

DR VAN SCOTT: We have been very successful. In approximately 70 cases in which we have given 200 μg of mechlorethamine hydrochloride in weekly injections before topical therapy, only about 10% have become allergic.

HERBERT GOLDSCHMIDT, MD: You would not want to use teleroentgen therapy with soft x-rays because the patient shows relatively small areas of involvement. I would start him on the Van Scott regime with mechlorethamine and if he did not respond or if he should become sensitized, I would then consider radiation treatment.

DR MOSCHELLA: In our limited experience, treating early cases of mycosis fungoides with electron beam therapy using doses of 2,700 to 3,000 rads, the results have been disappointing. The four patients treated experienced a severe immediate dermatitis and later radiodermatitis. All experienced relapse within six months. There is a considerable reluctance by the radiotherapist to pursue this form of treatment because of the relatively poor results and the resulting permanent change to the skin that prevents further beam therapy for several years.

DR PIROZZI: Does the fact that there is no pruritus disturb anyone? The British have described a condition, xanthoerythroderma perstans, or chronic superficial dermatitis, that they believe does not represent parapsoriasis and does not eventuate into mycosis fungoides. It is completely asymptomatic and appears similar clinically to the features seen in this case. I wonder if this patient's condition could represent xanthoerythroderma perstans?

DR OLIVO: I have known this patient for about eight years. For the most part, the lesions have been essentially unchanged and asymptomatic. In the past six months to a year, reticulated patches and slightly atrophic and scaly areas of the buttocks have developed. Now that we have the opinion of the pathologists that the lesions are those of mycosis fungoides, we will proceed to treat the patient.

Multiple Pilomatrixomas. Presented by MATTHEW OLIVO, MD, LT STEPHEN DAMM, MC, USN.

A 35-year-old woman has had acne vulgaris for about 20 years. Occasionally cysts had developed in the axillae. Eighteen months ago she noticed cysts appearing on the dorsum of her left arm and shortly thereafter, two similar hard lesions developed on the right arm and one lesion below the left ear. Physical examination revealed four very firm, irregular, nontender nodules located on the right and left forearms and beneath the left ear. Two fluctuant cysts were also present in the axillae. A biopsy specimen from one of the arm lesions was reported as a pilomatrixoma.

Discussion

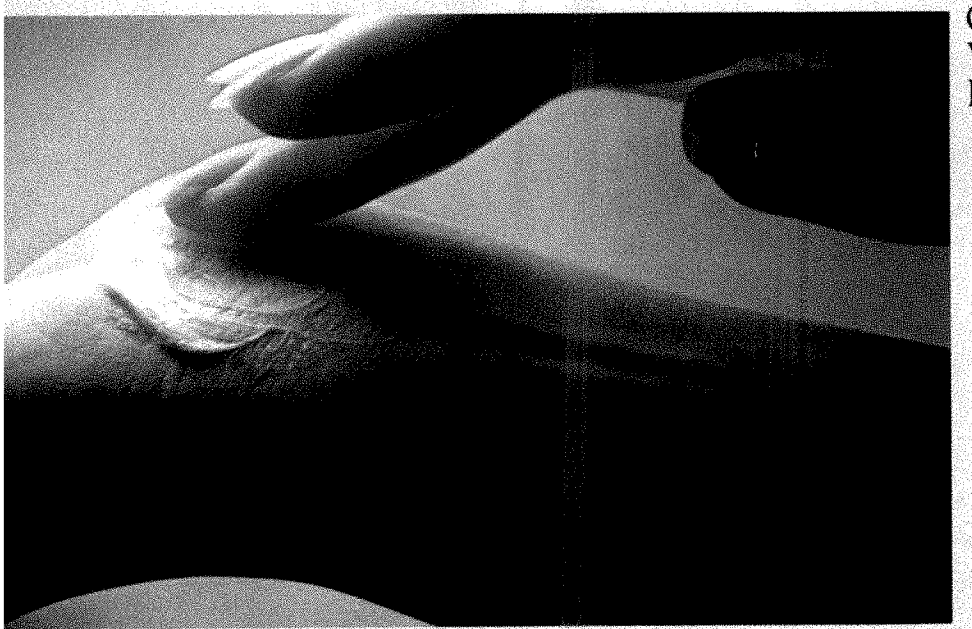
WAINE C JOHNSON, MD: The histology was characteristic of pilomatrixoma (calcifying epithelioma of Malherbe), with typical-appearing shadow cells and basalophilic cells and areas of ossification. This latter feature is seen in about 20% of the pilomatrixomas. Pilomatrixomas tend to occur in the younger age group; about one half of the patients reported in the literature have been younger than 20 years of age. The unusual aspect in this patient is the occurrence of multiple lesions. Of 228 patients reported by Drs Forbis and Helwig (ARCHIVES 83:606-618, 1961), only seven patients had multiple tumors and only one had as many as four tumors.

HOECHST-ROUSSEL PHARMACEUTICALS INCORPORATED

Announces a New topical fluorinated corticosteroid in a Unique Emollient Cream Base

NEW TOPICORT (DESOXIMETASONE)

THE SPECIALLY DEVELOPED, PRESERVATIVE-FREE BASE COMBINES THE EMOLLIENCE OF AN OINTMENT WITH THE COSMETIC ACCEPTABILITY OF A CREAM IN A WATER-IN-OIL EMULSION.



Well-documented efficacy and safety: Anti-inflammatory, antipruritic, vasoconstrictive Topicort (desoximetasone) has been demonstrated safe and effective in relieving the inflammatory manifestations of corticosteroid-responsive dermatoses.

Worldwide clinical experience: For up to 4 years, Topicort (desoximetasone) has been marketed by Hoechst in over 30 foreign countries. Extensive clinical trials in the United States, conducted by 23 investigators under a wide variety of climatic conditions, confirm the many years of worldwide experience.

A wide range of conditions in corticosteroid-responsive dermatoses: Topicort (desoximetasone) is useful on wet as well as dry lesions, in both acute and chronic cases, with a profile of adverse reactions similar to that seen with other topical corticosteroids.

Emollient Cream

0.25%

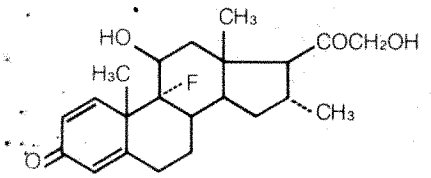
Available: 15-gram tubes.
In corticosteroid-responsive dermatoses
Convenient B.I.D. dosage.

Please consult full prescribing information on following page.

071033-677

TOPICORT® (desoximetasone) EMOLLIENT CREAM 0.25%

Description: Topicort® (desoximetasone) Emollient Cream 0.25% contains the active synthetic corticosteroid desoximetasone. The chemical name of desoximetasone is 9α - fluoro - 11β, 21 - dihydroxy - 16α - methylpregna - 1,4 - diene-3,20-dione. The chemical structure is:



Each gram of Topicort® (desoximetasone) Emollient Cream 0.25% contains 2.5 mg desoximetasone in an emollient cream consisting of isopropyl myristate, cetylstearyl alcohol, white petrolatum, mineral oil, lanolin alcohol and purified water.

Actions: Topicort® (desoximetasone) Emollient Cream is primarily effective because of its anti-inflammatory, antipruritic and vasoconstrictive actions.

Indications: Topicort® (desoximetasone) Emollient Cream is indicated for the relief of inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications: Topical steroids are contraindicated in vaccinia, varicella and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

Precautions: If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled.

Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time, or if occlusive technique is used.

If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Adverse Reactions: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria.

Dosage and Administration: Apply a thin film of Topicort® (desoximetasone) Emollient Cream 0.25% to the affected skin areas twice daily. Rub in gently.

How Supplied: Topicort® (desoximetasone) Emollient Cream 0.25% is supplied in 15-gram tubes.

UVAL helps prevent sunburn by screening out the sun's rays most harmful to human skin. Offers sun-sensitive patients real protection with a broad range of ultraviolet absorption (220-350nm).

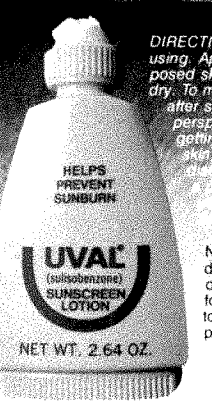
UVAL prevents burning, drying, wrinkling and freckling due to overexposure to the sun. Helps maintain softer, more youthful-looking skin. Provides protection with a low incidence of side effects.

UVAL has a creamy rich emollient base and may be used under makeup without loss of its sunscreening effectiveness.

UVAL frees your patients from the worry of painful sunburn. Lets them participate in outdoor work activity and enjoy fun in the sun year-round.

UVAL is alcohol-free and won't sting or dry skin. It protects with a nongreasy, almost invisible film that won't stain fabrics, skin or hair. Unlike PABA/Alcohol preparations, UVAL need not be applied one hour before sun exposure.

a sensible answer for sun-sensitive skin



DIRECTIONS: Shake well before using. Apply UVAL evenly to exposed skin, rub in well and allow to dry. To maintain protection, reapply after swimming or excessive perspiring. CAUTION: Avoid getting lotion into eyes. If skin sensitivity develops, discontinue use and consult your doctor. For external use only. Keep this preparation out of children's reach.

NOTE: If tanning is desired and permissible, direct your patients to follow The Guide to Tanning printed on every package of UVAL.

Letters to the Editor

A Substitute for Chloroform in Prescriptions

To the Editor.—I have just recently learned that the Food and Drug Administration has issued a ban on the use of chloroform in prescriptions. Several letters from dermatologists have already been received asking me to suggest a substitute for it in the prescription advocated in the article that I contributed to the ARCHIVES on the treatment of paronychia and onycholysis (92:726-730, 1965).

I recommended highly the technique of "absolute, continuous dryness" accomplished in general by avoidance of water, including liquid food materials, lotions, and ointments. Only of secondary importance medication with thymol was suggested because of its antibiotic efficacy against all fungi and bacteria. Chloroform was selected as the solvent vehicle because it is nonpolar (not miscible with water) and of specific gravity much more than water. It was the favorite of Hiram Miller (as well as Howard Morrow long before him), and they used 5% chrysarobin dissolved in it. They attributed its benefit to its ability to "float" water out of the interstices because of its high specific gravity. (The abstract of my article did not mention chloroform at all.)

If dermatologists cannot use chloroform in the future, it will indeed be difficult to duplicate the previous formula completely. I first thought of carbon tetrachloride, but it has already been banned for many purposes because of toxicity higher than that of chloroform. To find a substance equally heavy, all hydrocarbons are ruled out at once, because all have less than 1.0 specific gravities.

Halogenated hydrocarbon liquids do have high specific gravities and could be considered if the boiling points are high enough. Possibilities are trichloroethane (either methyl chloroform or vinyl chloride) or methyl iodide. Bromoform would create even more objections than chloroform.

However, I think the factor of "high specific gravity floating water out of crevices" has been overemphasized. I believe that either ethyl or isopropyl alcohol would serve adequately in spite of their specific gravities of less than water (about 0.8). For this particular purpose, they would need to be in the "absolute" form, to avoid the water contained in the usual 95% ethyl or the 70% isopropyl preparations so widely used.

J. WALTER WILSON, MD
Los Angeles

We suggest the use of 1% to 4% thymol, according to the concentrations suggested in Dr Wilson's original article in the "absolute" ethyl alcohol base.—ED.

Schistosomiasis of Spinal Cord and Skin

To the Editor.—In their article "Schistosomiasis: Paraplegia and Ectopic Skin Lesions as Admission Symptoms," which appeared in the May 1976 ARCHIVES (112:690-695), the authors, Wood et al, state that they were unable to find a case report of ectopic cutaneous schistosomiasis that occurred together with spinal cord involvement. We would like to draw the attention of the authors, and that of your readers, to our publication: "Schistosomiasis of Spinal Cord and Skin," (*S Afr Med J* 49(2):57-58, 1975).

Our patient was fortunate in receiving treatment in time to help her recover from her paralysis, and this stresses the importance of early diagnosis and treatment.

NORMA SAXE, MB, CHB, FF Derm (SA)
WALTER GORDON, MD, FRCP
Cape Town, South Africa

In Reply.—Our article was submitted to the ARCHIVES on Jan 14, 1975, prior to the publication of the paper by Drs Saxe and Gordon. The final proof of our paper was returned to the ARCHIVES' editor on March 15, 1975, at which time it did not occur to me to again research the literature. The subsequent delay until publication in May 1976 (16 months following submission of the paper, and 14 months following acceptance of the paper) is beyond my responsibility.

I certainly regret that I failed to see the article that was written by Drs Saxe and Gordon. They are to be congratulated on their early diagnosis and successful treatment.

MARGARET GRAY WOOD, MD
Philadelphia

Transient Acantholytic Dermatosis in South Africa

To the Editor.—A fair-haired, 63-year-old man, whose occupation was a builder, had had an intensely itching rash on his back of two months' duration. His work caused him to be in the sun for much of the day, and he also had many actinic keratoses on his face and arms.

On examination, he had a red, maculopapular rash on the back that resembled pityriasis rosea. The rash was slightly scaly. The individual lesions, however, seemed unusually firm. At the time, I was convinced of the diagnosis of pityriasis rosea and did a skin biopsy. The histologic characteristics showed hyperkeratosis with focal parakeratosis. The epidermis also showed suprabasal clefts and vesicles. Within the vesicles there were shrunken, distorted acantholytic cells. There were no corps ronds. As a result of the clinical history and the histologic findings, a diagnosis of transient acantholytic dermatosis was made. The following blood values were obtained: hemoglobin, 13.0 gm/100 ml; WBCs 6,900/cu mm: eosinophils, 2%; ESR, 15/min. A VDRL test for syphilis was negative.

The following therapeutic regimen was begun: clobetasol propionate cream (British, no US equivalent) three times daily; pyrilamine maleate, 50 mg three times daily; and trimeprazine, 10 mg nightly.

One month later, the rash on the back had improved, but there had been an eruption of new lesions around the shoulders and a few on the chest. He mentioned that the cortisone cream did not help the pruritus, but that the antihistamine tablets did. One month later, his skin was quite clear and he had no pruritus.

The patient had all the main features mentioned by Grover in his original description of transient acantholytic dermatosis.[1] The patient was male, 63 years of age, the eruption followed exposure to the sun, and the condition was transient and lasted approximately three months.

When I was in New York in August 1976, Grover reviewed the slide of this patient's skin biopsy specimen. A. Bernard Ackerman also reviewed the slide at New York Medical Center. They both believed that the scaliness of the lesions was unusual, but that otherwise it seemed to be a typical case of transient acantholytic dermatosis.

PETER LANE, MRCP (EDIN)
Durban, South Africa

1. Grover RW: Transient acantholytic dermatosis. *Arch Dermatol* 101:426-434, 1970.

Jejunoileal Bypass and Psoriasis

To the Editor.—The LETTER TO THE EDITOR by Nowlin and associates (*Arch Dermatol* 112:1465, 1976) has prompted us to report the following case.

Report of a Case.—In 1967, a 44-year-old woman developed plaques covered with slivery scales on her legs, sacrum, and abdomen. This eruption was diagnosed as psoriasis and treated topically with steroids. Later, similar lesions appeared over the scalp, eyelids, cheeks, chest, shoulders, back, groin, and nails. She was hospitalized in 1972 and in 1973, and treated with a modified Goeckerman technique. Excellent but short-lived control of the condition was obtained.

In 1974, the patient underwent a jejunoileal bypass for obesity: her weight decreased from 122 to 77 kg after one year, and to 68 kg after two years. Shortly after her surgery, she began to notice improvement of her psoriasis and, of her own accord, discontinued application of her psoriasis medication. This improvement had continued up to this report, and has included her nails. The only remaining lesions are 2-cm patches on both shins and vague arthritic aches. This patient is now considered to have a protein deficiency that resulted from her surgery, as evidenced by her total serum protein level of 4.4 gm/100 ml (normal, 6.35 ± 0.52 gm/100 ml) and her serum albumin level of 1.96 gm/100 ml (normal, 3.73 ± 0.42 gm/100 ml).

Comment.—This report points to an effect of jejunoileal bypass opposite to that described by Nowlin et al. It would be of interest to know whether this patient developed any type of nutritional deficiency. Whether this contradiction reflects differences in HLA antigens, type of nutritional deficiency, or other factors among psoriatic patients is an intriguing question. Further investigation of this point may shed some light on the pathogenesis of psoriasis in general.

Allergic Contact Dermatitis to Herbicides

To the Editor.—Since Spencer's original article in 1966[1] on herbicide dermatitis, little has been written on the sensitizing potentials of herbicides. Indeed, the exact incidence of contact dermatitis to herbicides remains unknown.

During the past 24 months, we have patch-tested 22 patients suspected of having herbicide-induced allergic contact dermatitis. They were tested for all or part of a "herbicides tray" consisting of ten herbicides. These herbicides were all of 1% concentration (commercial source) in petrolatum and were applied for 24 hours. The patch tests were then read at 24, 48, and often at 72 hours after application. The herbicides selected for administration were these: amiben, atrazine, Bladex, Dyfonate, Furadan, Lasso, Lorox, Ramrod, 2-4-D Weed Killer, and Treflan. All patients had a history of exposure to one or more herbicides.

Results.—The only positive or irritant reactions occurred with Ramrod and Lasso, plus one questionable reaction to Treflan at 72 hours. Of the 17 patients patch-tested to Ramrod, seven had positive reactions and five had irritant reactions. Only two of the seven patients with positive tests could directly implicate Ramrod and gave a history of using it. Among the 21 patients patch-tested to Lasso, five had positive results and one had an irritant reaction. Only two of the five patients with positive tests had a direct history of Lasso use.

Comment.—Ramrod and Lasso surpass the eight other herbicides tested, both in irritancy and in their sensitizing potentials. Patients were predominantly farmers who had simultaneous exposure to many herbicides. Despite ample warning on the labels provided by the manufacturer that indicated the possibility of skin irritation and sensitization, many of the patients admitted to careless or accidental contamination of skin or clothing without any attempt to remove the offending agent immediately. One of us has observed a patient for several years. This farmer is so highly sensitized to Ramrod that he develops a generalized airborne contact dermatitis each spring when his neighbors use this product.

Both Ramrod and Lasso are used in the pre-emergence and early post-emergence growth cycle of crops and have similar spectrums of weed control and crop tolerance. Ramrod (propachlor) (2-chloro-*N*-isopropylacetanilide) is used for the control of most annual grasses and certain broadleaf weeds. Resistant crops include corn, sorghum, soybeans, other legume crops, fruit trees, and many ornamentals.[2] Lasso (alchlor) (2-chloro-2',6'-diethyl - *N* - [methoxymethyl]acetanilide) is also used to control most annual grasses and certain broadleaf weeds and yellow nutsedge. Tolerant crops include corn soybeans, peanuts, cotton, woody fruits, and certain ornamentals.[3]

We suggest, for patch testing, the use of lower concentrations of Ramrod and Lasso in the future, perhaps 0.5%, 0.25%, or 0.1%, to reduce the number of irritant reactions. The irritancy of these two herbicides may well contribute to their sensitizing ability. The fact that both Ramrod and Lasso are acetanilides suggests that this moiety may be the sensitizing fraction. The fact that both contain chloride moieties may contribute as well. Spencer found that Randox, Randox-T, and Ramrod all contain chloroacetyl groups, which were stated to be quite reactive.[1] He suggested but could not confirm cross-sensitization among Randox, Randox-T, and Ramrod. Randox-T is no longer marketed (F. R. Johannsen, PhD, Monsanto Co, written communication). We found three patients who reacted to both Ramrod and Lasso. This suggests the possibility of cross-sensitization, but the small size of our group and the fact that not all patients were tested to both herbicides makes it impossible for us to confirm this.

Rasmussen and Cole[4] state that "The chief problem with propachlor (Ramrod), alachlor (Lasso), atrazine, and Treflan is contact dermatitis." We concur that allergic contact dermatitis to Ramrod and Lasso exists, but we cannot draw any conclusion about its incidence. Large amounts of these herbicides apparently are used. It may be that only a small fraction of users develop an allergic contact dermatitis. The possibility also exists that those who have become sensitized have violated normal precautions and put themselves at unnecessary risk.

Physicians who treat agriculturists should be aware of the possibility of acute allergic contact dermatitis from Ramrod and Lasso. They will then be in a position to advise their patients to avoid further contact with these agents and thus prevent future disability from a potentially chronic occupational dermatosis.

Treatment With Penicillamines

To the Editor.—As I read the "Comment" section of the case report of

Drs Campo and McDonald, which was entitled "Treatment of Acrodermatitis Enteropathica With Zinc Sulfate" (*Arch Dermatol* 112:687-689, 1976), an interesting thought occurred to me. The physicians point out that among many other treatments, penicillamines have been used for treatment. That being the case, and if their theory is correct, the penicillamine-treated babies should have gotten worse, since penicillamine is a nonselective chelator and it would, therefore, surely have chelated the zinc in an already presumably zinc-deficient baby. I hope that we hear from the penicillamine-users as to whether their patients did get worse, because it would be excellent indirect evidence of the correctness of the theory of Drs Campo and McDonald.

In my own experience, there was a child with Wilson's disease who, on long-term penicillamine therapy, developed a very severe dermatitis that responded very nicely to oral zinc sulfate therapy. Perhaps someday we will refer to congenital and induced acrodermatitis enteropathica.

As an additional item of thought, might not acrodermatitis enteropathica also be a dependency disease much like pyridoxine-dependent convulsive disorder or vitamin D-resistant rickets, such that the usual amount of zinc in the diet does not prevent disease, but in marked excess, it does? Since zinc is a well-known coenzyme in several enzyme systems, much as are pyridoxine and vitamin D, I think this theory at least deserves investigation.

ARTHUR N. WARD, MD
Smithfield, Pa

In Reply.—I have read with interest the letter from Dr Ward, and I have very few comments to make other than to indicate that our reference to the use of penicillamine in the treatment of acrodermatitis described regrowth of hair during penicillamine treatment. There was also a comment that the accompanying dermatitis initially cleared but then recurred to a rather great extent within several weeks after the treatment was begun.

This, to my knowledge, is the only reference to the treatment of acrodermatitis enteropathica with penicillamine. I agree that the administration of penicillamine to a patient with acrodermatitis may, in fact, exacerbate that disease; however, we have no reference material to which we can refer that would confirm our impression.

I also agree that as we learn more about the metabolism of zinc in the skin, we will find that there are a large number of zinc-deficiency dermatoses that until this time have, in all probability, gone unnoted and also undiagnosed.

CHARLES J. MCDONALD, MD
Providence, RI

In Reply.—I found Dr McDonald's reply fascinating—particularly his remark, ". . . we will find that there are a large number of zinc-deficiency dermatoses that until this time have, in all probability, gone unnoted and also undiagnosed." This letter comes then, as a "reply to a reply" because of several new ideas that I have.

First, I had a patient with a silvery, lichenified, pink lesion on each elbow that, though I unfortunately did not perform a biopsy on either, looked to me like classical psoriasis. Based on my appreciation of Dr McDonald's rationale in using zinc for acrodermatitis enteropathica, I thought to myself, in effect: "She's got a psoriasiform lesion—two small areas with no evidence of systemicity," (if I may coin a word along with, hopefully, a helpful idea). "Therefore, since psoriasis is a disease on which an origin has not been agreed (if it is even known), why not try zinc sulfate for treatment?"

Quaintly, the patient's lesions did heal! (I've tried zinc since—with failure, in all honesty—but I wonder, have others tried zinc for diagnosed psoriasis, atopic dermatitis, acne, and other such disorders?) I had given my patient a prescription for 250 mg of zinc sulfate daily, although I realize that this was about 15 times the minimum daily requirement (MDR) of zinc. I also, of course, warned her to discontinue usage of the medication if she vomited or if she felt nauseous, since this would be the earliest sign of zinc toxicity. Might the dosage, however, have been carried higher in a nonresponder based on the consideration of this as a possible zinc *dependency* disease (cf, hypophosphatemic vitamin-resistant rickets, which is of sex-linked, inherited origin and often requires 100 to 1,000 or more times the usual MDR of vitamin D to produce a response)?

A second thought that came to mind was: since penicillamine produced hair growth in patients with acrodermatitis, might it (or some other chelator) not help male pattern baldness? Perhaps such baldness is a holandrically-inherited propensity to over-absorb zinc and therefore, to lose hair. Of course, in bald men (such as myself) who happen to be allergic to penicillin, demercaprol, edetate, or potassium sulfide could be tried.

Finally, I wonder if topical steroids might not exert their favorable effect on skin by driving sodium ions into the systemic circulation and thereby selecting against *Staphylococcus aureus*. In a sense, these steroids may increase the skin's bacterial competition, since *Staphylococcus* bacteria are well known to flourish in high sodium concentrations (and even in the ocean). Might this not also implicate high sodium ion concentration in acne vulgaris, which arises in adolescents, who differ from children in that they have more hormone production and therefore, more sodium in their facial and thoracic perspiration? I've tried putting teenagers with severe, comedomatous acne on very low sodium diets, with some success clinically. I've also tried the "familial granulomatosis" regime, which consists of high doses of iodine and ascorbic acid, since acne is, at times, sort of a facial model of this disease; I perform neutral blue toluidine studies also, on occasion.

The relevance of all this to zinc is that one of the medicines that is used to treat acne is zinc oxide, which sometimes helps! Maybe sodium and zinc, as metallic ions, compete with each other on the skin in some unknown way. If this is so, a more soluble (ie, more ionic) zinc salt, such as zinc sulfate or zinc chloride, should be tried on the skin of acne sufferers.

Bits of Bicentennial Dermatology

To the Editor.—With all the current popularity of exhibits of colonial medicine as part of Bicentennial reviews, it is of interest to add some bits of dermatology.

First, Indian medicine; the chief dermatological problem was, of course, the epidemics of smallpox acquired from the white man.[1] Many of the herbs used by the Indians were later incorporated into the pharmacopeia.[2] Boils and superficial wounds were treated with the roots of the tobacco plant. Rothman, many years later, used an infusion of tobacco for the treatment of recalcitrant pustular dermatitis of the hands. Snake root (*Aristolochia serpentaria*) and lion's heart (prenanthese reubincunda) were used for snake bites.[2] Celandine (balsam, jewelweed, touch-me-not, snapweed, lady's earrings) that was popular with the Indians is used today

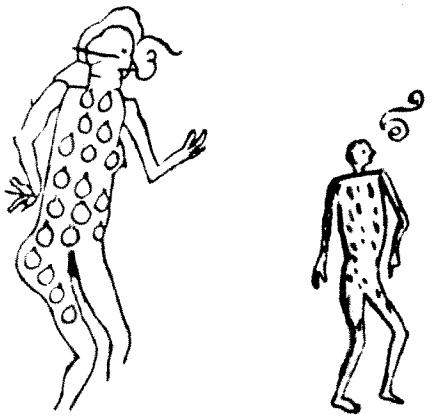

Fig 1.—Rock painting, portrayal of smallpox among Indians from Colorado and Dakota, 1779-1780.

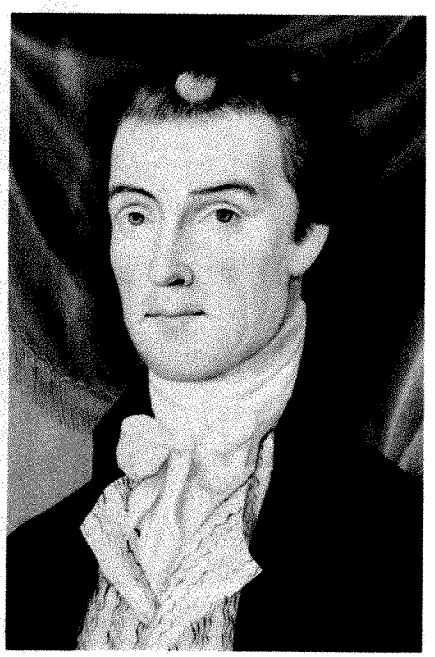

Fig 2.—Probable epidermal cysts: Amos Morrow (reprinted from Goldman.[5]).

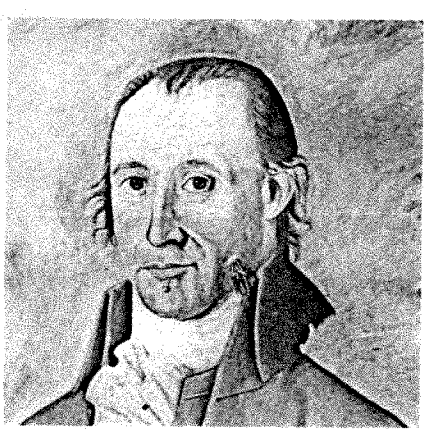

Fig 3.—Portrait of Nathaniel Allen, 1763 showing details of hairy nevi.

among farmers for the treatment of poison ivy dermatitis. A great variety of herbs were used in the treatment of venereal disease by the Indians. These were more effective with gonorrhea than with syphilis. The *Gazette of Williamsburg* also detailed some interesting remedies for the treatment of venereal diseases during the colonial period. It is perhaps not well known that Corlett, one of the early dermatologists of Cleveland, established a special room in the Allen Memorial Library in Cleveland for Indians and Indian Medicine. In lower Canada, the medical officers in 1782 were using mercury for syphilis, and the government issued pamphlets in regard to mercury therapy. This was one of the early evidences of public health measures for the control of venereal disease.

In regard to the physicians, Benjamin Rush included mercurial ointments in his medicine case and discussed skin diseases in his *Practice of Medicine*. He also taught that the skin was nonabsorptive. Reuben Mussey, in Cincinnati in 1838, proved that the skin was absorptive by putting his entire body in a tub of madder. Preston[3] indicates that for days afterwards he passed red dye in his urine. None of the other physicians of that period, Josiah Bartlett, Lyman Hall, or Matthew Thornton, wrote about skin diseases. Dr Richard Allison, a surgeon of the Fifth Pennsylvania Regiment during the Revolutionary War and the first physician in the Cincinnati area, wrote about the need for supplies and a hospital and not about dermatology, although he helped in the severe smallpox epidemic in Cincinnati in 1793.

Benjamin Franklin[4] evidently did not use his famed electric shock therapy for the treatment of his own recurrent eczema that he acquired in his 80s. This dermatitis covered his entire body except his hands and face. A flare of his severe gout once cleared his eczema briefly. Also, at times, warm baths helped.

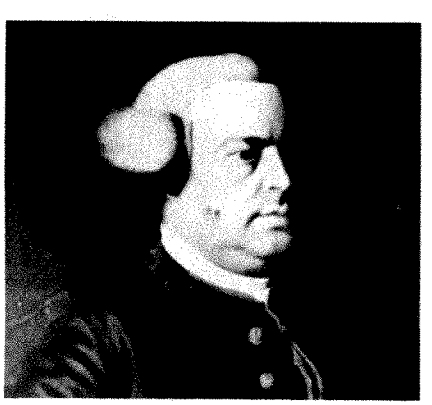

Fig 4.—Jonathan Dwight I (1743-1831) with filiform warts. Last decade 18th century.

Franklin, also, was treated by Sir John Pringle. It is of interest that Sir John Pringle wanted Franklin to "electrify" the epileptic daughter of the Duke of Ancaster. Franklin's remark about his gout could well be applied to his eczema. He said, "People who live long and who will drink the cup of life to the very bottom must expect to meet with some of the usual dregs."

The portrayal of skin lesions by colonial artists during that period has also shown some interesting samples. Four examples have been collected. Figure 1 is an Indian rock painting depicting smallpox. Figure 2 is of Amos Morrow[5] with scalp lesions (epidermal cysts), 1795. His portrait was presented as a case for diagnosis at the Cincinnati Dermatological Society. Figure 3 is a portrait of Nathaniel Allen with two hairy nevi. Jonathan Dwight with the extensive filiform warts of the face is seen in Fig 4.

These are interesting examples of the realism of the American painters of that period. Skin diseases of that period and later were described in much greater detail by Daniel Drake[6] in his famed books in 1815 and 1850.

LEON GOLDMAN, MD
Cincinnati

Beatrix Rumford, Director and Barbara Luck, Registrar of the Abby Aldrich Rockefeller Folk Collection of Williamsburg, helped in the collection of several of these examples. Lisabeth M. Holloway, Curator, Historical Collections Library of the College of Physicians of Philadelphia reviewed the publications about skin diseases in colonial dermatology.

Nonvenereal (?) Sclerosing Lymphangitis of the Penis

To the Editor.—The use of the adjective "nonvenereal" by Fiumara to describe sclerosing lymphangitis of the penis seems in error (*Arch Dermatol* 111:902-903, 1975). The lesion is associated with (or related to) sexual (venereal) acts *in every instance.* Why use nonvenereal to designate something clearly venereal?

THOMAS S. SAUNDERS, MD
Portland

In Reply.—The venereal history of the three patients in my report was clearly stated. Earlier reports stressed the nonvenereal nature, and until the studies of additional patients are accomplished the common nomenclature was used. My personal opinion is that sclerosing lymphangitis of the penis is acquired sexually.

NICHOLAS J. FIUMARA, MD, MPH
Boston

Atypical Fibroxanthoma

To the Editor.—In the August 1976 issue of the ARCHIVES (112:1155-1157), Goette and Odom present a case report entitled "Atypical Fibroxanthoma Masquerading as Pyogenic Granuloma." In their presentation they make several strong statements that add to their argument, with which I must take issue.

The future of a lesion that bears this diagnosis is not at all certain, and as they point out, "It has no characteristic morphological features that permit a diagnosis on clinical grounds alone, and, therefore, necessitates a biopsy for diagnosis." They go on:

> In order that unnecessary radical surgical procedures be avoided, it is imperative that clinical and histological aspects of every lesion that receives a serious consequential diagnosis be analyzed critically to avoid grave pitfalls of judgement clinically, histologically, and most important, therapeutically.

I am afraid that despite every scrutiny given by experts, these tumors can and do kill. Goette and Odom noted several reports in their article. I think it is wiser to point out that the entire concept of the nosology of "pseudotumors" begins with a misnomer. These are tumors whose destinies are not exactly predictable, despite their usual benignity. This is illustrated in the case of my patient.

My patient was a 62-year-old man with a lump on the back that was diagnosed as "pseudosarcomatous fasciitis," "angiosarcoma," "atypical dermatofibrosarcoma," and by Dr R.V.P. Hutten, as "atypical fibroxanthoma." Because of several postoperative recurrences, the patient received electron-beam therapy at Memorial Hospital in New York. However, he died of invasive fibrosarcoma of the lung. Schreiber's patient, a 43-year-old woman with "pseudosarcomatous fasciitis," met a similar fate.[1]

Until the immunologists work us out of the corner that we have painted ourselves into, rational therapy will continue to be empirical, based on the unlikely possibility of a dire end. It is an utter delusion to believe that we understand the clinical or pathological basis of whatever we finally agree to call this entity.

HOWARD S. YAFFEE, MD
Cambridge, Mass

1. Yaffee HS: Masked fibrosarcomas. *Cutis* 6:1353, 1970.

In Reply.—Dr Yaffee's comments pertaining to "pseudotumors," probably meaning *pseudomalignancies,* are generally applicable to the concept of pseudomalignancies, and we do not claim to have illusions about understanding any one or all of them. His unfortunate experience with a case of metastasizing fibrosarcoma points out the important fact that dermatologists should have a thorough knowledge of the histopathology and clinical manifestations of these tumors. The diversity of histological diagnoses that were rendered in his case points out the unfamiliarity of many a pathologist with these entities.

As Dr Yaffee certainly knows, a fibrosarcoma does not qualify as a pseudomalignancy. Misnomer or not, the fact remains that our statements about atypical fibroxanthoma (AFX) in particular, are substantiated by over 200 cases that are recorded in the literature. As pointed out in our article, two cases metastasized, and close follow-up examinations were recommended in all cases of AFX. In our opinion, the occasional, exceptional case does not detract from the fact that AFX generally is a condition with a histologically malignant appearance and a benign clinical course, or as some have called it, a pseudomalignancy.

LT COL DETLEF K. GOETTE, MD, MC
San Francisco

Peculiar Persistent Pruritic Affection of the Skin

To the Editor.—Itch, the prime dermatologic symptom, wears many faces. I have observed over the years a number of patients complaining of a peculiar type of itching that, to my knowledge, has not appeared in the dermatologic literature. When the patients are persuaded to describe the itching, several clear-cut characteristics emerge. The itch is momentary, attacks only a small area, and is relieved by a single scratch or pinch. The area in which the itch occurs is usually centripetal. It may be localized, as on one side of the back, the face or the perianum, or widespread areas of skin may be involved. If a social situation precludes scratching, the itch abates during a period of a few minutes, but often recurs in the same site a short time later. The condition usually affects older patients and usually is chronic. There is no evidence of dermatitis, and topical therapy is ineffective.

The spontaneous temporally and spatially localized character of the itch suggests that it is mediated via the delta fibers of A-class nerves, rather than the C fibers that conduct diffuse itching.[1] As to origin, I have no clue.

Alliteration using the letter P has been popular with dermatologists over the years.[2-5] Electing to follow this tradition I have chosen to name this entity, "peculiar persistent pruritic affection of the skin."

Isoniazid-Induced Pellagra

To the Editor.—In a communication on the subject of isoniazid-induced pellagra,[1] we mentioned preliminary evidence that rats receiving isoniazid showed evidence of increased epidermal lipid biosynthesis. This result was of interest first because isoniazid, as an antagonist of the hypocholesterolemic agent niacin, might be expected if anything to stimulate lipid and especially sterol biosynthesis. Second, increased levels of total epidermal lipogenesis and of sterol biosynthesis relative to other lipids are found in lesions of psoriasis and lichen simplex[2]

Present Results With Higher Doses of Isoniazid		
Group	Epidermal Lipogenesis (dpm* 3-mm Biopsy Specimen)	Sterols (% of Total Lipid Labeling)
Controls (N = 8)	6,620 ± 380	6.22 ± 0.69
Isoniazid-treated, 20 mg/kg/day for 8 wk (N = 8)	7,010 ± 630	4.93 ± 0.46
Isoniazid-treated 40 mg/kg/day for 8 wk (N = 7)	5,420 ± 540	5.50 ± 0.40

*dpm indicates disintegrations per minute.

and it seemed possible that a similar change might accompany isoniazid-induced hyperkeratosis.

When, however, our preliminary results were checked using larger groups of animals and higher doses of isoniazid, we were unable to substantiate the initial conclusion. Our present results (Table) are as follows (mean ± SEM).

The rats used were intact females aged eight to ten weeks at the start of the experiment and they were maintained on a standard breeding diet (Oxoid) ad libitum. Epidermal lipogenesis from tagged with carbon 14 glucose was measured as previously described.[3] Apart from showing no evidence of altered lipid metabolism, the epidermis from isoniazid-treated rats was histologically normal and there was no increase in the number of cell layers in the stratum corneum measured after alkali swelling.[4] These results are consistent with our failure to reproduce the cutaneous symptoms of pellagra by topical application of isoniazid in normally nourished individuals.[1] It seems possible that the induction of a pellagra-like syndrome by isoniazid requires a poor nutritional status in addition to the metabolic antagonism of niacinamide by the drug.

Treatment of *Mycobacterium marinum* Infections With Minocycline

To the Editor.—Two cases of *Mycobacterium marinum* infections were successfully treated with minocycline hydrochloride (Minocin). Loria reported his experience with this drug in 1976.[1] Prior to that, Dr E. Epstein remarked in the SOCIETY TRANSACTIONS that he knew of four cases that were successfully treated with minocycline.[2] Kim treated and cured six cases of *M marinum* with tetracycline, which patients took over a two- to three-month period.[3]

Report of Cases.—CASE 1.—A 50-year-old man had a four-year history of nonhealing granulomas on the lower aspect of his right leg. The lesion previously had been treated with penicillin without response. A punch biopsy showed a granuloma, and culture of the tissue at room temperature grew a photochromagen that was identified as *M marinum.* He was treated with 100 mg of minocycline hydrochloride twice a day and showed complete healing of the lesions after eight weeks. He was occasionally bothered with dizziness and a lightheaded feeling during the course of his therapy.

CASE 2.—A 61-year-old woman developed three deep, slightly tender nodules on the lower aspect of her right leg. One of the lesions spontaneously drained a purulent material. She was treated with cloxacillin sodium monohydrate for four weeks, without any change in the lesions. After confirmation of a *M marinum* infection by biopsy and culture, she was treated with 100 mg of minocycline hydrochloride twice a day. Within one week after minocycline therapy was started, there was improvement of all of the nodules. By the end of four weeks, the dosage was reduced to 50 mg twice daily because of dizziness. On this lower dose, the dizziness disappeared. After six weeks of therapy, almost all of the lesions had completely cleared.

Comment.—Both patients most likely obtained their infections in the Chesapeake Bay.[4,5] The first patient has a home at the edge of the bay and the second patient frequently sails on the bay. Although neither patient could recall any specific trauma to his or her leg, both were exposed to the Chesapeake Bay waters on many occasions.

From these two cases, as well as from the previously reported cases, it would seem that minocycline, tetracycline, or any other of the tetracycline derivatives would be the treatment of choice in *M marinum* infections.

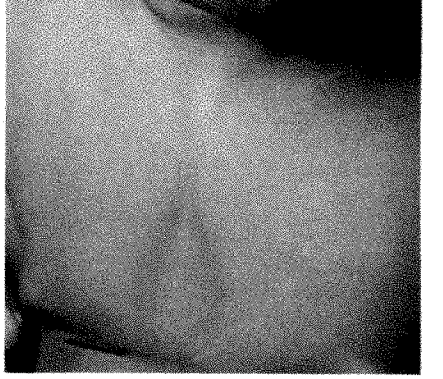
Congenital Pigment Formation

To the Editor. This figure shows an 8-month-old infant who has a congenital pigment formation in the shape of a deer track. It is not a nevus in the usual sense of the word, but seems to be outlined by the pale ventral median stripe and by a medial extension of the familiar pigment-border that is often found on the arm. The baby's



family history is not available, so we have no unsuperstitious explanation of the anomaly. Although I have seen several clear and definite deer tracks and many vague and imperfect ones in pediatric practice, I have neither heard of a name for this mark nor read a description of it; and my favorite dermatologist could not say much more. We would appreciate information from your staff; and if any mystery remains, we hope that you can publish the photograph for comment from your readers.

Grange S. Coffin, MD
Berkeley, Calif

Tetracycline-Resistant Granuloma Inguinale

To the Editor.—I have observed a case of granuloma inguinale in which prolonged treatment with 2 gm of oral tetracycline hydrochloride per day failed to produce clinical or microbiologic response.

Report of a Case.—A 40-year-old man was admitted to the University of Miami Dermatology service on Sept 6, 1975, for treatment of extensive granuloma inguinale. Ten years prior to admission, he developed a nodule on his left upper inner thigh that later ulcerated and enlarged. He had received numerous courses of oral antibiotics, mostly tetracyclines, but always stopped therapy before healing was complete. His medical follow-up was sporadic. On admission, he had a beefy-red, granular, eroded lesion involving the left upper inner thigh, left inguinal area, base of the scrotum, and the intergluteal and perianal areas. Its border was heaped up and serpiginous. Crush preparations of tissue from the lesion stained with Wright-Giemsa and Warthin-Starry stain showed numerous Donovan bodies in large mononuclear cells. Biopsy specimens of the lesion showed the inflammatory changes of granuloma inguinale and confirmed the presence of Donovan bodies.

Treatment consisted of sitz baths, compresses, and oral tetracycline hydrochloride (500 mg four times a day) taken on an empty stomach and administered by the nursing staff. This treatment was continued throughout his 38-day hospitalization. Ingestion and absorption of tetracycline was confirmed by bright-yellow fluorescence of the patient's urine under Wood's light as compared with control urine. During the hospitalization, the lesion became less purulent and foul-smelling, but showed only minimal signs of healing. Repeat biopsies and crush preparations on the 30th day of hospitalization showed persistence of an active inflammatory process typical of granuloma inguinale and the presence of Donovan bodies. Oral sulfisoxazole (1 gm, four times a day) was begun on the 31st hospital day, and the tetracycline treatment was continued. By the 38th day, signs of healing were noted, and biopsy specimens showed diminution of the inflammatory process and the absence of Donovan bodies. Crush preparations, likewise, showed no Donovan bodies. The patient insisted on continuing his treatment as an outpatient and was discharged, but failed to return for follow-up.

Comment.—Tetracycline is considered the treatment of choice for granuloma inguinale. Although failure of tetracycline in treating this disease has been suggested,[1,2] most patients received low doses or short periods of treatment. The present case demonstrates that under optimal conditions (ie, hospitalization, supervised drug administration in acceptable doses for a prolonged interval), clinical and microbiologic resistance to tetracycline can occur in granuloma inguinale. Repeated inadequate courses of tetracycline therapy may have fostered the emergence of resistant organisms in this patient.

Betamethasone and Its Derivatives

To the Editor.—May I draw your attention to a confusing nomenclature in the article entitled "Multicenter Trial Analysis: Fluocinonide and Betamethasone Gel in Psoriasis" (*Arch Dermatol* 112:1729-1733, 1976). The corticosteroid under study was betamethasone benzoate, and it is correctly referred to just once in the summary, once in the text, and in the figures. However, in the title and on most of the occasions in the text, it is referred to as betamethasone. Betamethasone benzoate, like betamethasone valerate, is an ester derived from betamethasone (alcohol), and all three substances have different biological properties. Betamethasone is a highly active anti-inflammatory corticosteroid when given systemically, but has little activity when applied to the skin. On the other hand, the two esters have a relatively low level of systemic activity but are highly active when applied topically. Further, considerable differences in activity can be seen between various esters derived from the same parent alcohol and betamethasone benzoate does not have the same properties as the valerate or other esters of betamethasone.[1]

In view of these differences, and with the growing understanding of the importance for clinicians to know exactly which topical corticosteroid they are using and to be fully acquainted with its strength,[2] it is important to consistently use the correct nomenclature. This is especially true in a field where there is such a large number of active principles with remarkably similar names.

Schering

New Diprosone®

brand of
betamethasone
dipropionate

Aerosol 0.1%

Clinical Considerations: INDICATIONS DIPROSONE Aerosol is indicated solely for the adjunctive topical management for the relief of inflammatory manifestations of acute contact dermatitis. DIPROSONE Aerosol has not been shown to be effective in any steroid-responsive dermatosis other than contact dermatitis. **CONTRAINDICATIONS** DIPROSONE Aerosol is contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of such preparations. DIPROSONE Aerosol is also contraindicated for use under occlusive dressings. **WARNINGS** Keep away from eyes or other mucous membranes. Use only as directed; intentional misuse by deliberately concentrating or inhaling the contents can be harmful or fatal. Avoid freezing of the tissue by not spraying for more than three seconds, at a distance of not less than six inches. Contents under pressure. Do not puncture. Do not use or store near heat or open flame. Exposure to temperatures above 120° Fahrenheit may cause bursting. Never throw container into fire or incinerator. Keep out of reach of children. **PRECAUTIONS** If irritation develops with the use of DIPROSONE Aerosol, treatment should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been absolutely established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time. DIPROSONE Aerosol is not for ophthalmic use. **ADVERSE REACTIONS** The following local adverse reactions have been reported with topical corticosteroids: burning; itching; irritation; dryness; folliculitis; hypertrichosis; acneiform eruptions; hypopigmentation; maceration of the skin; secondary infection; skin atrophy; striae; miliaria.

If there's
tinea versicolor
here
there's probably
malassezia furfur
here
here
here
and here.
Tinver®
sodium thiosulfate USP 25%, salicylic acid USP 1%
where tinea versicolor is seen and
where malassezia furfur is suspected

DESCRIPTION:
Sodium thiosulfate 25%, salicylic acid 1%, isopropyl alcohol NF 10%, propylene glycol USP, menthol USP, disodium edetate, colloidal alumina, and purified water.

INDICATIONS:
For topical use in the treatment of tinea versicolor (Malassezia furfur infection).

PRECAUTIONS:
If signs of irritation or sensitivity develop, discontinue use. Do not use on or about the eyes.

ADMINISTRATION:
Thoroughly wash, rinse and dry the affected areas before application of medication. Apply a thin film of lotion to all affected areas and other susceptible areas twice a day. Although diagnostic evidence of the disease may disappear in a few days, it is advisable to continue treatment for a much longer period. Clothing should be boiled to prevent reinfection.

HOW SUPPLIED:
6 fl. oz. plastic dispenser bottles.

CAUTION:
U.S. Federal law prohibits dispensing without prescription.

News and Notes

Dermal Pathology.—The nineteenth annual course in "Dermal Pathology" sponsored by The University of Texas Health Science Center at Houston, Division of Continuing Education, and The University of Texas System Cancer Center, M. D. Anderson Hospital and Tumor Institute at Houston and co-sponsored by the American Society of Dermatopathology, will be held August 21-26, 1977. During this 5½-day course, emphasis will be given to a review of the basic concepts of dermal pathology, including histology and anatomy, electron microscopy, histochemistry, inflammatory dermatoses, granulomatous dermatoses, reticuloendothelial and alterative dermatoses, and nevi and neoplasms. The course is designed primarily for pathologists and dermatologists. The curriculum will be similar to that of previous courses which have been held in Houston, at the Skin and Cancer Hospital of Temple University in Philadelphia, and the University of California at Irvine. This will be the sixth time that the course will have been held in Houston. In addition to the didactic presentations, emphasis will be given to microscopical slide study and self-evaluation examinations. This continuing medical education offering meets the criteria for 38 credit hours in category I of the Physician's Recognition Award of the American Medical Association.

For further information please write to the Office of the Director, The University of Texas Health Science Center at Houston, Division of Continuing Education, PO Box 20367, Houston, TX 77025.

Scholarship Program for Dermatologic Surgery.—The American Society for Dermatologic Surgery announces its Third Annual Scholarship Program to emphasize the scope and importance of surgery in dermatology and to disseminate surgical knowledge and training in our specialty. A number of grants of variable amounts and for variable periods of time will be awarded to defray some or all of the expenses of such training. Applicants must be in an approved dermatology residency training program and finish the surgical elective at least six months before the completion of the residency; or be a full-time faculty member in an approved dermatology program; or be actively involved in a dermatology training program in some other capacity. Surgical training in teaching institutions and private practices are acceptable. Other proposals for obtaining training suggested by the candidates will be considered. Applications, subject to the approval of the training director, should be submitted by Oct 31, 1977. Scholarship awards will be announced at the American Society for Dermatologic Surgery meeting at the American Academy of Dermatology in December.

For further information and applications, please write to Edward A. Krull, MD, Department of Dermatology, Henry Ford Hospital, Detroit, MI 48202.

New Officers.—At the 97th Annual Meeting of the American Dermatological Association in Phoenix, Ariz, March 19-24, 1977, the following officers were elected: president, Rudolf L. Baer, MD; vice president, Hermann Pinkus, MD; treasurer, Richard L. Dobson, MD; board of directors, Harry J. Hurley, MD.

Clinical Trials Methods.—The National Institutes of Health is sponsoring a "National Conference on Clinical Trials Methodology" to be held Oct 3-4, 1977, in the Masur Auditorium, the Clinical Center, National Institutes of Health in Bethesda, Md. This meeting is intended to bring together scientists involved in the design and conduct of clinical trials who come from a variety of disciplines, ie, clinical medicine, statistics, epidemiology, and who work in a variety of disease areas. The conference agenda includes many of the complex and unresolved issues inherent in the conduct of clinical trials—when and how to stop a trial, incentives to attract effective clinical trial investigators, patient recruitment, quality assurance of clinical data, ethical problems, and communication among investigators. No registration or notification of planned attendance is required. Additional information may be obtained by writing to Dr Robert Gordon, Building 1, Room 134, National Institutes of Health, Bethesda, MD 20014.

Books

Psychophysiological Aspects of Skin Disease, Major Problems in Dermatology series, vol 8, ed 1, F. A. Whitlock, MD, 248 pp, with illus, $18, Philadelphia, WB Saunders Co, 1976.

Psychophysiological Aspects of Skin Disease, which is from the series *Major Problems in Dermatology,* is a well-written, readable monograph. The first part of the book is a historical perspective of the subject. Inadequately controlled and biased studies are dissected in an attempt to extract information that may help the reader gain a perspective of the subject. Clinical experience more than scientific investigation was used to formulate the conclusions of these studies.

The first chapters are cumbersome reading because of painstaking reviews of the literature. Brief discussions of psychologic, physiologic, and hypnotic tools used to construct many recent psychophysiologic theories will be useful especially to the naive reader.

The second half of the book deals with specific skin disorders, with an introductory literature review and then a subsequent assessment of present interpretations. The inability of investigators to control their studies and remove their bias is again emphasized. Too much text, however, is devoted to this historical autopsy. Many methods for dealing with patients having urticaria, atopic dermatitis, anogenital pruritus, acne vulgaris, rosacea, hair problems, and self-inflicted dermatoses will be useful for the practicing dermatologist. In addition, a perspective of the possible benefits and problems of psychotherapeutic intervention is given.

The outstanding contribution of this book is to help dispel many unwarranted labels certain dermatological conditions have worn. Skin disease frequently has psychological components, but invalid prejudices make the clinician and researcher much less helpful.

STEPHEN Z. SMITH, MD
Louisville

Microvascular Injury, by Terence J. Ryan, 418 pp, 170 illus, $29.50, Philadelphia, WB Saunders Co, 1976.

Microvascular Injury cannot be recommended as light reading, reposing comfortably between *The Doonesbury Chronicles* and *Jaws.* Nor may its virtues be honestly extolled to the "bottom-line" clinician, whose interest in a disease process begins and ends with the prescription pad. It should, however, receive enthusiastic endorsement from the curious dermatologist who is anxious to clarify the often turbid exposition of microvascular pathology. And, of course, it certainly belongs on the shelf (the section with the thinnest veneer of dust) of any investigator who is attempting serious work in the field.

This book, like all books, is limited by the range of the author's personal interests; fortunately, the range of Terence Ryan's interest in vascular events is broad. The author and his contributors (M.W. Kanan and G.W. Cherry) carefully review the history, pathophysiology, diagnosis, and treatment of vasculitis. Yet, in Ryan's words, "This book is about injury to the small blood vessels of the skin," and not about vasculitis per se. Indeed, the authors have undertaken a courageously broad analysis of microvascular injury following a wide variety of unpleasant stimuli and have attempted to relate the process of vascular injury to a complex interplay of physiology and inflammation. If they have not always succeeded, we must recall the enormity of their self-appointed task.

Throughout this book, the authors have laudably (and successfully) attempted to vitiate the tyranny of jargon, to excise awkward morphological descriptions, and to make cutaneous microvascular pathology understandable to both the dermatologist and the nondermatologist. The emphasis here is consistently on the understanding of the pathophysiology of complicated microvascular aberrations and their relationship to clinical (largely dermatological) disease. Descriptive terminology has thus been stripped and cleaned in what seems to me a thoroughly reasonable fashion.

Every reviewer is entitled to sporadic outbursts of favoritism. My favorite chapters in this book were "Coagulation and Fibrinolysis" and "The Localization of Granulomatous Diseases and Vasculitis," and, since they conform only vaguely to my special vascular enthusiasms, I still lay claim to relative objectivity. If I were to criticize any chapter, it would be the one entitled "The Management of Vasculitis," and the deficiencies there seem to be those of the art, not of the authors. This is a useful book; I doubt that it will come out in "paperback," so order it now.

JOHN E. WOLF, JR, MD
Houston

KENALOG® SPRAY
Triamcinolone Acetonide Aerosol N.F.

DESCRIPTION: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) provides 3.3 mg triamcinolone acetonide per 50 grams in an isopropyl palmitate vehicle with alcohol (4.7%) and propellants.

INDICATIONS: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) is indicated for relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS: Topical steroids are contraindicated in viral diseases of the skin, such as vaccinia and varicella, and in patients with a history of hypersensitivity to any product component. This preparation is not for ophthalmic use. Topical steroids shou not be used when circulation is markedly impaired.

WARNINGS: Usage in Pregnancy– Although topical steroids have not been reported to have an adverse effect on the fetus, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

PRECAUTIONS: Administer suitable antifungal or antimicrobial therapy if infection exists; if there is not a prompt, favorable response, discontinue the corticosteroid unti the infection has been adequately controlled Discontinue the drug and institute appropriate therapy if irritation develops. If extensive areas are treated or if the occlusive techniqu is used, the possibility exists of increased systemic absorption of the corticosteroid anc suitable precautions should be taken. When used about the face, the eyes should be covered and inhalation of the spray avoided.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids either with or without occlusive dressings: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, miliaria, hypertrichosis, acneform eruptions, maceration of the skin and hypopigmentation; contact sensitivity to a particular dressing material or adhesive may occur occasionally. Some patients (particularly those with very dry skin or dry lesions) may find the cooling effect of the spray objectionable or complain of a transient burning or stinging sensation.

For full prescribing information, consult package insert.

HOW SUPPLIED: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) is available in spray dispenser cans of 50 and 150 g. with adapter.

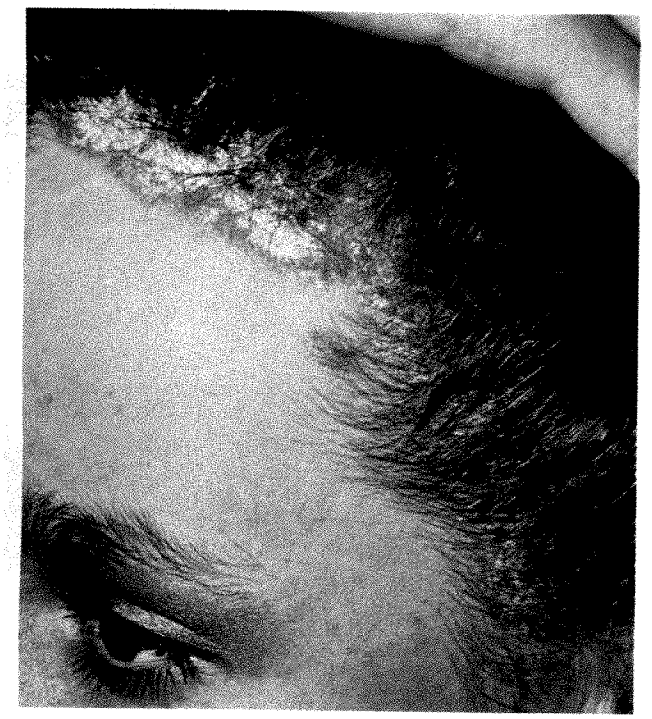
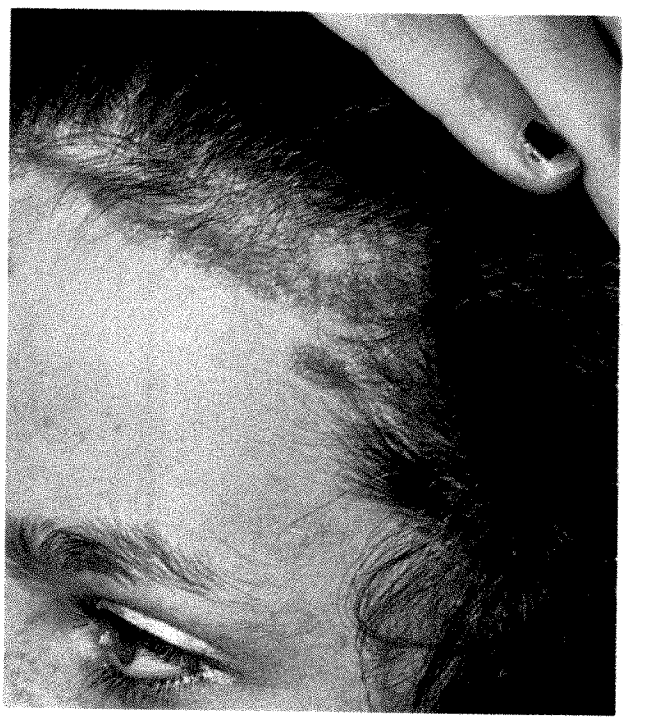
ANOTHER CASE FOR KENALOG®
TRIAMCINOLONE ACETONIDE

"INTRACTABLE" SCALP PSORIASIS



MARCH 4, 1977

A 15-year-old patient complaining of severe, intractable psoriasis of the scalp. Previous therapy with tar shampoo, keratolytic agents and fluorinated topical steroids had been unsuccessful. Because prior topical agents had been difficult to apply, Kenalog® Spray b.i.d. was prescribed.



AFTER 1 WEEK

Patient reported that pruritus had been relieved promptly. Marked improvement observed at this time: absence of scales, decrease in erythema and central clearing of plaques. Patient continuing on Kenalog® Spray b.i.d.
Case history on file at Squibb Institute for Medical Research.

A CASE FOR KENALOG® SPRAY

TRIAMCINOLONE ACETONIDE AEROSOL N.F.

See adjacent column for brief summary.

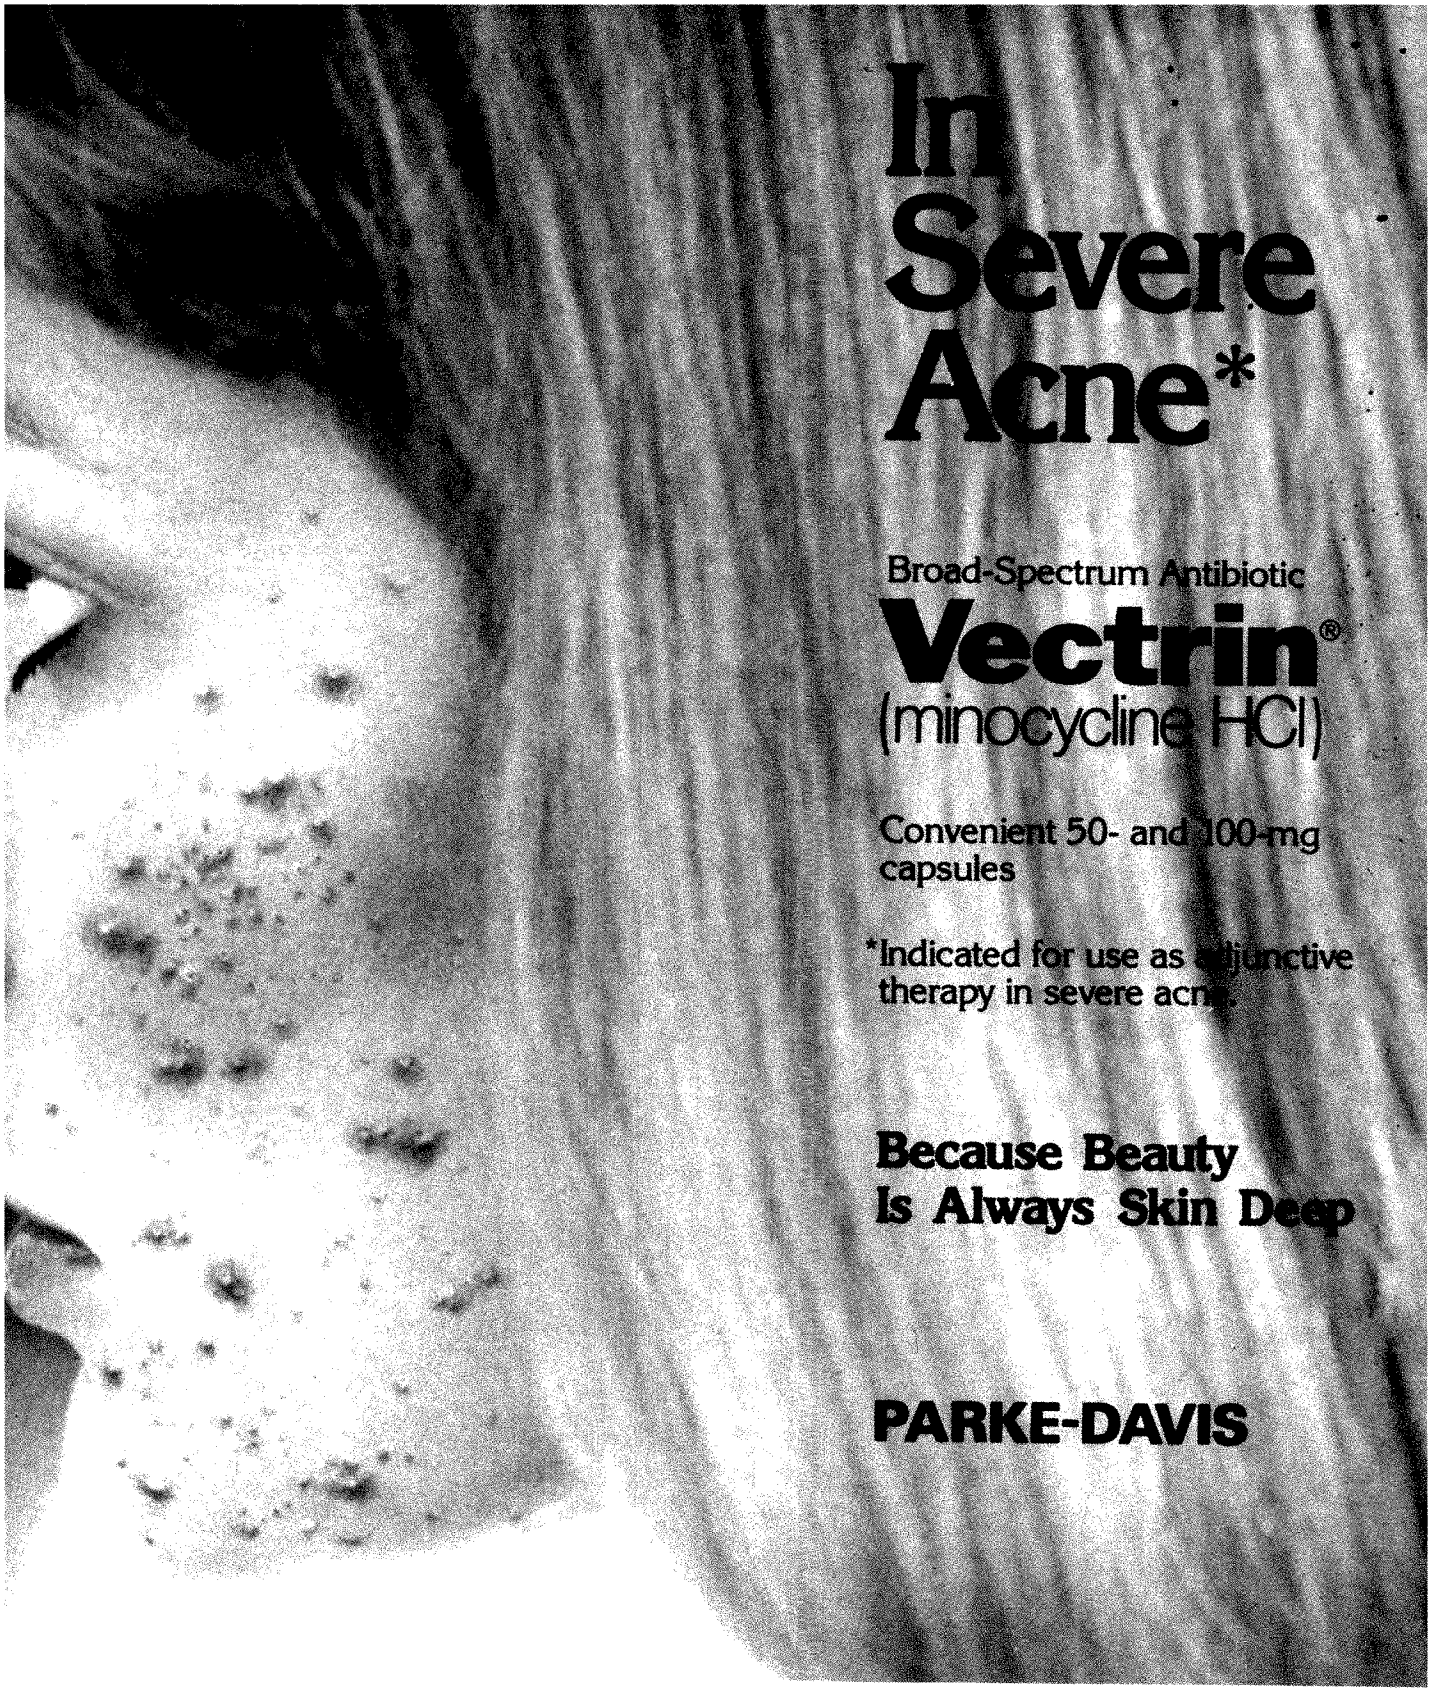
Acne illustrated by artist.

VECTRIN Capsules, 100 mg
(minocycline HCl capsules, USP)
Brief Summary of Prescribing Information

Indicated in severe acne as adjunctive therapy. Consult package insert for complete prescribing information.

Contraindication: Hypersensitivity to any tetracycline.

Warnings: When need for intensive treatment outweighs potential dangers, perform renal and liver function tests before and during therapy; also follow serum concentrations. In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, use lower total doses, and, in prolonged therapy, determine serum levels. The use of tetracyclines during tooth development (last half of pregnancy, infancy, and childhood to the age of 8 years) may cause permanent discoloration of the teeth (yellow-gray-brown). This is more common during long-term use but has been observed following repeated short-term courses. Enamel hypoplasia has also been reported. Tetracyclines, therefore, should not be used in this age group unless other drugs are not likely to be effective or are contraindicated. Photosensitivity manifested by an exaggerated sunburn reaction has been observed in some individuals taking tetracyclines. Advise patients apt to be exposed to direct sunlight or ultraviolet light that such reaction can occur, and discontinue treatment at first evidence of skin erythema. Studies with minocycline HCl indicated that photosensitivity did not occur. However, reports have been received. In patients with significantly impaired renal function, the antianabolic action of tetracycline may cause an increase in BUN leading to azotemia, hyperphosphatemia, and acidosis. **CNS side effects:** (light-headedness, dizziness, vertigo) have been reported, may disappear during therapy, and always disappear rapidly when drug is discontinued. Caution patients who experience these symptoms about driving vehicles or using hazardous machinery while taking this drug. **Pregnancy:** In animal studies, tetracyclines cross the placenta, are found in fetal tissues, and can have toxic effects on the developing fetus (often related to retardation of skeletal development). Embryotoxicity has been noted in animals treated early in pregnancy. The safety of minocycline HCl for use during pregnancy has not been established. **Newborns, infants, and children:** All tetracyclines form a stable calcium complex in any bone-forming tissue. Prematures, given oral doses of 25 mg/kg every six hours, demonstrated a decrease in fibula growth rate, reversible when drug was discontinued. Tetracyclines



In Severe Acne*

Broad-Spectrum Antibiotic

Vectrin®

(minocycline HCl)

Convenient 50- and 100-mg capsules

*Indicated for use as adjunctive therapy in severe acne.

Because Beauty Is Always Skin Deep

PARKE-DAVIS

are present in the milk of lactating women who are taking a drug in this class.

Precautions: Use may result in overgrowth of non-susceptible organisms, including fungi. If superinfection occurs, antibiotics should be discontinued and appropriate therapy instituted. In venereal diseases when coexistent syphilis is suspected, darkfield examination should be done before treatment is started and blood serology repeated monthly for at least four months. Patients on anticoagulant therapy may require downward adjustment of such dosage. Test for organ system dysfunction (eg, renal, hepatic, and hemopoietic) in long-term use. Treat all group A beta-hemolytic streptococcal infections for at least 10 days. Avoid giving tetracycline in conjunction with penicillin.

Adverse Reactions: GI: Anorexia, nausea, vomiting, diarrhea, glossitis, dysphagia, enterocolitis, inflammatory lesions (with monilial overgrowth) in anogenital region. **Skin:** Maculopapular and erythematous rashes. Exfoliative dermatitis (uncommon). Photosensitivity is discussed above. (See Warnings.) **Renal toxicity:** Rise in BUN, dose-related. (See Warnings.) **Hypersensitivity reactions:** Urticaria, angioneurotic edema, anaphylaxis, anaphylactoid purpura, pericarditis, exacerbation of systemic lupus erythematosus. In young infants, bulging fontanels have been reported following full therapeutic dosage, disappearing rapidly when drug was discontinued. **Blood:** Hemolytic anemia, thrombocytopenia, neutropenia, eosinophilia. **CNS:** (See Warnings.) When given over prolonged periods, tetracyclines may produce brown-black microscopic discoloration of thyroid glands; no abnormalities of thyroid function studies are known to occur.

NOTE: Concomitant therapy: Antacids containing aluminum, calcium, or magnesium impair absorption; do not give to patients taking oral tetracycline. Studies to date indicate that absorption of VECTRIN (minocycline hydrochloride) is not notably influenced by foods and dairy products.

Full prescribing information available upon request.

PARKE, DAVIS & COMPANY
Detroit, Michigan 48232

Gets to deep fungal infections

Actual photograph of tinea unguium infection (onychomycosis).
Note typical worm-eaten appearance of fingernail destroyed by fungus.

when topicals can't.

Potent, systemic fungistat

GRISACTIN provides the antifungal activity needed to control tinea infections, including onychomycosis, that invade the dermis and deeper regions. Systemic action penetrates where topical action often fails.

GRISACTIN is effective against a wide range of fungi: *Trichophyton rubrum, T. mentagrophytes, T. tonsurans, T. interdigitalis, T. verrucosum, T. megnini, T. gallinae, T. crateriform, T. sulphureum, T. schoenleini, Microsporum canis, M. audouini, M. gypseum,* and *Epidermophyton floccosum.*

Peak serum levels are usually produced in about four hours with a single 500 mg. tablet. To meet the requirements of different patients—depending on body weight, age, severity, and location of infection—dosage is easily individualized with 125 mg. and 250 mg. capsules, and 500 mg. tablets.

Grisactin® 500

BRAND OF

griseofulvin (microsize) TABLETS

BRIEF SUMMARY
(For full prescribing information, see package circular.)

Grisactin®
brand of
griseofulvin (microsize)

Indications: Griseofulvin is indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: *Tinea corporis, Tinea pedis, Tinea cruris, Tinea barbae, Tinea capitis, Tinea unguium* (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, T. tonsurans, T. mentagrophytes, T. interdigitalis, T. verrucosum, T. megnini, T. gallinae, T. crateriform, T. sulphureum, T. schoenleini, Microsporum audouini, M. canis, M. gypseum, Epidermophyton floccosum.*
NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.
The use of this drug is not justified in minor or superficial infections which will respond to topical agents alone.
Griseofulvin is *not* effective in the following: Bacterial infections, candidiasis (moniliasis), histoplasmosis, actinomycosis, sporotrichosis, chromoblastomycosis, coccidioidomycosis, North American blastomycosis, cryptococcosis (torulosis), *Tinea versicolor,* nocardiosis.

Contraindications: This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of hypersensitivity to griseofulvin.

Warnings: *Prophylactic Usage*—Safety and efficacy of griseofulvin for prophylaxis of fungal infections has not been established.
Animal Toxicology—Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorigenicity, these studies were not of adequate design to form a basis for conclusions in this regard.
In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.
Usage in Pregnancy—The safety of this drug during pregnancy has not been established.
Animal Reproduction Studies—It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.
Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.

Precautions: Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic, and hematopoietic, should be done.
Since griseofulvin is derived from a species of Penicillium, the possibility of cross-sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.
Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.
Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.
Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.

Adverse Reactions: When adverse reactions occur, they are most commonly of the hypersensitivity type such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities.
Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs.
When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

Dosage and Administration: Accurate diagnosis of the infecting organism is essential. Medication must be continued until the infecting organism is completely eradicated as indicated by appropriate clinical or laboratory examination. General measures in regard to hygiene should be observed to control sources of infection or reinfection. Concomitant use of appropriate topical agents is usually required, particularly in treatment of *tinea pedis.*
Dosage should be individualized, depending on age and severity of infection. *Adults*—0.5 Gm. daily (125 mg. q.i.d., 250 mg. b.i.d., or 500 mg./day). *Children*—10 mg./kg. daily is usually adequate (from 30 to 50 lb., 125 mg. to 250 mg. daily; over 50 lb., 250 mg. to 500 mg. daily, in divided doses).

How Supplied: GRISACTIN [griseofulvin (microsize)]—No. 442—GRISACTIN 125, each capsule contains 125 mg., in bottles of 100 and 500. No. 443—GRISACTIN 250, each capsule contains 250 mg., in bottles of 100 and 500. No. 444—GRISACTIN 500, each tablet (scored) contains 500 mg., in bottles of 60.

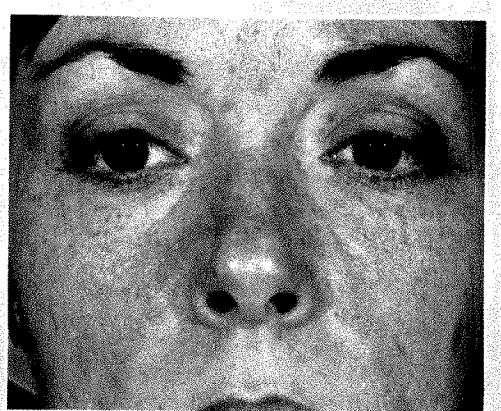
While every precaution is taken to insure accuracy, we cannot guarantee against the possibility of an

When the fluorinated steroid is gone–



Problems such as striae, or dermal atrophy leading to telangiectasia and fragility, especially on the face, in the groin, anal or axillary areas may be the result.

Consider Starting with Hytone® 2.5% (hydrocortisone)

For rapid control of the majority of inflammatory dermatitides seen in office practice.

Followed by–Hytone® 1% or 0.5%

for maintenance therapy and ultimate control– especially on the face or in children.

Hytone®–the conservative but effective approach

HYTONE® CREAM (hydrocortisone)

DESCRIPTION: Hydrocortisone 2½%, 1% and ½% in a water-washable cream containing purified water, propylene glycol, isopropyl myristate, cholesterol and related sterols, cetyl alcohol, sorbic acid, glyceryl monostearate, polysorbate 60, sorbitan monostearate and polyoxyl 40 stearate. ACTIONS: Topical corticosteroids are effective primarily because of their anti-inflammatory, antipruritic, and vasoconstrictive actions. INDICATIONS: For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses. CONTRAINDICATIONS: In viral diseases of the skin such as varicella and vaccinia and in patients with a history of hypersensitivity to any component. Not for ophthalmic use. Topical steroids should not be used when circulation is markedly impaired. WARNING: Should not be used extensively, in large amounts, or for prolonged periods in pregnancy. PRECAUTIONS: If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids, either with or without occlusive dressings: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation. DOSAGE AND ADMINISTRATION: Apply to affected areas 3 or 4 times daily. HOW SUPPLIED: Cream 2½%—Tubes ½ oz. and 1 oz. Cream 1% and ½%—Tube 1 oz. and Jar 4 oz. CAUTION: Federal law prohibits dispensing without prescription.

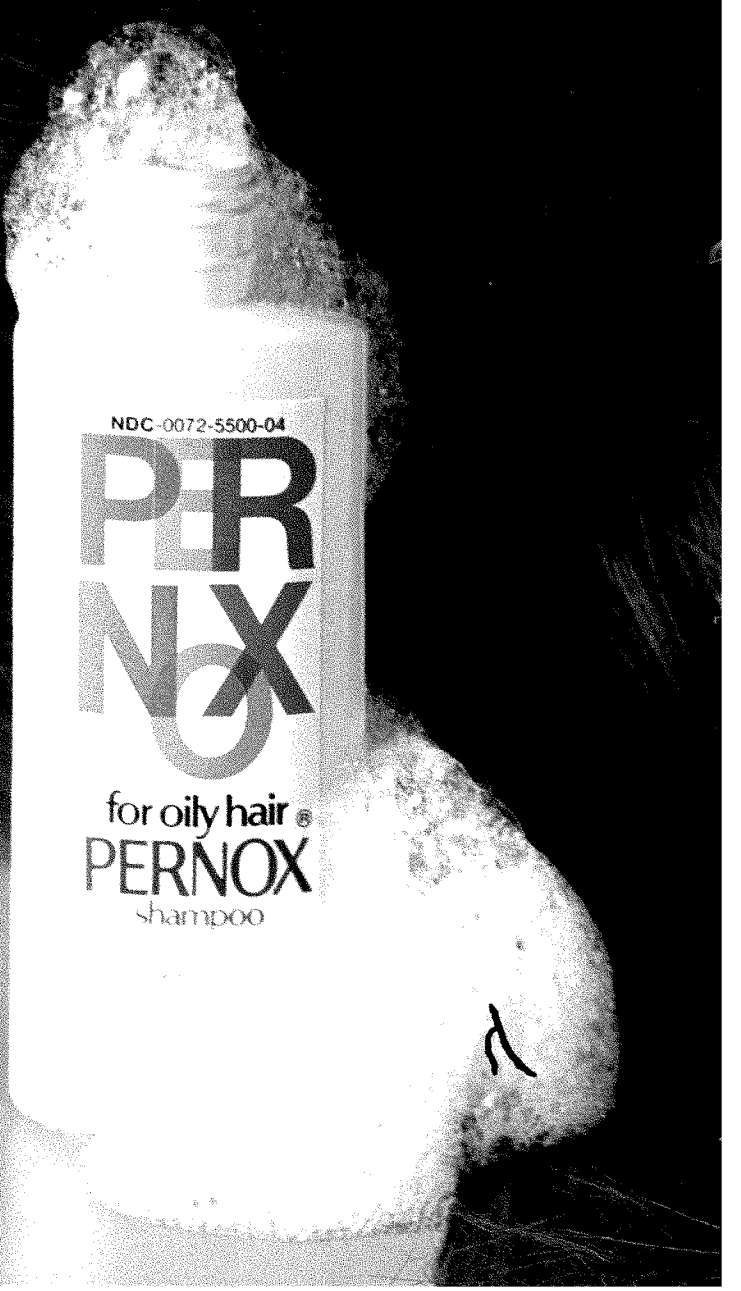
CONTEMPORARY AND EFFECTIVE

For seborrhea oleosa and the oily hair and scalp associated with acne



- Thorough cleansing of oily hair and scalp.
- Leaves patients' hair soft, manageable, fresh smelling.
- Elegant herbal scented shampoo.
- A special formulation designed to cleanse and condition oily hair.
- Its pH of 5.5 is gentle to the scalp.
- Can be used as often as necessary, preferably every day, to keep hair looking fresh and healthy.
- CONTAINS NO FORMALDEHYDE.

Supplied: 4 oz. and 8 oz. plastic bottles.

Pernox Shampoo® is adjunctive therapy especially formulated for oily scalps associated with acne.

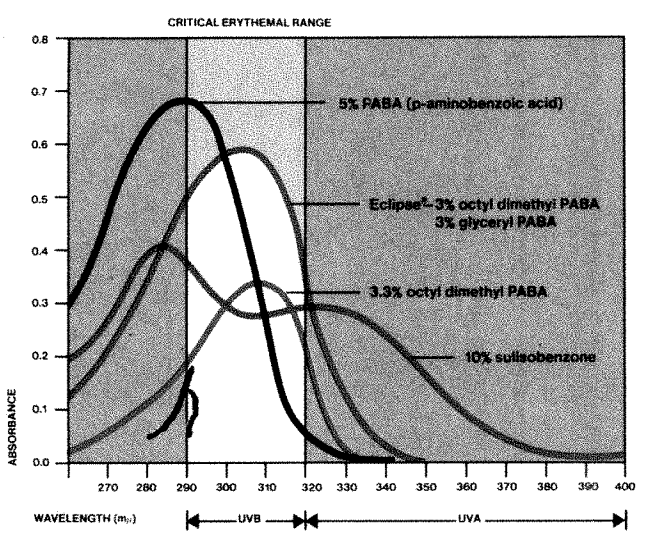
ECLIPSE®

(3% glyceryl PABA and 3% octyl dimethyl PABA)

For your patients

who can't-or won't-stay out of the sun.

For some, it's occupation. For others, the social desirability of a tan. Whatever the reason, many of your patients may be spending more time in the sun than you'd like.



Unique Eclipse formulation combines two PABA derivatives for maximum UVB absorption.

They need Eclipse—a highly effective sunscreen that works immediately upon application, resists wash-off, and contains our exclusive Aquacare® base to help relieve sun and wind-dried skin.

Can other sunscreens do all that? Take a minute to read the labels: we're confident you'll recommend Eclipse.

- Absorbs more than 99% of erythemogenic solar UVB.
- Spreads smoothly and predictably for even protection.
- Permits slow tanning.
- Resists wash-off; protects after swimming or sweating.
- Formulated in Aquacare® to relieve sun and wind-dried skin.

The cosmetically acceptable infection fighter

NEOSPORIN®G Cream

(polymyxin B-neomycin-gramicidin)

Each gram contains Aerosporin® brand Polymyxin B Sulfate 10,000 units; neomycin sulfate 5 mg (equivalent to 3.5 mg neomycin base); gramicidin 0.25 mg. Inactive ingredients: liquid petrolatum, white petrolatum, purified water, propylene glycol, polyoxyethylene polyoxypropylene compound, emulsifying wax, and 0.25% methylparaben as preservative.

NEOSPORIN®G Cream
(polymyxin B-neomycin-gramicidin)

When topical infection invades hairy areas, facial skin or intertriginous areas, Neosporin®G Cream provides broad antibacterial coverage. It contains three antibiotics that combat virtually all pathogenic bacteria found topically.*

These antibiotics are seldom used systemically, so the patient is spared the possibility of sensitization to those antibiotics which might later be required systemically.

Smooth vanishing cream base leaves no greasy residue on skin, no stains on fabric.

Wellcome / **Burroughs Wellcome Co.**
Research Triangle Park
North Carolina 27709

*INDICATIONS: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows: "Possibly" effective: For topical administration for the treatment of the listed localized infections or for suppressive therapy in such conditions: • primary pyodermas (impetigo, ecthyma, sycosis vulgaris, paronychia) • secondary infected dermatoses (eczema, herpes, and seborrheic dermatitis) • traumatic lesions (inflamed or suppurating as a result of bacterial infection).

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS: Not for use in the eyes or in the external ear canal if the eardrum is perforated. This product is contraindicated in those individuals who have shown hypersensitivity to any of its components.

WARNING: Because of the potential hazard of nephrotoxicity and ototoxicity due to neomycin, care should be exercised when using this product in treating extensive burns, trophic ulceration and other extensive conditions where absorption of neomycin is possible. In burns where more than 20 percent of the body surface is affected, especially if the patient has impaired renal function or is receiving other aminoglycoside antibiotics concurrently, not more than one application a day is recommended.

When using neomycin-containing products to control secondary infection in the chronic dermatoses, such as chronic otitis externa or stasis dermatitis, it should be borne in mind that the skin in these conditions is more liable than is normal skin to become sensitized to many substances, including neomycin. The manifestation of sensitization to neomycin is usually a low grade reddening with swelling, dry scaling and itching; it may be manifest simply as failure to heal. During long-term use of neomycin-containing products, periodic examination for such signs is advisable and the patient should be told to discontinue the product if they are observed. These symptoms regress quickly on withdrawing the medication. Neomycin-containing applications should be avoided for that patient thereafter.

PRECAUTIONS: As with other antibacterial preparations, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs.

ADVERSE REACTIONS: Neomycin is a not uncommon cutaneous sensitizer. Articles in the current literature indicate an increase in the prevalence of persons allergic to neomycin. Ototoxicity and nephrotoxicity have been reported (see Warning section).

HOW SUPPLIED: Tube of 15 g.

SUBSCRIPTION RATES: The yearly rate of the ARCHIVES OF DERMATOLOGY is as follows: United States and US Possessions, one year, $18; two years, $28; all other countries, one year, $28; two years, $38. Special yearly price to residents, interns and medical students in the United States and US Possessions, $9.

THE ARCHIVES OF DERMATOLOGY is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

Selsun®
(SELENIUM SULFIDE LOTION, U.S.P.) ℞

Brief Summary

Contains:
Selenium sulfide, 2½%, w/v; bentonite; lauric diethanolamide; ethylene glycol monostearate; titanium dioxide; amphoteric—2; sodium lauryl sulfate; sodium phosphate (monobasic); glyceryl monoricinoleate; citric acid; captan; perfume; and water.

Indications:
For the treatment of dandruff and seborrheic dermatitis of the scalp.

Contraindications:
Should not be used by patients allergic to any of its components.

Warnings:
Safety for use on infants has not been established.

Precautions:
Cutaneous sensitization of the scalp or adjacent areas has been reported; if sensitivity reactions should occur, discontinue use. Chemical conjunctivitis may result if product enters the eyes. Do not use when acute inflammation or exudation is present as an increase in absorption may occur.

Adverse Reactions:
As with other shampoos, oiliness or dryness of the hair and scalp may occur following use; there have been occasional reports of an increase in the amount of normal hair loss. Hair discoloration may occur; can be avoided or minimized by thorough rinsing.

Conditions for Acceptance of Color Illustrations

Illustrations in full color are accepted for publication in ARCHIVES OF DERMATOLOGY if the editor believes that color will add significantly to the published manuscript.

When color illustrations are accepted, the American Medical Association will pay part of the expense of reproduction and printing, the remainder to be borne by the author or the institution with which he is affiliated. After deducting AMA's contribution, the author's share is $275 for up to six square finished illustrations. Additional illustrations and special effects, such as outlining, opaquing, or surprinting, will be billed to the author at cost.

Color transparencies must be submitted for evaluation. Do not send color prints unless accompanied by original transparencies. If transparencies are mounted in frames or glass, the material should be carefully packed in gauze and sent with the manuscript in a separate container or between two pieces of pressboard.

Advertising and Subscription Information

ADVERTISING OFFICES: 535 N Dearborn St, Chicago, IL 60610, Area Code 312, 751-6000; and 600 Third Ave, New York, NY 10016, Area Code 212-867-6640.

ADVERTISING PRINCIPLES: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

CHANGE OF ADDRESS: Please notify the publisher at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

AZTEC® SUNSCREEN LOTION.

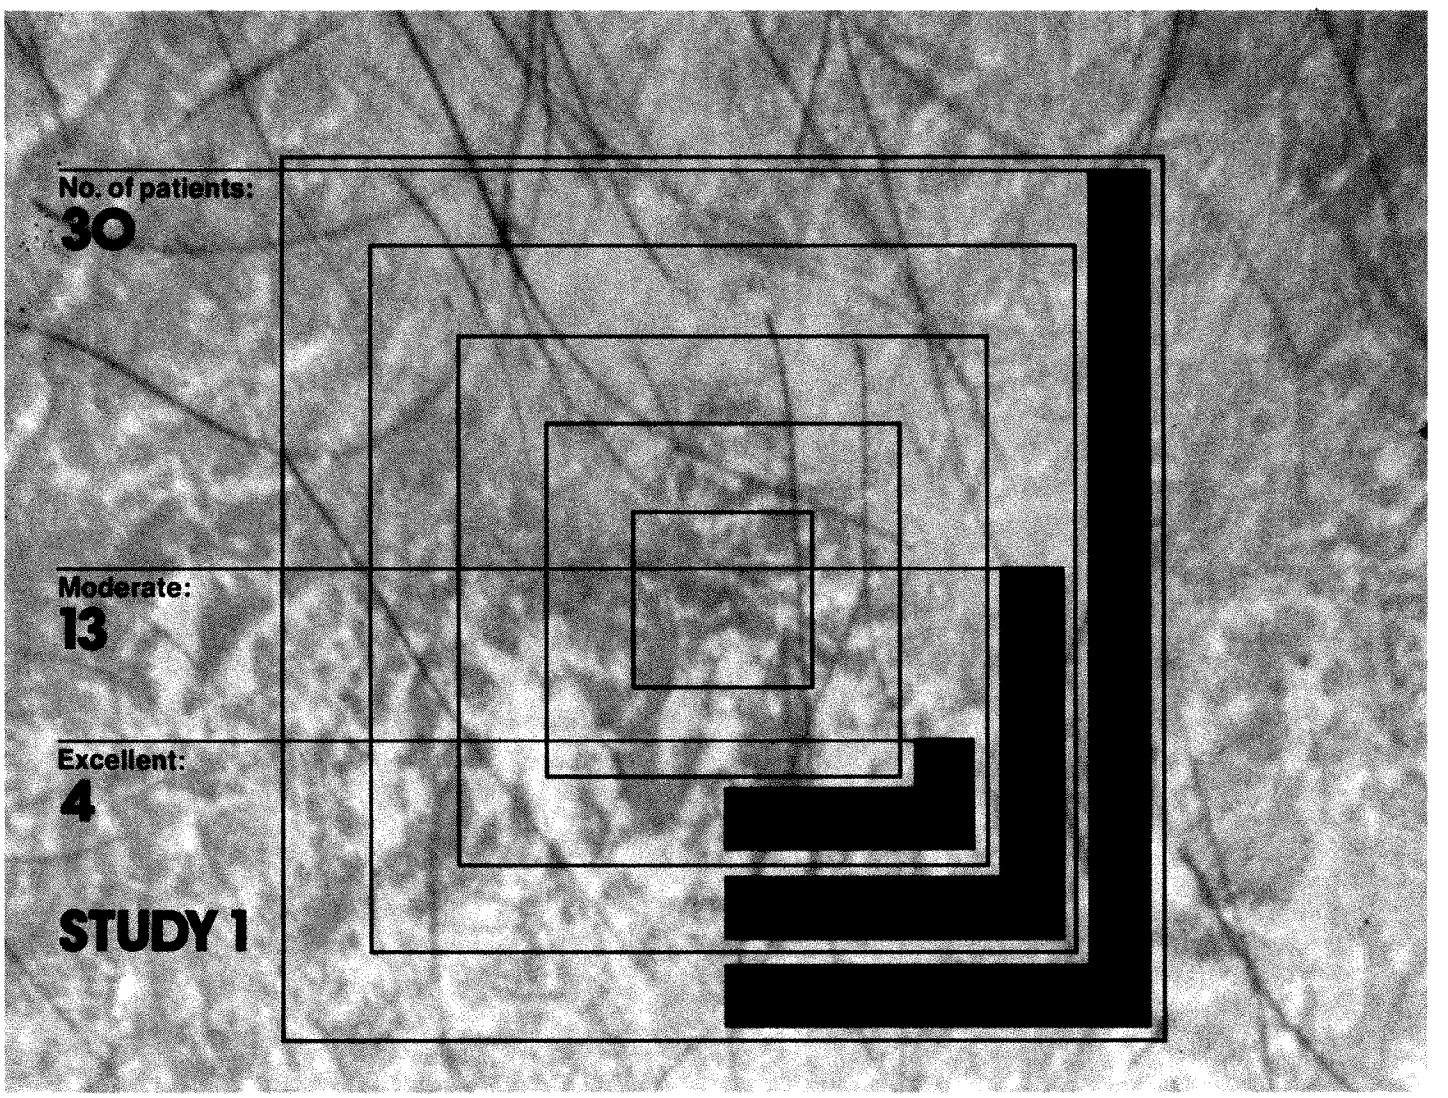
Protects better because it stays on longer. Even after swimming.

Almost all professional sunscreen products protect against overexposure to the sun. Aztec does it with two complementary sunscreening agents for full coverage in the critical 280-315 nm range.

Maintaining protection during activity is another matter altogether. Swimming, perspiration, even toweling can easily wipe other lotions away, leaving your sun-sensitive patients exposed.

Only Aztec contains a patented acrylate polymer base which forms an umbrella-like matrix on the skin. This matrix holds both sunscreening agents on the skin for maximum protection...inhibits the loss of protection caused by swimming, evaporation or wiping away.

New measures of response in psoriasis patients



ARISTOCORT-A (Triamcinolone Acetonide 0.1%) Cream was applied t.i.d. without occlusion for 14 days, by a total of 60 patients with psoriasis, in 2 similar studies.*

The % of moderate or excellent response was 57% in Study 1 and 50% in Study 2. A combined overall response rate of 90% was achieved if 22 patients showing slight response are included.*

■ Overall patient acceptance of the Cream in both these studies was high, when evaluated against 10 criteria.

Data on file. Lederle Laboratories. Dept. of Medical Research

New studies show 50-57% moderate or excellent response in 14 days

INDICATIONS: For relief of inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS: Viral skin diseases, such as varicella and vaccinia; hypersensitivity to any component (not for ophthalmic use); when circulation is markedly impaired.

WARNINGS: Safety of use in pregnancy has not been absolutely established. Do not use extensively, in large amounts, or for prolonged periods of time in pregnant patients.

PRECAUTIONS: If irritation develops, discontinue use and institute appropriate therapy. In infections, use appropriate antifungal or antibacterial agents; if a favorable response does not occur promptly, discontinue the corticosteroid until the infection is adequately controlled. If extensive areas are treated or the occlusive technique is used, increased systemic absorption of the corticosteroid may occur; take suitable precautions.

ADVERSE REACTIONS: (local) Burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.

ARISTOCORT A CREAM: Each gram of ARISTOCORT A contains 0.25 mg. (0.05%), 1 mg. (0.1%) or 5 mg. (0.5%) of the highly active steroid, Triamcinolone Acetonide (a derivative of triamcinolone) in AQUATAIN, a specially formulated base composed of emulsifying wax NF, isopropyl palmitate, glycerin USP, sorbitol solution USP, lactic acid, 2% benzyl alcohol and purified water. AQUATAIN is non-staining, water-washable, paraben-free, spermaceti-free and has a light texture and consistency.

ARISTOCORT A OINTMENT: Each gram of ARISTOCORT A Ointment contains 1 mg. (0.1%) or 5 mg. (0.5%) of the highly active steroid, Triamcinolone Acetonide (a derivative of triamcinolone) in a specially formulated base composed of emulsifying wax NF, white petrolatum, and propylene glycol. In addition, the 0.1% Ointment contains Tenox II and lactic acid.

Instructions for Authors

Send manuscripts by first-class mail to the Chief Editor, John H. Epstein, MD, 450 Sutter St, San Francisco, CA 94108. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

Author Responsibility.—All accepted manuscripts are subject to copy editing. The author will receive an edited typescript rather than galley proofs for approval. The author is responsible for all statements in his work, including changes made by the copy editor.

Designate one author as correspondent and provide his address and telephone number. Order reprints at the time the typescript is returned after editorial processing. Specify address to which requests for reprints should be sent.

Manuscript Preparation.—Submit an original typescript and two high-quality copies of the entire manuscript. All copy (including references, legends, and tables) must be typed double-spaced on 22 × 28-cm (8½ × 11-inch), heavy-duty white bond paper. Ample margins should be provided.

Refer to patients by number (or, in anecdotal reports, by fictitious given names). Real names or initials should not be used in the text, tables, or illustrations.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines, if possible. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Style of Writing.—The style of writing should conform to acceptable English usage and syntax. Slang, medical jargon, obscure abbreviations, and abbreviated phrasing are to be avoided.

Informed Consent.—Manuscripts reporting the results of experimental investigations of human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Abstract.—Provide an abstract (135-word maximum) of the article, including statements of the problem, method of study, results, and conclusions. The abstract replaces the summary.

References.—List references in consecutive numerical order (not alphabetically). Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communications should not be listed as references. References to journal articles should include (1) author, (2) title, (3) journal name (as abbreviated in *Index Medicus*), (4) volume number, (5) inclusive page numbers, and (6) year, in that order. References to books should include (1) author(s), (2) chapter title (if any), (3) editor (if any), (4) title of book, (5) city of publication, (6) publisher, and (7) year. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. The author is responsible for the accuracy and completeness of the references and for their correct text citation.

Metrication.—All measurements must be in metric units. English units may also be given parenthetically if the measurements were originally done in English units.

Illustrations.—Use only those illustrations that clarify and augment the text. Submit illustrations in duplicate, unmounted and unrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Magnification and stain should be provided when pertinent. Illustrations should preferably be in a proportion of 12.5 × 18 cm (5 × 7 inches).

An experienced medical illustrator should be employed whenever possible for the preparation of all artwork. Template lettering or preset type is preferred to hand-lettered labels. If halftone artwork with labels is submitted, affix type and leaders to a clear acetate overlay registered to the base drawing. Labels and leaders should be applied directly to the drawing board surface if the artwork consists only of line ink technique.

Illustrations in full color are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay part of the expense of reproduction and printing color illustrations, the remainder to be borne by the author or his sponsor. After deducting the ARCHIVES contribution, the author's share is $275.00 for up to six square-finished illustrations that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35 mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies. All transparencies should be carefully packed and sent with the manuscript.

Legends.—Legends should be typed double-spaced, beginning on a separate sheet of paper. Length should be limited to a maximum of 40 words.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: author(s), title of article, title of journal or book, volume number, page(s), month, and year. The publisher's permission to reprint should be submitted to the ARCHIVES after the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluations should include the name and affiliation of the statistical reviewer.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm (8½ × 11-inch) paper. Do not use larger size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

New fast way with spray
for contact dermatitis control

New Diprosone® Aerosol 0.1%
brand of
betamethasone dipropionate (Potency expressed as betamethasone)

Rapid improvement of moderate to very severe contact dermatitis signs/symptoms*

	Per cent of patients improved†		
	Pruritus 129 patients	**Erythema 129 patients**	**Vesiculation 77 patients**
After 3 days	**85%**	**78%**	**82%**
After 7 days	**92%**	**93%**	**94%**

*Improvement is defined as a reduction of signs or symptoms. †Data in files of Headquarters Medical Research Division, Schering Corporation.

- Easily penetrates hairy areas...convenient for hard-to-reach sites.
- Cools and soothes hot, oozing, itching lesions.
- Cosmetically elegant...invisible, odorless, stainless.

Diprosone is also available in cream, ointment, and lotion.

See Clinical Considerations section on opposite page...

Schering

New Diprosone®

brand of
betamethasone
dipropionate
Aerosol 0.1%

Clinical Considerations: INDICATIONS DIPROSONE Aerosol is indicated solely for the adjunctive topical management for the relief of inflammatory manifestations of acute contact dermatitis. DIPROSONE Aerosol has not been shown to be effective in any steroid-responsive dermatosis other than contact dermatitis. **CONTRAINDICATIONS** DIPROSONE Aerosol is contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of such preparations. DIPROSONE Aerosol is also contraindicated for use under occlusive dressings. **WARNINGS** Keep away from eyes or other mucous membranes. Use only as directed; intentional misuse by deliberately concentrating or inhaling the contents can be harmful or fatal. Avoid freezing of the tissue by not spraying for more than three seconds, at a distance of not less than six inches. Contents under pressure. Do not puncture. Do not use or store near heat or open flame. Exposure to temperatures above 120° Fahrenheit may cause bursting. Never throw container into fire or incinerator. Keep out of reach of children. **PRECAUTIONS** If irritation develops with the use of DIPROSONE Aerosol, treatment should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been absolutely established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time. DIPROSONE Aerosol is not for ophthalmic use. **ADVERSE REACTIONS** The following local adverse reactions have been reported with topical corticosteroids: burning; itching; irritation; dryness; folliculitis; hypertrichosis; acneiform eruptions; hypopigmentation; maceration of the skin; secondary infection; skin atrophy; striae; miliaria.

FDA soon to approve fat emulsions for clinical use!
Prepare yourself with this new AMA book...

Fat Emulsions in Parenteral Nutrition

A digest of the latest important research findings

FAT EMULSIONS IN PARENTERAL NUTRITION, the proceedings of the June, 1975 meeting sponsored by the Department of Foods and Nutrition and the Nutrition Advisory Group of the AMA, will provide you with a review of experimental and clinical studies and discussions of problems encountered with the use of fat emulsions.

Divided into three sections, the book covers the metabolism of fatty acids and function of essential fatty acids with information on EFA deficiency; fat as an energy source; and the pathophysiology with discussions on side effects, interrelations with other nutrients, and the current status of products available.

To avoid potential problems and to become thoroughly acquainted with the intricacies of this about-to-be-approved nutritional supplement, every hospital physician, nurse and pharmacist should make this publication required reading.

Order Dept. OP-140, AMA, 535 N. Dearborn St., Chicago, Ill. 60610

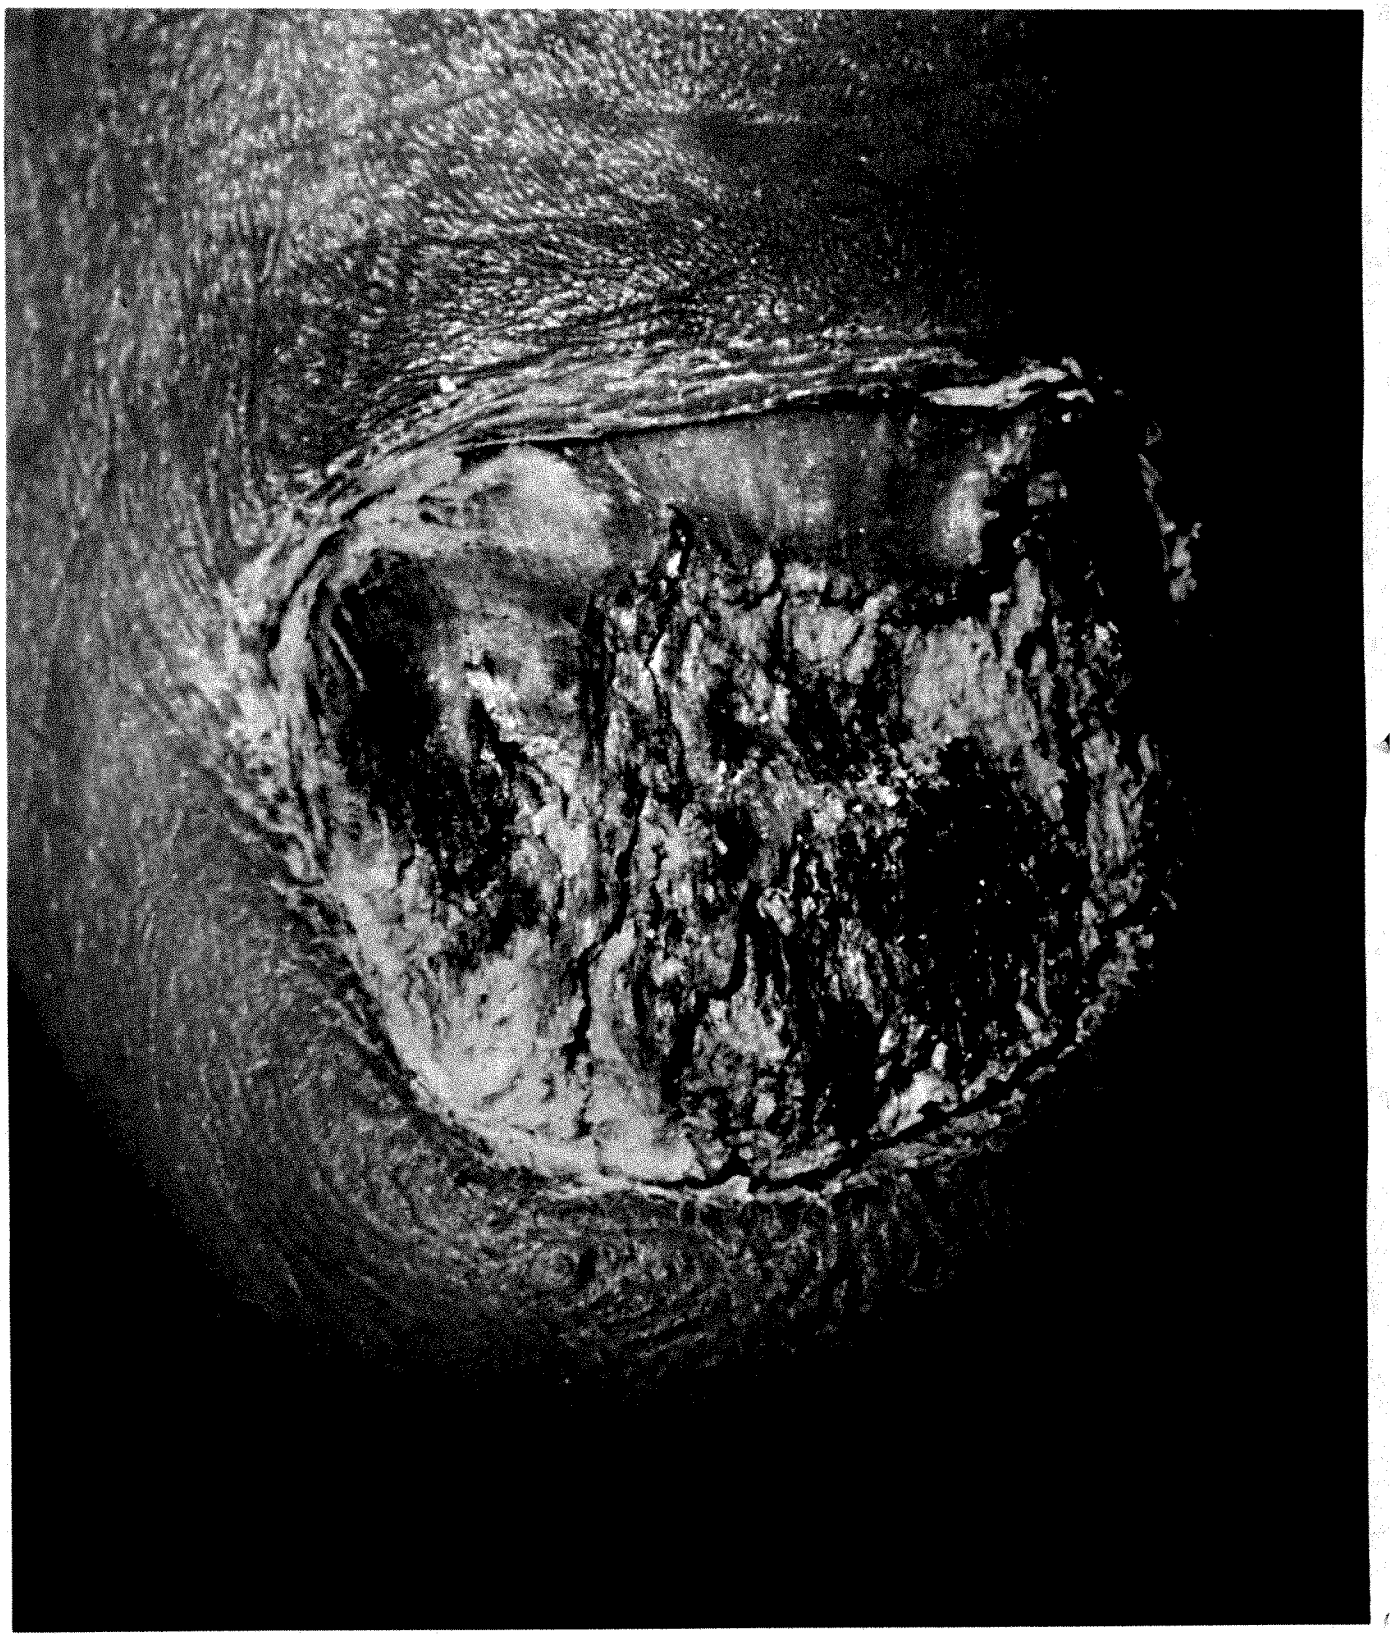
Gets to deep fungal infections



Actual photograph of tinea unguium infection (onychomycosis).
Note typical worm-eaten appearance of fingernail destroyed by fungus.

when topicals can't.

Potent, systemic fungistat

GRISACTIN provides the antifungal activity needed to control tinea infections, including onychomycosis, that invade the dermis and deeper regions. Systemic action penetrates where topical action often fails.

GRISACTIN is effective against a wide range of fungi: *Trichophyton rubrum, T. mentagrophytes, T. tonsurans, T. interdigitalis, T. verrucosum, T. megnini, T. gallinae, T. crateriform, T. sulphureum, T. schoenleini, Microsporum canis, M. audouini, M. gypseum,* and *Epidermophyton floccosum.*

Peak serum levels are usually produced in about four hours with a single 500 mg. tablet. To meet the requirements of different patients—depending on body weight, age, severity, and location of infection—dosage is easily individualized with 125 mg. and 250 mg. capsules, and 500 mg. tablets.

Grisactin® 500

BRAND OF

griseofulvin (microsize) TABLETS

BRIEF SUMMARY
(For full prescribing information, see package circular.)

Grisactin®
Brand of
Griseofulvin (microsize)

Indications: Griseofulvin is indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: *Tinea corporis, Tinea pedis, Tinea cruris, Tinea barbae, Tinea capitis, Tinea unguium* (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, T. tonsurans, T. mentagrophytes, T. interdigitalis, T. verrucosum, T. megnini, T. gallinae, T. crateriform, T. sulphureum, T. schoenleini, Microsporum audouini, M. canis, M. gypseum, Epidermophyton floccosum.*
NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.
The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone.
Griseofulvin is *not* effective in the following: Bacterial infections, candidiasis (moniliasis), histoplasmosis, actinomycosis, sporotrichosis, chromoblastomycosis, coccidioidomycosis, North American blastomycosis, cryptococcosis (torulosis), *Tinea versicolor,* nocardiosis.
Contraindications: This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of hypersensitivity to griseofulvin.
Warnings: *Prophylactic Usage*—Safety and efficacy of griseofulvin for prophylaxis of fungal infections has not been established.
Animal Toxicology—Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorigenicity, these studies were not of adequate design to form a basis for conclusions in this regard.
In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.
Usage in Pregnancy—The safety of this drug during pregnancy has not been established.
Animal Reproduction Studies—It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.
Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.
Precautions: Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic, and hematopoietic, should be done.
Since griseofulvin is derived from a species of Penicillium, the possibility of cross-sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.
Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.
Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.
Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.
Adverse Reactions: When adverse reactions occur, they are most commonly of the hypersensitivity type such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities.
Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs.
When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.
Dosage and Administration: Accurate diagnosis of the infecting organism is essential. Medication must be continued until the infecting organism is completely eradicated as indicated by appropriate clinical or laboratory examination. General measures in regard to hygiene should be observed to control sources of infection or reinfection. Concomitant use of appropriate topical agents is usually required, particularly in treatment of *tinea pedis.*
Dosage should be individualized, depending on age and severity of infection. *Adults*—0.5 Gm. daily (125 mg. q.i.d., 250 mg. b.i.d., or 500 mg./day). *Children*—10 mg./kg. daily is usually adequate (from 30 to 50 lb., 125 mg. to 250 mg. daily; over 50 lb., 250 mg. to 500 mg. daily, in divided doses).
How Supplied: GRISACTIN [griseofulvin (microsize)]—No. 442—GRISACTIN 125, each capsule contains 125 mg., in bottles of 100 and 500. No. 443—GRISACTIN 250, each capsule contains 250 mg., in bottles of 100 and 500. No. 444—GRISACTIN 500, each tablet (scored) contains 500 mg., in bottles of 60.

Diprosone®
brand of
betamethasone dipropionate
Cream 0.05%
(Potency expressed as betamethasone)

Twice a day for prompt relief of corticosteroid-responsive dermatoses

In contact dermatitis

90% of patients showed marked or moderate improvement in seven days*
34 of 38 contact dermatitis patients responded to therapy.

In atopic dermatitis

86% of patients showed marked or moderate improvement in seven days*
133 of 155 atopic dermatitis patients responded to therapy.

In psoriasis

62% of patients showed marked or moderate improvement in only seven days*
116 of 188 psoriasis patients responded to therapy.

Additional benefits:

- Rapid onset of response.
- Economy and convenience of b.i.d. dosage.
- Occlusive dressings infrequently needed.
- Sensitivity is rare.
- Choice of convenient package sizes—in 15 Gm. and moneysaving 45 Gm. tubes.

Diprosone® brand of betamethasone dipropionate
Cream 0.05%/Ointment 0.05%

Clinical Considerations:

DESCRIPTION DIPROSONE is betamethasone dipropionate (9-fluoro-11β, 17,21-trihydroxy-16β-methylpregna-1,4-diene-3,20-dione 17,21-dipropionate). Each gram of DIPROSONE **Cream** 0.05% contains 0.64 mg. betamethasone dipropionate (equivalent to 0.5 mg. betamethasone) in a hydrophilic, emollient cream consisting of purified water, mineral oil, white petrolatum, polyethylene glycol 1000 monocetyl ether, cetostearyl alcohol, phosphoric acid, and monobasic sodium phosphate with 4-chloro-*m*-cresol as preservative. Each gram of DIPROSONE **Ointment** 0.05% contains 0.64 mg. betamethasone dipropionate (equivalent to 0.5 mg. betamethasone) in an ointment base of mineral oil and white petrolatum. **CONTRAINDICATIONS** DIPROSONE **Cream** and **Ointment** are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of such preparations. **PRECAUTIONS** If irritation develops with the use of DIPROSONE **Cream** or **Ointment,** treatment should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been absolutely established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time. DIPROSONE **Cream** and **Ointment** are not for ophthalmic use. **ADVERSE REACTIONS** The following local adverse reactions have been reported with topical corticosteroids: burning; itching; irritation; dryness; folliculitis; hypertrichosis; acneiform eruptions; hypopigmentation. The following may occur more frequently with occlusive dressings than without such therapy: maceration of the skin; secondary infection; skin atrophy; striae; miliaria. **DOSAGE AND ADMINISTRATION** Apply a thin film of DIPROSONE **Cream** to the affected skin areas twice daily, in the morning and at night. Clinical studies of DIPROSONE have indicated that applications twice a day are generally adequate. Apply a small quantity of DIPROSONE **Ointment** to the affected skin areas twice daily, in the morning and at night.

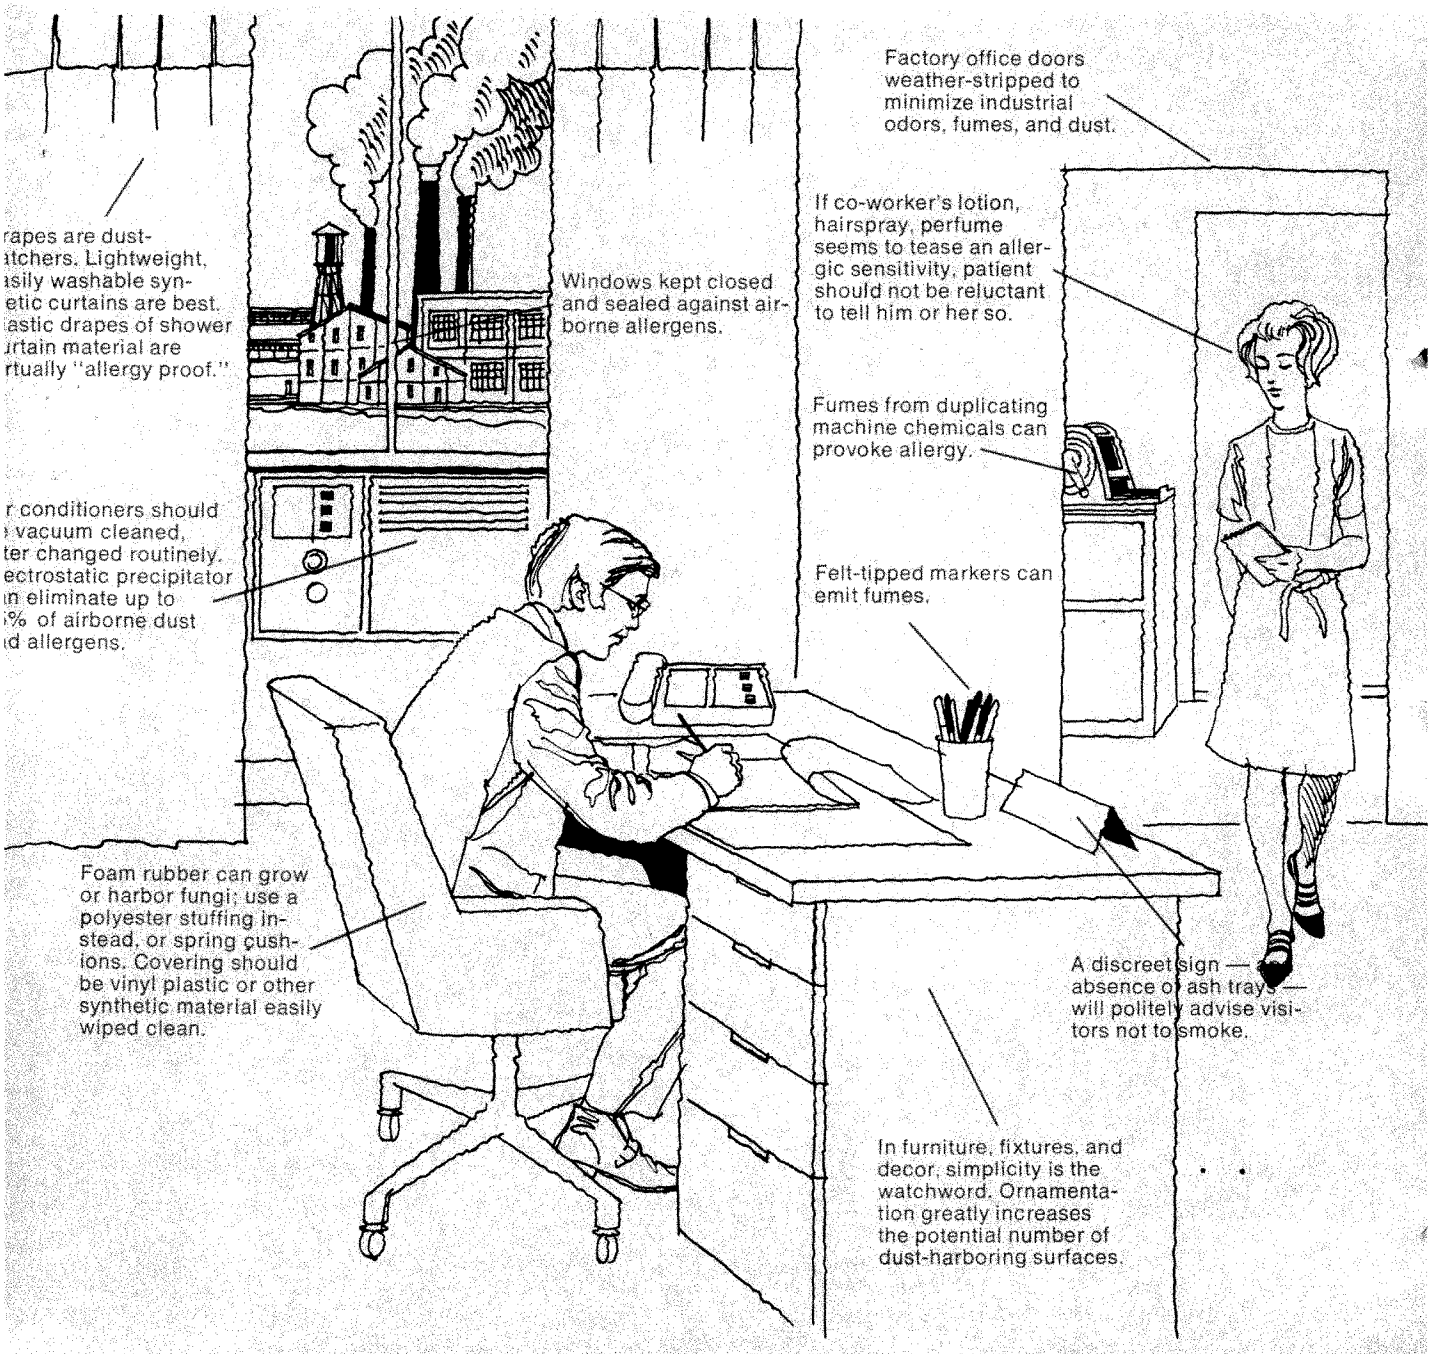
SLS-710

Ways to help allergy patients avoid "a bad day at the office"

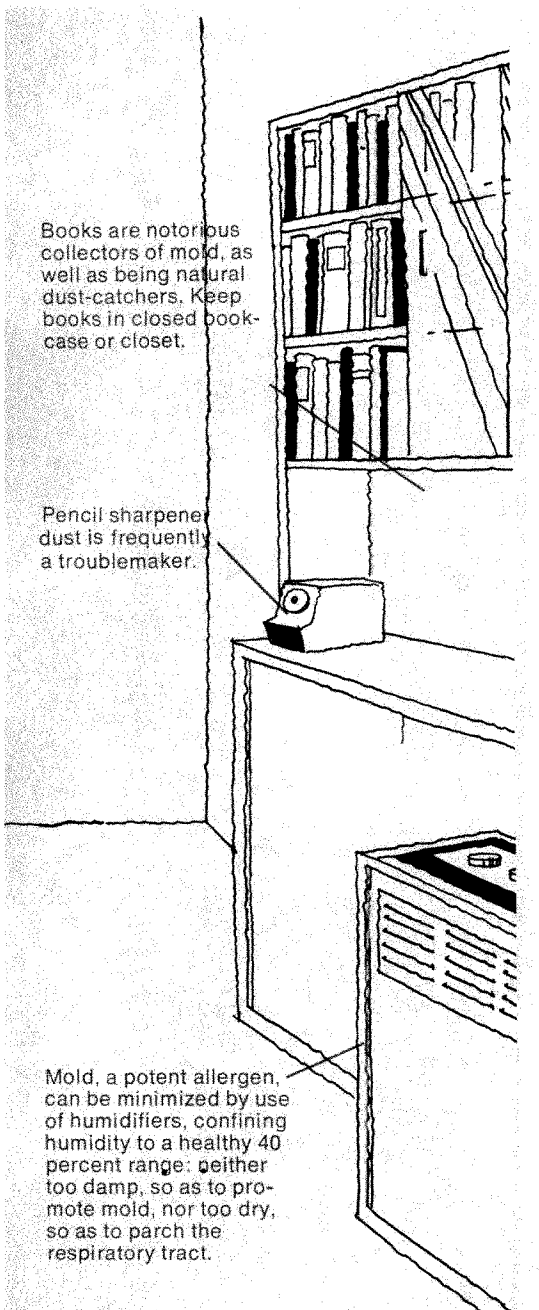
Your allergy patients who are office workers may spend a quarter of their adult life in a hostile environment – from an allergen standpoint. Here are suggestions that might, with the help of an understanding employer, lessen the allergic burden.



All measures to minimize exposure can be helpful. Still, allergic symptoms may occur and an antihistamine will be needed to bring these reactions under control. Dimetane Extentabs keep working for 10-12 hours, are economical, and are likely to produce good results in stubborn as well as routine cases, usually without drowsiness or overstimulation.

DIMETANE Extentabs®

(BROMPHENIRAMINE MALEATE, NF 8 mg. and 12 mg.)



Indications: Perennial and seasonal allergic rhinitis; vasomotor rhinitis; allergic conjunctivitis due to inhalant allergens and foods; mild, uncomplicated allergic skin manifestations of urticaria and angioedema; amelioration of allergic reactions to blood or plasma; dermatographism; as therapy for anaphylactic reactions *adjunctive* to epinephrine and other standard measures after the acute manifestations have been controlled. **Contraindications:** *Use in Newborn or Premature Infants.* This drug should **not** be used in newborn or premature infants. *Use in Nursing Mothers.* Because of the higher risk of antihistamines for infants generally and for newborns and prematures in particular, antihistamine therapy is contraindicated in nursing mothers. *Use in Lower Respiratory Disease.* Antihistamines should NOT be used to treat lower respiratory tract symptoms including asthma. Antihistamines are also contraindicated in the following conditions: hypersensitivity to brompheniramine maleate and other antihistamines of similar chemical structure; monoamine oxidase inhibitor therapy (see Drug Interaction section). **Warnings:** Antihistamines should be used with considerable caution in patients with: narrow angle glaucoma; stenosing peptic ulcer; pyloroduodenal obstruction; symptomatic prostatic hypertrophy; bladder neck obstruction. *Use in Children.* In infants and children, especially, antihistamines in **overdosage** may cause hallucinations, convulsions, or death. As in adults, antihistamines may diminish mental alertness in children. In the young child, particularly, they may produce excitation. *Use in Pregnancy.* Experience with this drug in pregnant women is inadequate to determine whether there exists a potential for harm to the developing fetus. *Use with CNS Depressants.* Dimetane has additive effects with alcohol and other CNS depressants (hypnotics, sedatives, tranquilizers, etc.). *Use in Activities Requiring Mental Alertness.* Patients should be warned about engaging in activities requiring mental alertness, such as driving a car or operating appliances, machinery, etc. *Use in the Elderly (approximately 60 years or older).* Antihistamines are more likely to cause dizziness, sedation, and hypotension in elderly patients. **Precautions:** As with other antihistamines, Dimetane has an atropine-like action and, therefore, should be used with caution in patients with: history of bronchial asthma; increased intraocular pressure; hyperthyroidism; cardiovascular disease; hypertension. **Drug Interactions:** MAO inhibitors prolong and intensify the anticholinergic (drying) effects of antihistamines. **Adverse Reactions:** The most frequent adverse reactions are italicized: *General:* Urticaria, drug rash, anaphylactic shock, photosensitivity, excessive perspiration, chills, dryness of mouth, nose, and throat. *Cardiovascular System:* Hypotension, headache, palpitations, tachycardia, extrasystoles. *Hematologic System:* Hemolytic anemia, thrombocytopenia, agranulocytosis. *Nervous System: Sedation, sleepiness, dizziness, disturbed coordination,* fatigue, confusion, restlessness, excitation, nervousness, tremor, irritability, insomnia, euphoria, paresthesias, blurred vision, diplopia, vertigo, tinnitus, acute labyrinthitis, hysteria, neuritis, convulsions. *G.I. System: Epigastric distress,* anorexia, nausea, vomiting, diarrhea, constipation. *G.U. System:* Urinary frequency, difficult urination, urinary retention, early menses. *Respiratory System: Thickening of bronchial secretions,* tightness of chest and wheezing, nasal stuffiness. **Overdosage:** Antihistamine overdosage reactions may vary from central nervous system depression to stimulation. Stimulation is particularly likely in children. Atropine-like signs and symptoms – dry mouth; fixed, dilated pupils; flushing; and gastrointestinal symptoms may also occur. *If vomiting has not occurred spontaneously,* the patient should be induced to vomit. This is best done by having him drink a glass of water or milk after which he should be made to gag. Precautions against aspiration must be taken, especially in infants and children. *If vomiting is unsuccessful,* gastric lavage is indicated within 3 hours after ingestion and even later if large amounts of milk or cream were given beforehand. Isotonic and ½ isotonic saline is the lavage solution of choice. *Saline cathartics,* as milk of magnesia, by osmosis draw water into the bowel and therefore, are valuable for their action in rapid dilution of bowel content. *Stimulants* should **not** be used. Vasopressors may be used to treat hypotension. **Dosage and Administration:** DOSAGE SHOULD BE INDIVIDUALIZED ACCORDING TO THE NEEDS AND THE RESPONSE OF THE PATIENTS. *Adults:* One to two 4 mg tablets three or four times a day. One Extentab (8 or 12 mg) every eight to twelve hours or twice daily. Two to four teaspoonfuls of elixir three or four times a day. *Children over six.* One 4 mg tablet three or four times a day. One Extentab (8 or 12 mg) every twelve hours. One or two teaspoonfuls of elixir three or four times a day. *Children under six.* 0.5 mg of brompheniramine maleate per kg of body weight per 24 hours, or 15 mg per M^2 per 24 hours, divided into 3-4 doses.

Clear choice

When dermatoses become infected with bacteria or fungi, plain topical steroids are generally not the recommended therapeutic choice.

A clear choice, however, is Vioform® Hydrocortisone. With its unique four-way action, it supplies the kind of comprehensive treatment many common dermatoses* require.

*This drug has been evaluated as possibly effective for these indications. See brief prescribing information.

Vioform®-Hydrocortisone
(iodochlorhydroxyquin and hydrocortisone)

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: Contact or atopic dermatitis; impetiginized eczema; nummular eczema; infantile eczema; endogenous chronic infectious dermatitis; stasis dermatitis; pyoderma; nuchal eczema and chronic eczematoid otitis externa; acne urticata; localized or disseminated neurodermatitis; lichen simplex chronicus; anogenital pruritus (vulvae, scroti, ani); folliculitis; bacterial dermatoses; mycotic dermatoses such as tinea (capitis, cruris, corporis, pedis); moniliasis; intertrigo. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Hypersensitivity to Vioform-Hydrocortisone, or any of its ingredients or related compounds; lesions of the eye; tuberculosis of the skin; most viral skin lesions (including herpes simplex, vaccinia, and varicella).

WARNINGS
This product is not for ophthalmic use.
In the presence of systemic infections, appropriate systemic antibiotics should be used.

Usage in Pregnancy
Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been established. Therefore, they should not be used extensively on pregnant patients in large amounts or for prolonged periods of time.

PRECAUTIONS
May prove irritating to sensitized skin in rare cases. If this occurs, discontinue therapy. May stain.
If used under occlusive dressings or for a prolonged period, watch for signs of pituitary-adrenal axis suppression.
May interfere with thyroid function tests. Wait at least one month after discontinuance of therapy before performing these tests. The ferric chloride test for phenylketonuria (PKU) can yield a false-positive result if Vioform is present in the diaper or urine.
Prolonged use may result in overgrowth of nonsusceptible organisms requiring appropriate therapy.

ADVERSE REACTIONS
Few reports include: Hypersensitivity, local burning, irritation, pruritus. Discontinue if untoward reaction occurs. Rarely, topical corticosteroids may cause striae at site of application when used for long periods in intertriginous areas.

DOSAGE
Apply a thin layer to affected areas 3 or 4 times daily.

HOW SUPPLIED
Cream, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of 5 and 20 Gm. *Ointment*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a petrolatum base; tubes of 20 Gm. *Lotion*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearic acid, cetyl alcohol, lanolin, propylene glycol, sorbitan trioleate, polysorbate 60, triethanolamine, methylparaben, propylparaben, and perfume Flora in water; plastic squeeze bottles of 15 ml. *Mild Cream*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of ½ and 1 ounce. *Mild Ointment*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a petrolatum base; tubes of 1 ounce.

Once-a-day dosage

NEW Fulvicin® P/G*

brand of griseofulvin [ultramicrosize], USP

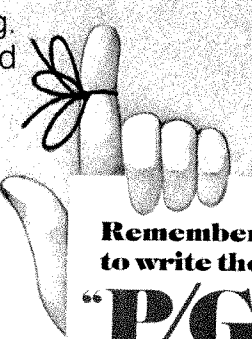
(specially processed) **125 mg. tablets**

*"P/G" means a new polyethylene glycol system for enhanced absorption –

A 250 mg. daily dose (two 125 mg. tablets) of new FULVICIN P/G can replace 500 mg. of griseofulvin (microsize), USP. This is made possible by a special process in which the ultramicrosize griseofulvin crystals are partly dissolved in polyethylene glycol and dispersed through the tablet matrix for enhanced absorption.

Patient convenience –

FULVICIN P/G can be prescribed as two 125 mg. tablets once a day. Compliance is further assured by the easy-to-swallow size of the tablets.



Remember to write the "P/G"

Patient savings –

FULVICIN P/G is up to 35 per cent less expensive per dose than all microsize griseofulvin formulations.**

**Based on list-price comparison.

Schering

NEW P/G Fulvicin® P/G

griseofulvin [ultramicrosize], USP

(specially processed) **125 mg. tablets**

Clinical Considerations: INDICATIONS FULVICIN P/G Tablets are indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: tinea corporis, tinea pedis, tinea cruris, tinea barbae, tinea capitis, tinea unguium (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes, Trichophyton interdigitale, Trichophyton verrucosum, Trichophyton megnini, Trichophyton gallinae, Trichophyton crateriform, Trichophyton sulphureum, Trichophyton schoenleini, Microsporum audouini, Microsporum canis, Microsporum gypseum,* and *Epidermophyton floccosum*. Note: Prior to therapy, the type of fungi responsible for the infection should be identified. The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone. Griseofulvin is not effective in the following: Bacterial infections, Candidiasis (Moniliasis), Histoplasmosis, Actinomycosis, Sporotrichosis, Chromoblastomycosis, Coccidioidomycosis, North American Blastomycosis, Cryptococcosis (Torulosis), Tinea versicolor, and Nocardiosis. **CONTRAINDICATIONS** This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of hypersensitivity to griseofulvin. **WARNINGS** *Prophylactic Usage*: Safety and efficacy of griseofulvin for prophylaxis of fungal infections have not been established. *Animal Toxicology*: Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5%, of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin once a week during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorogenicity, these studies were not of adequate design to form a basis for conclusions in this regard. In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals. *Usage in Pregnancy*: The safety of this drug during pregnancy has not been established. *Animal Reproduction Studies*: It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress. Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this. **PRECAUTIONS** Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic, and hematopoietic, should be done. Since griseofulvin is derived from species of penicillin, the possibility of cross sensitivity with penicillin exists, however, known penicillin-sensitive patients have been treated without difficulty. Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated. Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy. Barbiturates usually depress griseofulvin activity, and concomitant administration may require a dosage adjustment of the antifungal agent. **ADVERSE REACTIONS** When adverse reactions occur, they are most commonly of the hypersensitivity type, such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are: oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities. Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs. When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

A valuable guide to diagnostic and therapeutic procedures for the cancer patient

Current Concepts in Cancer

While national attention focuses on cancer through specialized cancer centers, physicians are aware that the majority of cancer patients are treated in office practices. For most practicing physicians, cancer treatment is not a research objective, but a very practical problem in patient management.

Current Concepts in Cancer, a compilation of articles originally published in the *Journal of the American Medical Association,* is designed to be a guide for the practitioner in the choice of diagnostic and therapeutic procedures for many types of malignancies. It presents an objective interdisciplinary view by MDs outstanding in their respective fields, emphasizing principles of diagnosis and surgical, radiotherapeutic, and chemotherapeutic treatment.

Make this important resource a part of your reference file. Order your copy today.

MINOCIN Minocycline HCl
Oral and Intravenous Brief Summary
Contraindications: Hypersensitivity to any tetracycline.
Warnings: Intravenous use, particularly in pregnancy, in daily doses exceeding 2 grams has been associated with deaths through liver failure. When need for intensive treatment outweighs potential dangers, perform renal and liver function tests before and during therapy, also follow serum concentrations. In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, use lower total doses, and, in prolonged therapy, determine serum levels. This hazard is of particular importance in I.V. use in pregnant or postpartum patients with pyelonephritis. In such cases, the blood cyclines during tooth development (last half of pregnancy, infancy and childhood to the age of 8 years) may cause permanent discoloration of the teeth (yellow-gray-brown). This is more common during long-term use but has been observed following repeated short-term courses. Enamel hypoplasia has also been reported. Tetracyclines, therefore, should not be used in this age group unless other drugs are not likely to be effective or are contraindicated. Photosensitivity manifested by an exaggerated sunburn reaction has been observed in some individuals taking tetracyclines. Advise patients apt to be exposed to direct sunlight or ultraviolet light that such reaction can occur, and discontinue treatment at first evidence of skin erythema. Studies to date indicate that photosensitivity is rarely reported with MINOCIN acidosis. CNS side effects (lightheadedness, dizziness, vertigo) have been reported, may disappear during therapy, and always disappear rapidly when drug is discontinued. Caution patients who experience these symptoms about driving vehicles or using hazardous machinery while taking this drug. **Pregnancy:** In animal studies, tetracyclines cross the placenta, are found in fetal tissues, and can have toxic effects on the developing fetus (often related to retardation of skeletal development). Embryotoxicity has been noted in animals treated early in pregnancy. **Newborns, infants and children:** All tetracyclines form a stable calcium complex in any bone-forming tissue. Prematures, given oral doses of 25 mg./kg. every 6 hours, demonstrated a decrease in fibula growth rate, reversible when drug was discontinued. Tetracy-

taph infection:

OCIN Minocycline HCl
l and Intravenous Brief Summary (continued)
anisms, including fungi. If superinfection occurs, institute
ropriate therapy. In venereal diseases when coexistent syphi-
s suspected, darkfield examination should be done before
atment is started and blood serology repeated monthly for at
t four months. Patients on anticoagulant therapy may require
nward adjustment of such dosage. Test for organ system
function (e.g., renal, hepatic and hemopoietic) in long-term
Treat all group A beta-hemolytic streptococcal infections for
east 10 days. Avoid giving tetracycline in conjunction with
cillin.
erse Reactions: GI: (with both oral and parenteral use): anorex-
dermatitis (uncommon). Photosensitivity is discussed above
("Warnings"). **Renal toxicity:** rise in BUN, dose-related (see
"Warnings"). **Hypersensitivity reactions:** urticaria, angioneurotic
edema, anaphylaxis, anaphylactoid purpura, pericarditis, exacer-
bation of systemic lupus erythematosus. In young infants, bulging
fontanels have been reported following full therapeutic dosage;
disappearing rapidly when drug was discontinued. **Blood:** hemoly-
tic anemia, thrombocytopenia, neutropenia, eosinophilia. **CNS:**
(see "Warnings"). When given in high doses, tetracyclines may
produce brown-black microscopic discoloration of thyroid glands;
no abnormalities of thyroid function studies are known to occur.
NOTE: Concomitant therapy: Antacids containing aluminum, calci-
um, or magnesium impair absorption; do not give to patients
taking oral minocycline. Studies to date indicate that absorption

CNS side effects including light-headedness, dizziness, or vertigo have been reported with MINOCIN. Patients who experience these symptoms should be cautioned about driving vehicles or using hazardous machinery while on minocycline therapy.

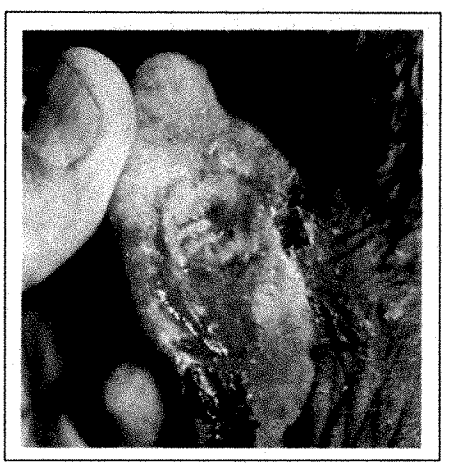
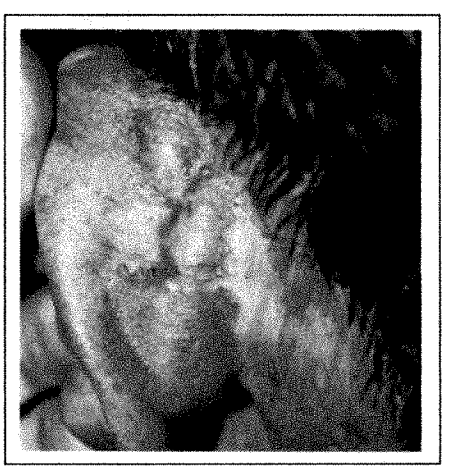
An effective tool for superficial basal cell

2/6/70—Before treatment a 3.0 cm lesion was present behind left ear. Biopsy revealed it to be a superficial basal cell carcinoma. Treatment with Efudex (fluorouracil) 5% Cream was begun.



5/1/70—After 11 weeks' therapy, lesion site was necrotic and escharified; surrounding skin showed minimal inflammation. Treatment was terminated 4/24/70.

9/10/70—Area completely healed; posttreatment biopsy revealed no further carcinoma.



6/15/72—Patient 25 months posttreatment. No evidence of recurrence.

Management of superficial basal cell carcinoma is often complicated by multiple lesions which extend over large areas of the body. Until now, primary treatment has been surgery or radiation therapy. However, these modalities may be followed by scarring and disfigurement.

Topical chemotherapy with Efudex (fluorouracil) 5% is a valuable alternative when conventional methods are impractical. For example, it is an effective agent for the concurrent treatment of superficial lesions over large areas of the body, or for use on difficult treatment sites.

Although during treatment with Efudex the lesion and some of the surrounding skin may become inflamed and blistered temporarily, final results are cosmetically gratifying, with minimal or no scarring.

Efudex 5% Cream offers the dermatologist:

- An effective topical alternative to surgery for multiple lesions and difficult treatment sites.
- Cosmetically gratifying results, with minimal or no scarring. No systemic toxicity.
- Convenient, economical b.i.d. application. Apply with care near eyes, nose and mouth; wash hands immediately afterward if applied with fingers.

Efudex® 5% Cream
fluorouracil/Roche
An exclusive Roche formulation
Also available as 5% Efudex Solution

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Multiple actinic or solar keratoses; superficial basal cell carcinomas when conventional methods are impractical (5% strength only).

Contraindications: If occlusive dressing is used, may increase inflammatory reactions in adjacent normal skin. Avoid prolonged exposure to ultraviolet rays. Safe use in pregnancy not established.

Precautions: If applied with fingers, wash hands immediately. Apply with care near eyes, nose and mouth. Solar keratoses failing to respond should be biopsied; perform follow-up biopsies in superficial basal cell carcinoma.

Adverse Reactions: Local—pain, pruritus, hyperpigmentation and burning at application site most frequent; also dermatitis, scarring, soreness, tenderness, suppuration, scaling and swelling. Also reported—insomnia, stomatitis, irritability, medicinal taste, photosensitivity, lacrimation, telangiectasia, leukocytosis, thrombocytopenia, toxic granulation and eosinophilia.

Dosage and Administration: *Actinic or solar keratosis*—apply sufficient quantity to cover lesions, twice daily. Usual length of therapy is 2 to 4 weeks. *Superficial basal cell carcinomas*—apply sufficient quantity (only 5% strength recommended) to cover lesions, twice daily. Continue treatment for at least 3 to 6 weeks, but possibly as long as 10 to 12.

How Supplied: Solution, 10-ml drop dispensers containing 2% or 5% fluorouracil on a weight/weight basis. Cream, 25-Gm tubes containing 5% fluorouracil in a vanishing cream base.

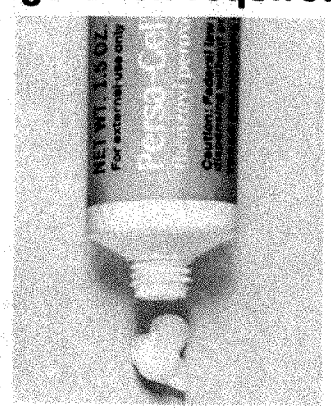
Persa-Gel™
(BENZOYL PEROXIDE)

Unique Acetone Gel 5% and 10%

TPC
TEXAS PHARMACAL COMPANY
San Antonio, Texas 78296

Unique acetone base enhances stability and cosmetic acceptability.

Two and one-half year dating
No refrigeration required



CAUTION: Federal law prohibits dispensing without prescription.
DESCRIPTION: Persa-Gel™ 5% contains 5% benzoyl peroxide; Persa-Gel™ 10% contains 10% benzoyl peroxide; in a gel base containing acetone, carboxyvinyl polymer, triethanolamine, sodium lauryl sulfate, propylene glycol and purified water.
ACTIONS: Benzoyl peroxide is primarily effective because of its drying, peeling and antiseptic action.
INDICATION: For adjunctive topical therapy of acne vulgaris.
CONTRAINDICATIONS: Benzoyl peroxide is contraindicated in patients with acute inflammation and in patients with a history of hypersensitivity to any of the components of the preparation.
PRECAUTIONS: If excessive irritation develops, discontinue use and institute appropriate therapy. After the reaction clears, treatment may often be resumed with less frequent applications. Avoid contact with eyes, eyelids, lips and other mucous membranes, and anterior neck. May bleach hair and colored fabrics.
ADVERSE REACTIONS: Allergic contact dermatitis and severe erythema with crusting have been reported with topical benzoyl peroxide.
DOSAGE AND ADMINISTRATION: Persa-Gel™ (benzoyl peroxide) should be applied thinly to cover affected area after cleansing with non-medicated soap and water or a degreaser. Initial application once daily before bedtime is recommended, increasing to twice daily as tolerance develops. Feelings of warmth and stinging and slight erythema may be noted initially. It is advisable to initiate therapy with Persa-Gel™ 5% shifting to the use of Persa-Gel™ 10% after 3 or 4 weeks, or earlier if tolerance to the 5% has been determined. Therapeutic results are usually seen within 2 weeks with continued improvement therafter.
HOW SUPPLIED: Persa-Gel™ 5% 1.5 oz. tubes

LENOX HILL HOSPITAL
Announces a Symposium on

TUMORS OF THE EYELIDS, ORBIT AND OCULAR ADNEXAE

October 27, 28, 29, 1977

This Symposium will be devoted to the diagnosis, pathogenesis and treatment of tumors of the eyelids and orbit, emphasizing basal cell carcinoma of the eyelids. The course will be presented by outstanding ophthalmologists, ophthalmic plastic surgeons, plastic surgeons, x-ray therapists, dermatologists, immunotherapists, cryosurgeons and pathologists.

The format will consist of lectures, panel discussions, surgical films and videotapes of surgery.

THE FACULTY WILL INCLUDE:
Albert Hornblass, M.D., Course Director
Edgar Berry, M.D.
Charles Beyer, M.D.
Jackson Coleman, M.D.
Anthony Domonkis, M.D.
Andrew Ferry, M.D.
Paul Henkind, M.D.

HOECHST-ROUSSEL PHARMACEUTICALS INCORPORATED

Announces a New topical fluorinated corticosteroid in a Unique Emollient Cream Base

NEW TOPICORT®
(DESOXIMETASONE)

THE SPECIALLY DEVELOPED, PRESERVATIVE-FREE BASE COMBINES THE EMOLLIENCE OF AN OINTMENT WITH THE COSMETIC ACCEPTABILITY OF A CREAM IN A WATER-IN-OIL EMULSION.

Well-documented efficacy and safety: Anti-inflammatory, antipruritic, vasoconstrictive Topicort (desoximetasone) has been demonstrated safe and effective in relieving the inflammatory manifestations of corticosteroid-responsive dermatoses.

Worldwide clinical experience: For up to 4 years, Topicort (desoximetasone) has been marketed by Hoechst in over 30 foreign countries. Extensive clinical trials in the United States, conducted by 23 investigators under a wide variety of climatic conditions, confirm the many years of worldwide experience.

A wide range of conditions in corticosteroid-responsive dermatoses: Topicort (desoximetasone) is useful on wet as well as dry lesions, in both acute and chronic cases, with a profile of adverse reactions similar to that seen with other topical corticosteroids.

Emollient Cream 0.25%

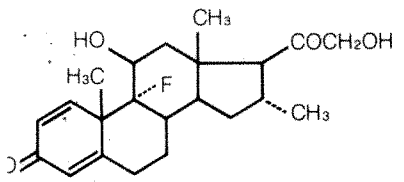
Available: 15-gram tubes.
In corticosteroid-responsive dermatoses
Convenient B.I.D. dosage.

Please consult full prescribing information on following page.

071083-677

TOPICORT®(desoximetasone) EMOLLIENT CREAM 0.25%

Description: Topicort® (desoximetasone) Emollient Cream 0.25% contains the active synthetic corticosteroid desoximetasone. The chemical name of desoximetasone is 9α - fluoro - 11β, 21 - dihydroxy - 16α - methylpregna - 1,4 - diene-3,20-dione. The chemical structure is:



Each gram of Topicort® (desoximetasone) Emollient Cream 0.25% contains 2.5 mg desoximetasone in an emollient cream consisting of isopropyl myristate, cetylstearyl alcohol, white petrolatum, mineral oil, lanolin alcohol and purified water.

Actions: Topicort® (desoximetasone) Emollient Cream is primarily effective because of its anti-inflammatory, antipruritic and vasoconstrictive actions.

Indications: Topicort® (desoximetasone) Emollient Cream is indicated for the relief of inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications: Topical steroids are contraindicated in vaccinia, varicella and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

Precautions: If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled.

Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time, or if occlusive technique is used.

If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Adverse Reactions: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria.

Dosage and Administration: Apply a thin film of Topicort® (desoximetasone) Emollient Cream 0.25% to the affected skin areas twice daily. Rub in gently.

How Supplied: Topicort® (desoximetasone) Emollient Cream 0.25% is supplied in 15-gram tubes.

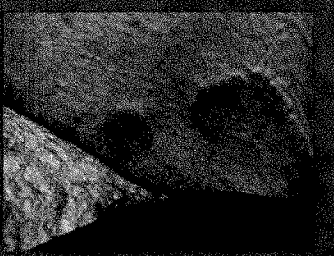
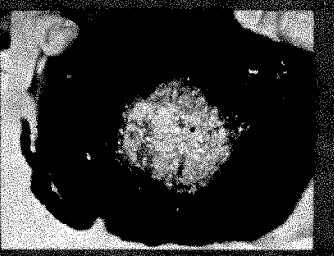
When Griseofulvin is indicated...

TINEA PEDIS*

TINEA UNGUIUM*



TINEA CRURIS*



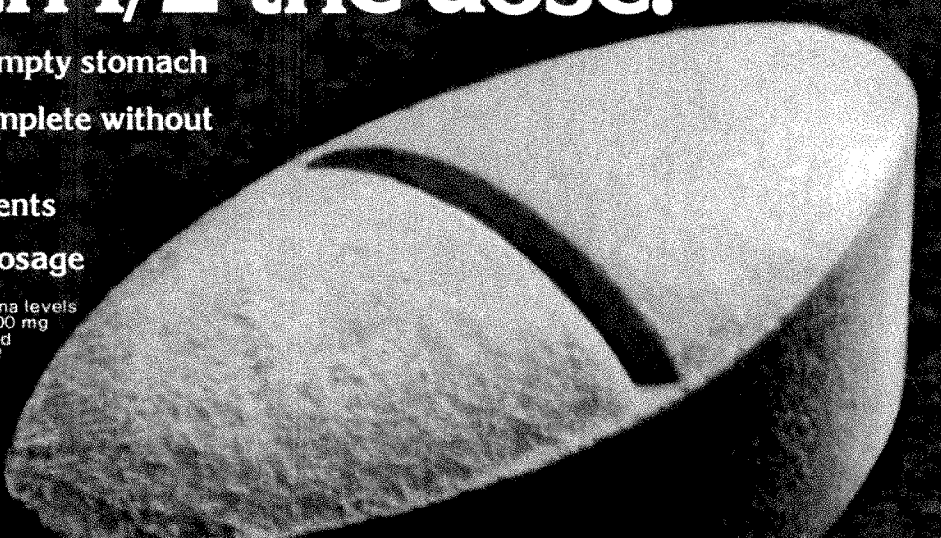
TINEA CAPITIS*

*Also *Tinea barbae* and *Tinea corporis* when caused by fungi from genera known to be sensitive to griseofulvin.

Gris-PEG®
(griseofulvin ultramicrosize) Tablets 125 mg
offers effective therapy with 1/2 the dose.†

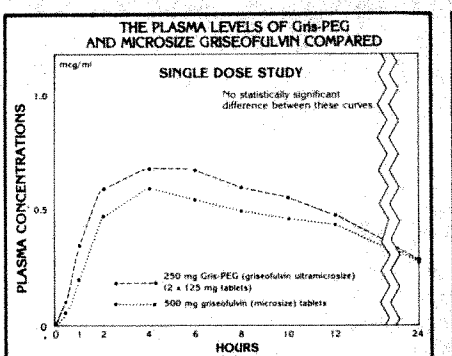
- Can be taken on an empty stomach
- Absorption nearly complete without fatty meals
- Reduced cost for patients
- Once-a-day or b.i.d. dosage

†250 mg of Gris-PEG® provides plasma levels equivalent to those obtained with 500 mg microsize griseofulvin. This improved absorption permits the oral intake of half as much griseofulvin but there is no evidence, at this time, that this confers any significant clinical difference in regard to safety or efficacy.

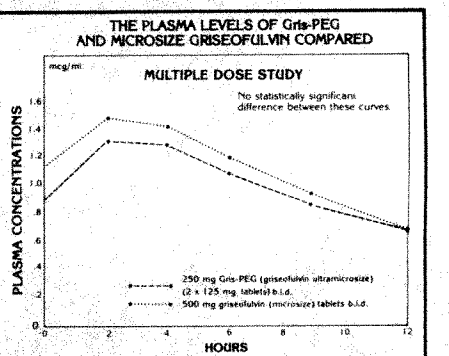


Dorsey LABORATORIES
Division of Sandoz, Inc.
LINCOLN, NEBRASKA 68501

Gris-PEG®
(griseofulvin ultramicrosize) Tablets 125 mg
The ½ dose griseofulvin.



Based on a single dose double-blind bioavailability study conducted in 24 human volunteers comparing the average griseofulvin (microsize) and Gris-PEG plasma levels. There is no significant difference between peak plasma levels, times to peak, and areas under the curve. Gas chromatographic assay.



Based on a double-blind multiple dose steady state crossover bioavailability study conducted in 17 human volunteers comparing the average griseofulvin (microsize) and Gris-PEG plasma levels obtained on days 9, 11 and 13. There is no significant difference between times to peak, peak plasma levels, and areas under the curve. Gas chromatographic assay.

DESCRIPTION

Griseofulvin is an antibiotic derived from a species of *Penicillium*.

Gris-PEG is an ultramicrocrystalline solid-state dispersion of griseofulvin in polyethylene glycol 6000.

Gris-PEG Tablets differ from griseofulvin (microsize) tablets USP in that each tablet contains 125 mg of ultramicrosize griseofulvin biologically equivalent to 250 mg of microsize griseofulvin.

ACTION

Microbiology: Griseofulvin is fungistatic with *in vitro* activity against various species of *Microsporum*, *Epidermophyton* and *Trichophyton*. It has no effect on bacteria or other genera of fungi.

Human Pharmacology: The peak plasma level found in fasting adults given 0.25 g of Gris-PEG occurs at about four hours and ranges between 0.37 to 1.6 mcg/ml.

Comparable studies with microsize griseofulvin indicated that the peak plasma level found in fasting adults given 0.5 g occurs at about four hours and ranges between 0.44 to 1.2 mcg/ml.

Thus, the efficiency of gastrointestinal absorption of the ultramicrocrystalline formulation of Gris-PEG is approximately twice that of conventional microsized griseofulvin. This factor permits the oral intake of half as much griseofulvin per tablet but there is no evidence, at this time, that this confers any significant clinical differences in regard to safety and efficacy.

Griseofulvin is deposited in the keratin precursor cells and has a greater affinity for diseased tissue. The drug is tightly bound to the new keratin which becomes highly resistant to fungal invasions.

INDICATIONS

Gris-PEG (griseofulvin ultramicrosize) is indicated for the treatment of the following ringworm infections:

Tinea corporis (ringworm of the body)
Tinea pedis (athlete's foot)
Tinea cruris (ringworm of the thigh)
Tinea barbae (barber's itch)
Tinea capitis (ringworm of the scalp)
Tinea unguium (onychomycosis, ringworm of the nails)

when caused by one or more of the following genera of fungi:

Trichophyton rubrum
Trichophyton tonsurans
Trichophyton mentagrophytes
Trichophyton interdigitalis
Trichophyton verrucosum
Trichophyton megnini
Trichophyton gallinae
Trichophyton crateriform
Trichophyton sulphureum
Trichophyton schoenleini
Microsporum audouini
Microsporum canis
Microsporum gypseum
Epidermophyton floccosum

NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.

The use of the drug is not justified in minor or trivial infections which will respond to topical agents alone.

Griseofulvin is *NOT* effective in the following:

Bacterial infections
Candidiasis (Moniliasis)
Histoplasmosis
Actinomycosis
Sporotrichosis
Chromoblastomycosis
Coccidioidomycosis
North American Blastomycosis
Cryptococcosis (Torulosis)
Tinea versicolor
Nocardiosis

CONTRAINDICATIONS

This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of sensitivity to griseofulvin.

WARNINGS

Prophylactic Usage: Safety and Efficacy of Griseofulvin for Prophylaxis of Fungal Infections Has Not Been Established.

Animal Toxicology: Chronic feeding of griseofulvin, at levels ranging from 0.5 to 2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorigenicity, these studies were not of adequate design to form a basis for conclusions in this regard.

In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.

Usage in Pregnancy: The safety of this drug during pregnancy has not been established.

Animal Reproduction Studies: It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress. Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.

PRECAUTIONS

Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic and hematopoietic, should be done.

Since griseofulvin is derived from species of *Penicillium* the possibility of cross sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.

Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.

Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.

Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.

ADVERSE REACTIONS

When adverse reactions occur, they are most commonly of the hypersensitivity type such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities.

Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs.

When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

DOSAGE AND ADMINISTRATION

Accurate diagnosis of the infecting organism is essential. Identification should be made either by direct microscopic examination of a mounting of infected tissue in a solution of potassium hydroxide or by a culture on an appropriate medium.

Medication must be continued until the infecting organism is completely eradicated as indicated by appropriate clinical or laboratory examination. Representative treatment periods are—*tinea capitis*, 4 to 6 weeks; *tinea corporis*, 2 to 4 weeks; *tinea pedis*, 4 to 8 weeks; *tinea unguium*—depending on rate of growth—fingernails, at least 4 months; toenails, at least 6 months.

General measures in regard to hygiene should be observed to control sources of infection or reinfection. Concomitant use of appropriate topical agents is usually required particularly in treatment of *tinea pedis*. In some forms of athlete's foot, yeasts and bacteria may be involved as well as fungi. Griseofulvin will not eradicate the bacterial or monilial infection.

An oral dose of 250 mg of Gris-PEG (griseofulvin ultramicrosize) is biologically equivalent to 500 mg of griseofulvin (microsized) USP (see ACTION Human Pharmacology).

Adults: A daily dose of 250 mg will give a satisfactory response in most patients with *tinea corporis*, *tinea cruris* and *tinea capitis*. One 125 mg tablet twice per day or two 125 mg tablets once per day is the usual dosage. For those fungal infections more difficult to eradicate such as *tinea pedis* and *tinea unguium*, a divided daily dose of 500 mg is recommended. In all cases, the dosage should be individualized.

Children: Approximately 5 mg per kilogram (2.5 mg per pound) of body weight per day is an effective dose for most children. On this basis the following dosage schedule for children is suggested: Children weighing over 25 kilograms (approximately 50 pounds) 125 mg to 250 mg daily; children weighing 15-25 kilograms (approximately 30 to 50 pounds) 62.5 mg to 125 mg daily; children 2 years of age and younger, dosage has not been established.

Dosage should be individualized, as is done for adults. Clinical experience with griseofulvin in children with *tinea capitis* indicates that a single daily dose is effective. Clinical relapse will occur if the medication is not continued until the infecting organism is eradicated.

HOW SUPPLIED

Gris-PEG (griseofulvin ultramicrosize) Tablets (white) differ from griseofulvin microsized tablets (USP) in that each tablet contains 125 mg of ultramicrosize griseofulvin, biologically equivalent to 250 mg of microsized griseofulvin. Two 125 mg tablets of Gris-PEG are biologically equivalent to 500 mg of microsized griseofulvin. In bottles of 100 and 500 scored, film-coated tablets.

For Skin Without Water

Neutrogena® Dry Skin products are specially formulated to supplement surface fats and aid in the retention of moisture.

- Neutrogena® Dry-Skin Soap contains humectants, lubricants, and emollients to soften and moisturize, and is nonirritating to sensitive skin.
- Neutrogena® Rainbath® Dry Skin Bath Gel is lipid-free, cleanses with a rich lather without the drying effect of ordinary soap, and leaves skin soft and smooth. Available both scented and unscented.
- Neutrogena® Hand Cream is a heavy-duty formula containing a special blend of naturally occurring oils and glycerin, and is a useful adjunct in steroid-responsive hand dermatoses.[1]

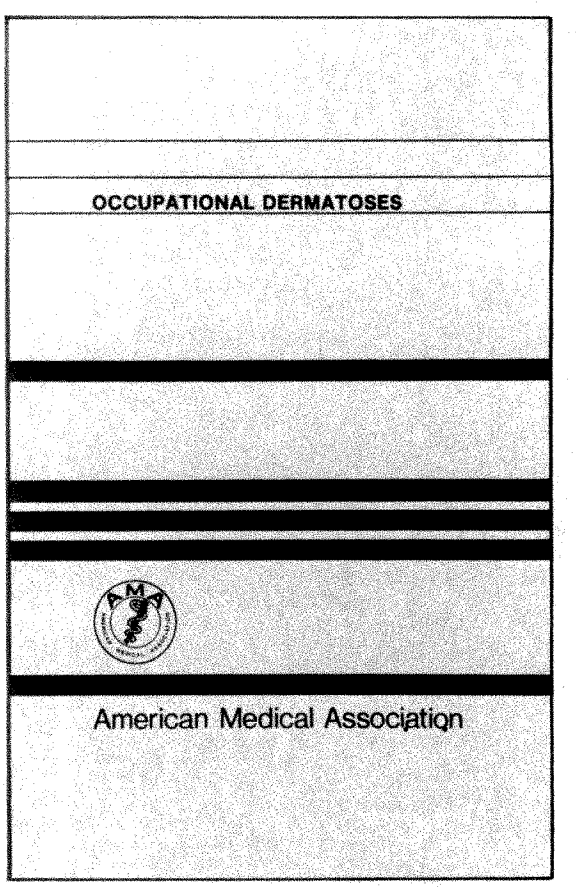
for the part-time occupational physician...

an invaluable quick reference guide to occupational dermatoses

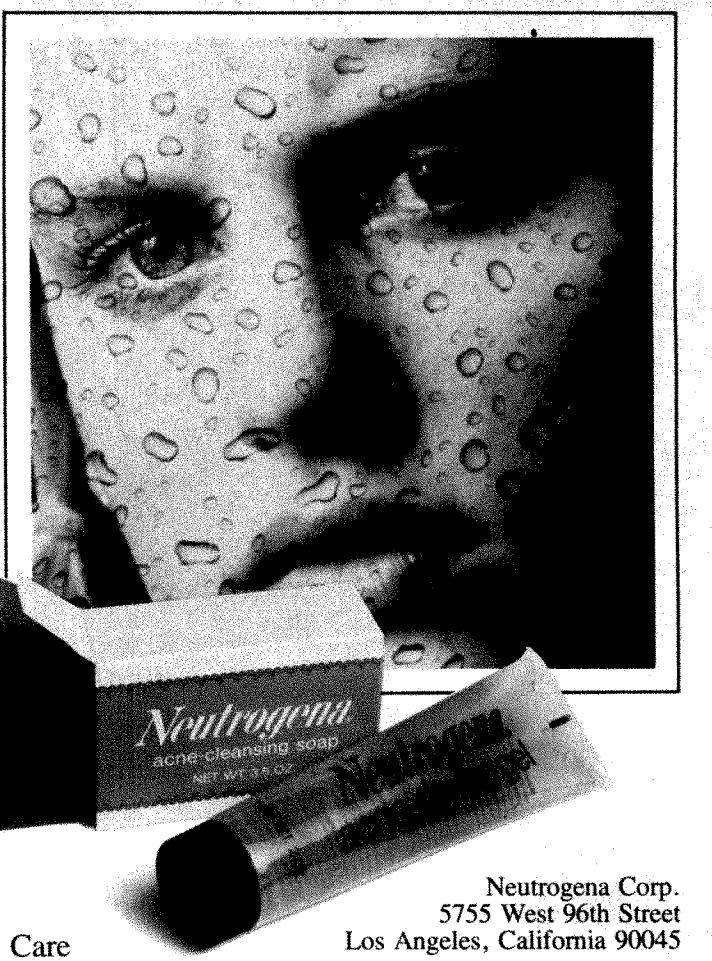
The AMA's new guide, *Occupational Dermatoses*, is an invaluable aid for physicians working part-time in occupational health programs.

It provides a ready reference for specific information on the causes, diagnosis, prevention, and treatment of occupational skin diseases. It also discusses management of prolonged and recurrent dermatoses, medico-legal aspects, and provides extensive references.

To order your copy ($1 ea.) of *Occupational Dermatoses, OP-108,* write: Order Dept., American Medical Association, 535 N. Dearborn St., Chicago, Ill. 60610.



For Skin Plagued by Acne



Neutrogena® Acne products aid in drying while they clean and degrease acne-plagued skin.

- Neutrogena® Acne-Cleansing Soap gently cleanses and degreases the skin, and does not interfere with topical or systemic acne treatment.
- Neutrogena® Acne-Drying Gel combines antisepsis with astringency, contains 47% active drying agents, is perfume-free, can be applied under or over makeup, and is imperceptible on the skin.

Profile of Medical Practice
Socioeconomic Issues of Health!

Invaluable for anyone needing a quick, authoritative reference to relevant data on the U.S. health care delivery system, these unique publications are compiled annually by the AMA Center for Health Services Research & Development.

The Red book, PROFILE OF MEDICAL PRACTICE, presents data from the AMA Physician Masterfile and the Periodic Survey of Physicians describing characteristics of medical practice such as utilization of physicians' services; physicians' net income, expenses, fees; and other selected practice characteristics. It also includes essays on issues affecting the practice of medicine.

The Blue book, SOCIOECONOMIC ISSUES OF HEALTH, includes data on characteristics of the U.S. population; the health care delivery system; medical education and licensure. Also included are essays on relevant health issues of general interest.

Quantities are limited so order yours today!

HALOG® CREAM (Halcinonide Cream 0.1%)

Each gram of Halog Cream (Halcinonide Cream 0.1%) contains 1 mg. halcinonide (0.1%) in a cream base.

INDICATIONS: This product is intended for topical application for adjunctive therapy and symptomatic relief of inflammatory manifestations of acute and chronic corticosteroid responsive dermatoses.

CONTRAINDICATIONS: Topical steroids are contraindicated in vaccinia, varicella, and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

PRECAUTIONS: *General*—If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled. Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time. If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Occlusive Dressing Technique—The use of occlusive dressing increases the percutaneous absorption of corticosteroids; their extensive use increases the possibility of systemic effects. For patients with extensive lesions it may be preferable to use a sequential approach, occluding one portion of the body at a time. The patient should be kept under close observation if treated with the occlusive technique over large areas and over a considerable period of time. Occasionally, a patient who has been on prolonged therapy, especially occlusive therapy, may develop symptoms of steroid withdrawal when the medication is stopped. Thermal homeostasis may be impaired if large areas of the body are covered. Use of the occlusive dressing should be discontinued if elevation of the body temperature occurs. Occasionally, a patient may develop a sensitivity reaction to a particular occlusive dressing material or adhesive and a substitute material may be necessary. If infection develops, discontinue the use of the occlusive dressing and institute appropriate antimicrobial therapy.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions, and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria. Contact sensitivity to a particular dressing material or adhesive may occur occasionally (see PRECAUTIONS).

For full prescribing information, consult package insert.

HOW SUPPLIED: In tubes of 15 and 60 g. and in jars of 240 g. (8 oz.).

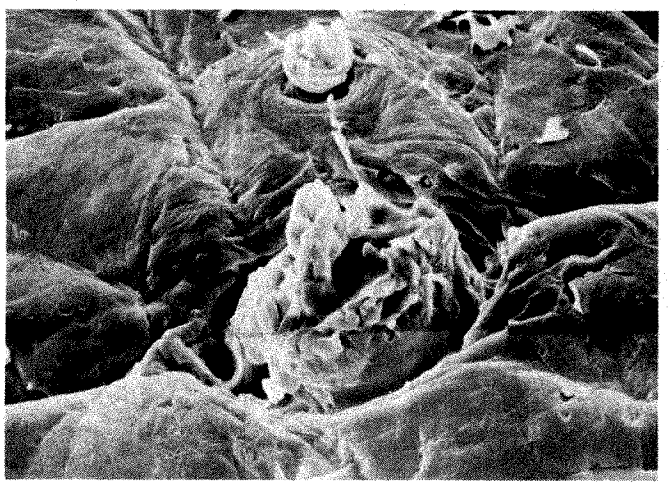
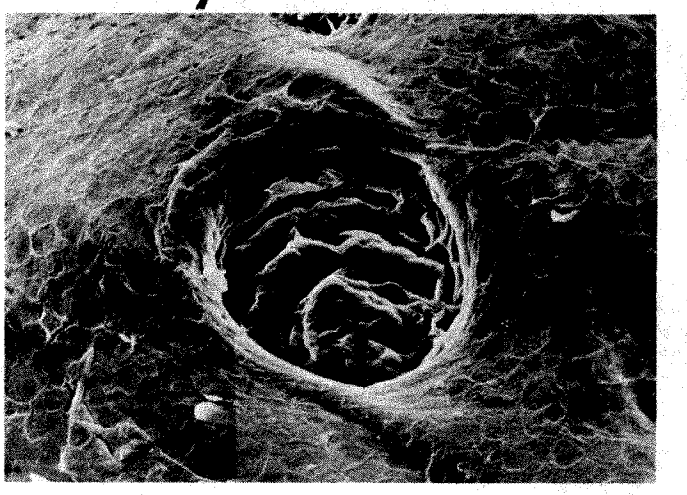
Pernox® Can Improve an Acne Lesion in Two Days



BEFORE TREATMENT: Comedo plugged with keratinous debris. (Scanning electron microscopy courtesy of Structure Probe Inc.)



AFTER 2 DAYS (Two one-minute Pernox® Scrub washes daily): Depth of orifice indicates removal of plug in large central comedo.

When we formulated Pernox® Scrub, we had a goal in mind. Make it abradant . . . a harsh word, yet make it smooth for acne skin. Pernox accomplishes just that.

Washing varies from patient to patient. You determine the regimen by frequency of washing and the amount of water used during the wash.

Patients respond to Pernox rapidly, often noticing improvement after the first wash. The unique combination of ingredients in Pernox emulsifies oil and dries affected areas, contributing to this success.

Two pleasant forms, regular and lemon-scented scrub and lemon-scented lotion offer you a choice for your patients' therapy.

Pernox . . . an acne regimen formulated to give you more than you're now getting from your present acne scrub.

PERNOX®

Scrub/Lotion

Lathering Scrub Cleanser for Acne

Pernox Scrub, Regular and Lemon-Scented in 2 and 4 oz. plastic tubes.

New Lemon-Scented Pernox Lotion in 6 oz. bottles.

Bullous Pemphigoid

Clinical and Immunologic Follow-up After Successful Therapy

A. Razzaque Ahmed, MD; John C. Maize, MD; Thomas T. Provost, MD

• Thirty-six patients with bullous pemphigoid (BP) have been periodically evaluated for four years. This study demonstrates that BP may occur in a transient predominantly localized form that remits spontaneously, and most BP patients after successful therapy remain in prolonged clinical remission. In this study, all patients with active or recurrent disease had IgG and/or C3 basement membrane zone (BMZ) deposition. Serum anti-BMZ antibodies was an inconstant feature. In most instances, clinical remission of BP was associated with disappearance of BMZ Ig and C3 deposition and serum BMZ antibodies. Fluorescein-conjugated, antihuman C3 appears to be a more sensitive immunoreagent than antihuman, class specific, immunoglobulin antisera in detecting positive BMZ staining in BP. Combined therapy with azathioprine plus prednisone appears to be superior to prednisone alone in the treatment of BP.

(*Arch Dermatol* 113:1043-1046, 1977)

Lever, in 1953,[1] described bullous pemphigoid (BP) and differentiated it from pemphigus vulgaris. Jordon et al[2] demonstrated the presence of basement membrane zone (BMZ) antibodies and their specificity for BP. Others have confirmed these observations and have demonstrated the deposition of various immunoglobulin and complement components as well as components of the alternative complement pathway along the BMZ.[3-9] However, their pathogenetic role has yet to be proved. For example, a number of authors have observed a lack of correlation between BP disease activity and serum antibody titers.[5,10,11] In addition, after infusion of high titer BP serum, monkeys demonstrated BMZ IgG deposition but failed to develop either clinical or histological disease resembling BP.[12]

Lever emphasized that BP may be a relatively benign disease capable of spontaneous remission. Brennan and Montgomery[13] reported 15 of 22 untreated BP patients in remission for 8 to 30 years supporting Lever's contention.[14] Rook and Waddington[15] subsequently reported 38 untreated BP patients in clinical remission ranging from one to five years. Stevenson, in 1960,[16] reported that of 62 BP patients treated with steroids, 25 were in full remission and required no maintenance therapy. Church,[17] however, that same year reported that only four of 36 BP patients treated with steroids were in full remission.

We decided to evaluate the therapeutic response of BP patients and the possible pathogenetic role of immunoglobulins and complement by the following: (1) clinical observation of BP patients after successful therapy; (2) correlation of the presence of in vivo bound immunoglobulins and complement and serum BMZ antibodies with clinical disease activity; and (3) determination of the fate of in vivo bound and circulating BMZ antibody after successful therapy.

PATIENTS AND METHODS

Thirty-six patients have been included in this study. Sixteen were men (45%) and 20 were women (55%). Thirty-two were white (82%) and 4 were black (12%). All patients were hospitalized initially. The patients had classic clinical disease, ie, subepidermal, tense bullae arising on inflamed or normal-appearing skin.

The extent of the patient's disease was classified into one of the following four groups depending on the number of lesions: 1+, < 20 lesions; 2+, 20 to 40 lesions; 3+, 40 to 60 lesions; and 4+, > 60 lesions.

Fourteen patients were treated with prednisone alone. The initial dose ranged from 40 to 180 mg/day (mean, 70 mg). Fifteen patients were treated with azathioprine, 1.5 mg/kg of body weight/day, (mean, 100 mg daily), plus prednisone, initially 40 to 240 mg/day (mean, 60 mg). Before therapy, all patients had a complete blood count, urinalysis, chest roentgenogram, blood glucose, BUN, bilirubin determination, as well as stool examinations for occult blood, ova, and parasites. The patients receiving azathioprine had a bimonthly CBC. The patients were treated until clinical remission occurred and their serum and skin failed to demonstrate BMZ antibodies or C3 deposition. The patients' records were then evaluated for length of hospitalization (equated here with time to control disease), mean steroid maintenance dose, complications, and duration of therapy. All patients were thereafter examined clinically and immunologically at four- to six-month intervals.

Specific immunofluorescent studies were conducted during the initial and subsequent follow-up examinations. Direct immunofluorescent examination of the peribullous normal-appearing skin was performed with standard immunofluorescent techniques as previously described.[8] Monospecific antisera, as judged by immunoelectrophoresis and/or gel double diffusion, specific for IgA, IgG, IgM, IgE, IgD, and C3 were employed. The antisera were made in our laboratory or were purchased commercially. The specificities of the antisera have been previously described.[8] Fluorescein-conjugated goat antihuman IgD antiserum was purchased commercially. All antisera demonstrated specific staining as judged either by absorption with purified myeloma protein or with blocking experiments employing a sandwich technique with unlabelled, class specific antiimmunoglobulin antisera.

Indirect immunofluorescent studies were employed using previously described standard techniques, ie, fluorescein-conjugated rabbit anti-human IgG with monkey esophagus and, at times, normal human skin as a substrate to determine serum basement membrane antibodies.[8] In addition, the patients' sera were examined in the Erie County Laboratories for various autoantibodies against nuclear components, smooth muscle, gastric parietal cells, mitochondria, and adrenal and thyroid glands employing standard immunofluorescent techniques.

Biopsy specimens of peribullous and

normal skin were obtained using a 4 mm punch. Normal skin from the extensor forearm was obtained at four to six monthly intervals when the patients were clinically free of disease and therapy had been discontinued.

A total of 117 biopsies have been performed on these 36 patients. One hundred thirty-one serum specimens have been examined for BMZ antibodies.

RESULTS

The clinical data of these patients are presented in Table 1. All seven patients with 1+ disease had localized involvement. In six patients, the disease was limited predominantly to one extremity. The seventh patient had only scalp involvement. All of these patients remitted on topical therapy alone (wet dressings and 0.1% triamcinolone acetonide cream). There were no recurrences in this group.

All patients with 2+, 3+, and 4+ activity had generalized disease. Three patients were noted to have oral lesions that healed without sequelae after therapy. Also, 12 patients had significant pruritus that was controlled with hydroxyzine hydrochloride. In general, the more extensive the bullous eruption, the longer the period of time for initial control of the blistering disease.

Seven patients had recurrences. Four patients had more than one recurrence. Each recurrence reproduced the clinical picture of the initial episode. The interval between recurrences was highly variable ranging from six weeks to 20 months and did not correlate with clinical severity or duration of initial disease.

No autoantibodies to nuclei, smooth muscle, adrenal, thyroid, and mitochondria were noted.

Table 2 contains results of the initial direct immunofluorescent examinations. There was no apparent relation between extent of clinical disease and class or number of classes of immunoglobulin BMZ deposition. The IgG and C3 were the most common immunoreactants detected along the BMZ. The C3 was observed in four initial examinations in the apparent absence, as judged by immunofluorescent techniques, of BMZ immunoglobulin deposition. This phenomenon occurred early in the initial disease and was not related to clinical severity. Subsequent biopsies performed two to three weeks later in two patients demonstrated IgG BMZ deposition. A similar immunofluorescent observation of C3 BMZ deposition in the apparent absence of Ig deposition was found in five additional instances during recurrence of bullous pemphigoid.

The IgD was seen in four patients and IgE in five. The IgD, IgE, IgA, and IgM deposition always occurred in association with IgG.

Eleven of the 36 patients initially had either no demonstrable serum BMZ antibody, or if noted, was present only in undiluted (neat) serum (Table 3). There was no correlation between the absence of serum anti-BMZ antibody and clinical disease activity.

The fates of BMZ antibody deposition and serum BMZ antibody after therapy are displayed in Table 4. Sixteen patients, off all therapy, have been free of serologic and immunohistologic evidence of BP for a mean period of 23 months. Six additional patients being treated are free of disease with no serologic or direct immunofluorescent evidence of BMZ antibody or C3 deposition.

Five patients, free of disease for a mean of ten months, have persistent

Table 5.—Treatment

Treatment Group	No. of Patients	Clinical Category				Dose of Prednisone, mg/Day			
		1+	2+	3+	4+	Initial Dose, mg/Day	Duration of Initial Dose /Day	Maintenance Dose, mg/Day	Duration Maintenance, wk
Steroids	14	...	12	2	...	30-180 Mean 60	6-60 Mean 20	5-30 Mean 30	4-40 Mean 21
Steroids and azathioprine	15	...	...	4	11	40-240 Mean 70	10-60 Mean 21	10-60 Mean 35	4-24 Mean 16

pure IgG BMZ deposition but no serum BMZ antibody. Two have not had therapy for at least 12 months.

Three patients, disease-free and not being treated, persist in displaying serum IgG BMZ antibodies but direct immunofluorescence of normal skin failed to demonstrate in vivo C3 and immunoglobulin BMZ deposition.

Twelve patients with 2+ (moderate) and two patients with 3+ (moderately severe) disease were treated with prednisone alone (Table 5). Patients classified as having very severe disease (11 patients with 4+ disease) and four patients with 3+ disease received a combination of azathioprine and prednisone. The prednisone maintenance dose and length of time on treatment were less in those patients treated with the combined therapy than in the group of BP patients with milder disease that received prednisone alone.

COMMENT

In this paper, we confirm Lever's observations on the heterogeneous nature of BP.[11] During a prolonged observation of BP patients before the availability of corticosteroids, Lever noted 11 BP patients with localized disease who remitted spontaneously.[14] The seven patients with a predominantly localized disease (1+) included in our series all displayed classic indirect and/or direct immunofluorescent findings of BP. Once in the hospital, the localized bullous disease rapidly responded to topical steroids and wet dressings. Results of follow-up serologic examination and direct immunofluorescence of the skin were available in only three (Table 4), but clinical follow-up results in the other four reveals no evidence of BP.

There was no correlation between the extent of the disease and the antibody titer, a finding that has been observed previously.[10] Thirty percent of our patients' initial sera had either no detectable serum BMZ antibodies, or if present, the titer was neat (undiluted serum). Most laboratories would report the three neat sera noted in our series as negative for BMZ antibodies. Follow-up examination of these patients two to three weeks later generally demonstrated a detectable serum BMZ antibody titer. The reason for the failure to detect the serum BMZ antibody initially may be related to the fact that early in the disease, all the antigenic determinants on the BMZ may not be occupied. In a sense, these unoccupied antigenic sites absorb out the serum antibody. It is likely that once the antigenic sites on the BMZ are occupied, the serum antibody titer rises and becomes detectable.

This study also demonstrates the value of fluorescein-conjugated anti-human C3 as a diagnostic reagent. In nine instances (four initial disease and five with recurrent episodes), C3 BMZ deposition was noted in the apparent absence of Ig deposition. In two of three patients tested, we were unable to demonstrate Clq or C4 staining. One patient demonstrated Clq staining. Subsequent examination of biopsy specimens of two additional patients taken three weeks later demonstrated IgG BMZ deposition. Surprisingly, six patients demonstrating only C3 deposition along the BMZ had detectable serum antibodies (mean titer 40). We cannot explain this apparent discrepancy between serum and skin BMZ antibody detection. Our general experience indicates that a direct immunofluorescent examination of perilesional skin is a superior diagnostic procedure to serum antibody determination. On the other hand, the ease in detecting C3 in the apparent absence of Ig BMZ deposition, as judged by immunofluorescent technique, is most likely explained by the fact that one IgM and two IgG molecules are capable of activating hundreds of C3 molecules at the site of an antigen-antibody reaction.[18]

All patients when examined initially or during subsequent recurrences of their BP had IgG and/or C3 BMZ deposition. During recurrence, we could demonstrate a serum anti-BMZ antibody in 50% of patients. Again these patients were examined early in their recurrence, which in view of our previous results (see above), probably explains the low incidence of detectable serum antibodies.

Our most significant observation, however, is that 16 of our patients with generalized disease have, after therapy, remained in prolonged clinical remission and without serologic or direct immunofluorescent evidence of BMZ antibodies. Five of these patients have been observed for at least 36 months; five for 18 months; four for 12 months; and two for 6 months.

Five patients persist in demonstrating pure IgG BMZ deposition after prolonged therapy given for a systemic effect. Two of these patients have not had therapy for at least 12 months. The reason for the persistence of IgG deposition is unknown. This may represent delayed catabolism of IgG but this seems unlikely because of the duration of the persistence. On the other hand, the IgG BMZ deposition could represent a subclinical immunologic assault on the basement membrane that may, with time, either abate or result in formation of new bullae. These patients remain under observation.

Three patients clinically free of disease have persisted in displaying serum BMZ antibodies without direct, immunofluorescent evidence of Ig or C3 in normal skin. These antibodies are easily detected with monkey esophagus but are difficult to detect when homologous or autologous skin is employed as a substrate. The titer of these antibodies on autologous skin is 20 compared to 80 on monkey esophagus. The reason for the discrepancy between the presence of serum antibodies in these patients in the absence of direct immunofluorescent evidence of BMZ Ig deposition is

unknown. Perhaps the in vitro techniques provide a more favorable milieu for the low titer serum antibody to react with the human basement membrane than is present in the in vivo setting. Alternatively, or perhaps related to this observation, may be the weak avidity of these BMZ antibodies for human BMZ antigen(s).

The IgD and IgE BMZ deposition was noted in a small percentage of our patients. Similar observations have been previously noted.[8-19] Three of the five patients with IgE basement membrane deposition demonstrated serum IgE antibasement membrane antibodies in weak titers.[2-6] The IgD serum antibasement membrane antibodies were found in a neat titer in one of the four patients demonstrating IgD basement membrane staining.

This study suggests that the combined use of prednisone with azathioprine (1.5 mg/kg of body weight) is of benefit in treating BP. Our data indicate that not only may the length of therapy be reduced (in our series 30%) but that the maintenance dose of prednisone may be substantially lowered (50%).

The steroid-sparing effect of the combined use of prednisone and azathioprine appears to be of real benefit in the prolonged steroid treatment of an elderly patient. To date, employing the combination of azathioprine (1.5 mg/kg of body weight/day) and prednisone as described in the study, we have not had any serious side effects due to either the prednisone or azathioprine.

On the other hand, in half of the 14 patients treated with high doses of prednisone alone, side effects either secondary to or partially attributable to the steroids were noted. Two deaths occurred in this group; one secondary to massive gastrointestinal bleeding, the other secondary to a gram negative septicemia. Four patients developed depression or psychosis. Mild gastrointestinal bleeding, steroid-induced diabetes mellitus, and osteoporosis were noted in individual patients.

Other investigators, however, have noted toxicity with azathioprine.[20,21] Our lack of side effects may be explained, at least in part, by the relatively low dose (1.5 mg/kg of body weight) employed in our study compared to the 2.5 mg/kg of body weight by others.

Admittedly, our experience with this combined therapy is preliminary and has not been subjected to the scrutiny of a double-blind control, but our observations suggest that the combined therapeutic effect of low doses of azathioprine and prednisone are additive but their toxicity is not.

Finally, it must be emphasized that during a prolonged evaluation all patients with BP (initial or recurrent disease) had positive immunofluorescence along the perilesional BMZ. We believe that the pure C3 deposition, noted in nine instances (four during initial disease, five during recurrent disease), is secondary to an immunologic reaction. This is supported by the subsequent ability to demonstrate IgG BMZ deposition (two to three weeks later). This pure C3 BMZ deposition is similar to the findings noted in herpes gestationis in which C3 is often noted along the BMZ in the apparent absence, as judged by immunofluorescent techniques, of other complement components and immunoglobulins.[22,23] Unlike the herpes gestationis patients, the serum of these BP patients lacking antibasement antibodies failed to deposit C3 on normal human skin or monkey esophagus. Jordon et al[23] and Katz et al,[24] however, have provided evidence that the serum factor in herpes gestationis capable of depositing C3 along the BMZ frequently in the absence of demonstrable BMZ antibodies is an avid complement fixing IgG anti BMZ antibody, which may be present in the serum in such low quantities as to frequently escape detection by routine immunofluorescent techniques.

We, therefore, feel that the consistent findings of IgG and/or C3 at the site of pathology in all patients with active or recurrent BP provides supporting, but by no means conclusive evidence, for a role of Ig and C in the pathogenesis of bulla formation in this disease.

This investigation was supported by Public Health Research grant R01 AM 16593-03 from the National Institute of Arthritis and Metabolic Diseases.

Christine Perpetus, Gail Raimondo, and Marilyn Fitzsimmons gave technical assistance.

Photochemotherapy for Mycosis Fungoides

Henry H. Roenigk, Jr, MD

• **Twelve cases of cutaneous mycosis fungoides (MF) with erythroderma, plaques, and tumors were treated with photochemotherapy. Methoxsalen followed two hours later by ultraviolet light (UVA) resulted in clinical clearing of skin lesions in seven patients with plaque stage MF and one patient with erythrodermic MF. Four patients with both plaque and tumor stage MF showed clearing of plaques but not the tumors. Phototherapy units consisted of boxes with 16 to 64 UVA lights. The mean number of treatments to clear was 17.4. The mean total dose to clear was 134.8 joules. The mean dose of maintenance UVA was 5.6 joules/sq cm. Histopathologic clearing of mycosis fungoides was demonstrated with the clinical clearing.**

(*Arch Dermatol* 113:1047-1051, 1977)

Mycosis fungoides (MF) is a form of malignant lymphoma that arises in the skin and over many years steadily progresses to plaques and tumors. Autopsy findings often reveal significant visceral involvement at time of death.[1] The premycotic stage is characterized by scaly erythematous patches that clinically resemble nonspecific eczemas, psoriasis, or parapsoriasis. When skin lesions reach the plaque and tumor stage in the skin, the clinical and histologic diagnosis is more evident.

Therapy of MF is controversial. The course of MF varies from either a long-term chronic process to early mortality. This variability in the natural course of the disease makes evaluation of therapy difficult. Staging of the disease[2,3] is important in deciding if therapy should be confined to skin lesions or given for systemic effect to irradicate visceral involvement. Topical approaches to therapy include corticosteroids,[4] nitrogen mustard painting,[5-7] and electron beam irradiation.[8]

Methoxsalen has been used for systemic effect for the treatment of vitiligo for over 20 years.[9] Parrish et al[10] reported successful treatment of psoriasis combining oral methoxsalen given for systemic effect and a high intensity longwave (320 to 390 mm) ultraviolet light (UVA) system. Our studies,[11] using several different phototherapy units in 168 patients with psoriasis, have confirmed the effectiveness of this therapy.

The present study describes the beneficial effect of photochemotherapy with methoxsalen and UVA in patients with MF.

SUBJECTS AND METHODS

Twelve patients, eight women and four men, aged 27 to 82 years, with clinical cutaneous lesions of MF were studied. The diagnosis was confirmed histologically on repeated skin biopsies. All biopsy specimens were reviewed and confirmed by the pathology panel of the MF cooperative study.[12]

Complete evaluation of all patients included routine laboratory studies, microscopic examination of bone marrow biopsy specimens, roentgenograms of upper and lower gastrointestinal tract, intravenous pyelogram, liver scan, brain scan, lymphangiograms, and lymph node biopsies. Laparotomy staging was done in one patient. Only patients with no detectable visceral lesions of MF were entered into the therapy.

Ten-milligram capsules of methoxsalen

*Intensity measured in the center of the chamber.

were given according to the method of Parrish et al[10] based on patient body weight as follows: up to 50 kg of body weight, 20 mg; 51 to 65 kg, 30 mg; 66 to 80 kg, 40 mg; and over 80 kg, 50 mg. Most of the patients were taking 40 mg of methoxsalen. Patients were instructed to take the methoxsalen two hours before their scheduled light therapy.

Phototherapy units utilized the following two different light bulbs: General Electric blacklight (F 72 T12 BL H0) and Sylvania (Parrish et al).[10] Both lamps emit a continuous spectrum of long UVA in the range of 320 nm to 400 nm with a peak emission between 350 and 380 nm. Both lamps are 72 inches long and units were developed with various numbers of bulbs. Sylvania lamps have an internal reflector system and the General Electric units utilize external reflectors. Table 1 compares the phototherapy units used in this study. Each unit has a timer and meter for hours of operation. Output of the units was measured with an international light 254 photometer and 700 research radiometer calibrated at 360 nm (Table 1).

Initial exposure times of patients to longwave UVA were based on the degree of pigmentation before therapy, history of ability to tan, and the type of phototherapy units to be used. Exposure times were increased with each treatment depending on patient response, evidence of erythema, and type of phototherapy unit used. Initial UVA dose was between 1.5 to 3 joules/sq cm. Dosage of phototherapy was recorded in both minutes and joules per square centimeter. Exposure times were increased at each treatment by at least 0.5 joules/sq cm or more depending on presence of erythema. Ultraviolet light blocking goggles were worn over the eyes during therapy and UVA blocking sunglasses for five hours after therapy.

Once the MF lesions had cleared completely, the patient was placed on a maintenance schedule. The UVA exposure (joules/sq cm) during maintenance was the same as the patient's last treatment during the clearing phase. Photochemotherapy was usually given every 48 hours (three times a week) during clearing. Maintenance was either once or twice per week or every other week (Table 2).

Table 2.—Follow-up of Mycosis Fungoides Treated With Photochemotherapy

Photographs and skin biopsies from identical locations were taken before and after therapy with photochemotherapy to evaluate results.

Eight of the 12 patients had received other therapy previously for MF with topical corticosteroids, mechlorethamine, superficial x-ray, electron beam, and chemotherapy (Table 3). Four patients had no prior therapy.

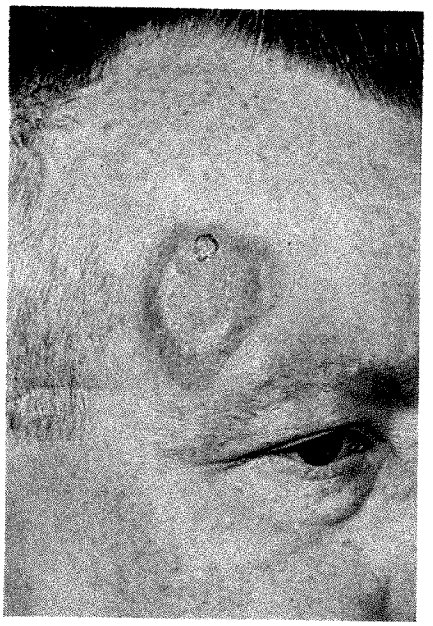

Fig 1.—Case 1, plaque-like lesions of MF before PUVA.

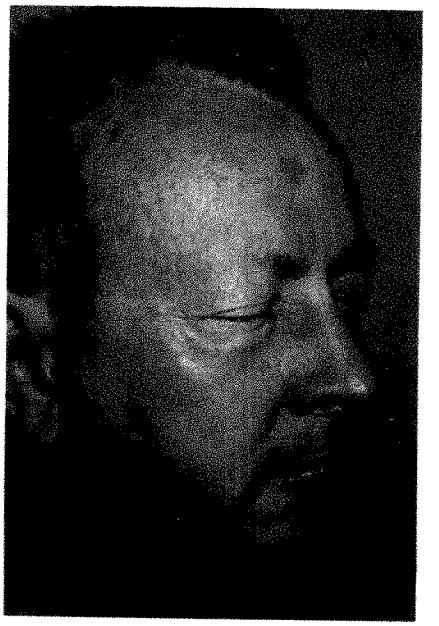

Fig 2.—Case 1, clearing of plaque lesions of MF of face after PUVA therapy.

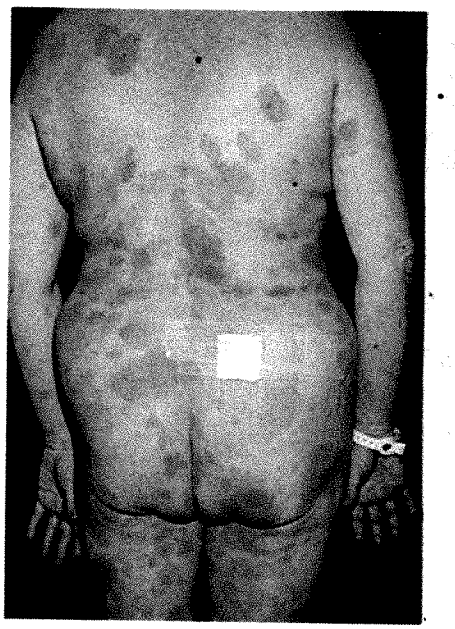

Fig 3.—Case 2, plaque-like lesions MF over back before PUVA therapy.

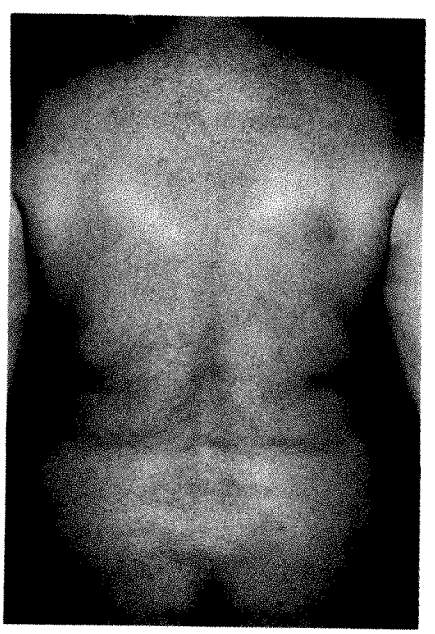

Fig 4.—Case 2, clearing of all plaque-like lesions of MF after PUVA therapy.

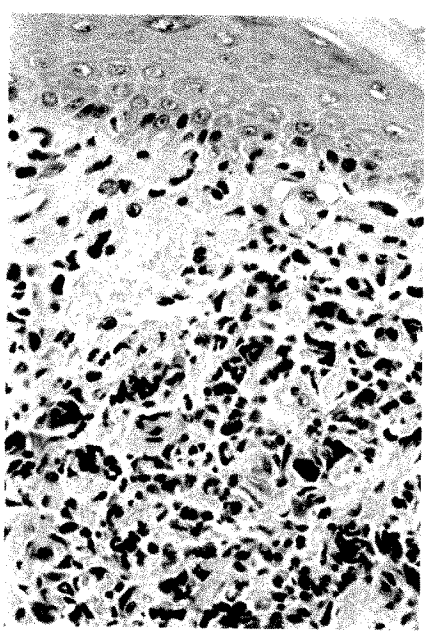

Fig 5.—Case 4, skin biopsy specimen before PUVA therapy compatible with MF (hematoxylin-eosin, original magnification ×40).

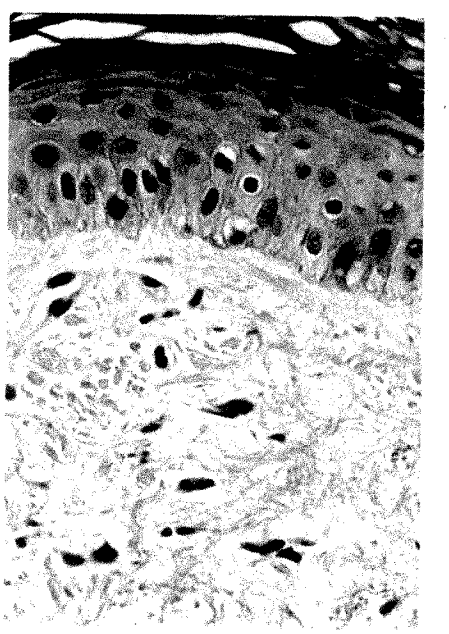

Fig 6.—Case 4, skin biopsy specimen after PUVA therapy showing the atypical dermal infiltrate is cleared (hematoxylin-eosin, original magnification ×40).

RESULTS

Seven patients (cases 1 (Fig 1 and 2), 2 (Fig 3 and 4), 3, 6, 8, 9, and 11) had plaque-type MF and had the best response to PUVA (Table 4). All of them cleared their MF with a mean total dose of 134.8 joules (Table 4). They have subsequently been placed on maintenance therapy, and all have remained clear with a mean maintenance dose of UVA of 5.6 joules/sq cm (Table 4). Average follow-up of the cleared patient is greater than one year. Patient 8 had erythroderma and was difficult to control because of the erythema from UVA. She is now maintained on 5 joules/sq cm of methoxsalen-UVA (PUVA)-16 twice per week. As the lesions cleared, a deep tan developed in all patients.

Four patients (cases 4, 5, 10, 11) had both plaque and tumor lesions. The plaque lesions in all four patients responded to PUVA. Cases 4 and 5

Table 4.—Mycosis Fungoides-PUVA

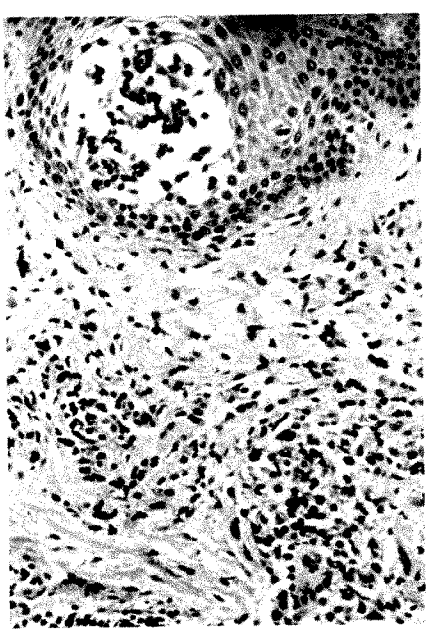

Fig 7.—Case 8, skin biopsy specimen before PUVA compatible with MF large pustular abscess in the epidermis and atypical dermal infiltrate (hematoxylin-eosin, original magnification ×20).

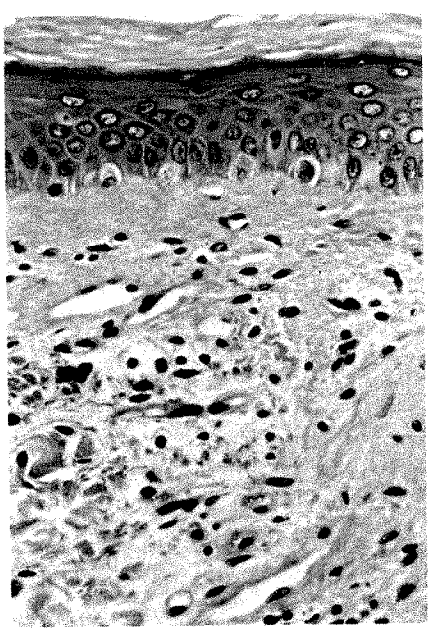

Fig 8.—Case 8, skin biopsy specimen after two months of PUVA, abscess and atypical dermal infiltrate is cleared (hematoxylin-eosin, original magnification ×20).

required deep x-ray therapy to isolated tumor lesions that showed no response to PUVA. The plaques of MF in case 10 were clearing but the patient was randomized in the MF cooperative study because of tumor lesions. Case 12 was initially treated and responded to PUVA at an outside institution. After complete examination at Cleveland Clinic, he was found to have visceral involvement with MF and was subsequently randomized in the MF cooperative study to electron beam and chemotherapy.

Patients were treated with various phototherapy units (Table 4). The number of minutes per treatment at time of clearing varied with the phototherapy unit used (PUVA-16 takes longer to give 5 joules/sq cm than does PUVA-64). The average maintenance treatment was 5.6 joules/sq cm.

Histological sections of skin from plaques before and after PUVA confirm the clinical clearing of lesions in all patients (Fig 5 through 8).

COMMENT

Because of the chronicity of MF and its unpredictable course, treatment must be individualized. Although, Van Scott and Winters[13] have advocated an aggressive approach with topical mechlorethamine hydrochloride. Fuks et al[8] have presented data that intensive early electron beam therapy may be curative. Bluefarb[14] recommended a conservative approach with topical corticosteroids and UVA exposure in mild cases. Chemotherapy following therapeutic outlines used for Hodgkin's disease have not increased survival of patients with MF.[1]

Photochemotherapy has become a new method of controlling severe generalized psoriasis.[10] Two large cooperative studies in the United States are presently evaluating this therapy and its possible adverse reactions.

Gilchrest et al[15] have treated nine patients in various stages of MF using methoxsalen and the Sylvania phototherapy unit. Case 6 is one of their cases and has been followed by Cleveland Clinic for the past year. This report of 11 additional cases that have responded confirms the short-term effectiveness of this new therapy in MF. We used methoxsalen in a similar dosage to Gilchrest et al[15] but utilized various phototherapy units with both General Electric and Sylvania light sources (Table 1).

Mycosis fungoides in the plaque stage responds best to photochemotherapy. Seven patients in our series who only had plaque stage mycosis fungoides responded and cleared completely. Follow-up for greater than one year (Table 2) shows they remain clear if maintenance therapy is continued. None of them have developed tumors or symptoms of visceral involvement. Patients with both plaque and tumor stage MF showed a good response in plaques only. The tumors were not responsive to photochemotherapy, and several of our patients in this group required other therapy to control tumors.

Skin biopsy specimens taken from identical plaque lesions of MF before and after photochemotherapy confirm the clearing of plaque lesions. Even lesions with abnormal lymphocytes deep in dermis and Pautrier abscesses in epidermis resolved with photochemotherapy. The histological clearing of deep dermal lymphocytes confirms the depth of penetration of UVA (Fig 5 through 8).

The mechanism of action of photochemotherapy in clearing lesions of MF is not completely understood. Methoxsalen is a furocoumarin derivative and a potent photosensitizer with an action spectrum in the long ultraviolet wave light range (320 to 400 nm). Methoxsalen-induced damage is related to the formation of photoproducts between the chemical and pyrimidine bases of the cellular DNA.[16,17] Epstein and Fukuyama[18] have shown that the phototoxic reaction induced by methoxsalen and UVA inhibits semiconservative premitotic DNA synthesis in mammalian epidermis but caused minimal depression of RNA formation. This depression of DNA synthesis is the presumed rationale for its effect on the rapidly proliferating epidermis in psoriasis.

Musajo et al[19] demonstrated that irradiation with UVA and methoxsalen inhibited tumor transmitting capacity of Ehrich ascites tumor cells. They indicated the tumor inhibition may be due to inhibition of DNA and RNA synthesis.[17] Similar tumor inhibiting effects have been reported with methoxsalen and UVA in several different tumor systems.[20] A similar effect on DNA synthesis and to a lesser extent, RNA synthesis, may be the explanation for the clinical and histological improvement seen in MF exposure to methoxsalen and UVA.

Because of the complications that can occur from other forms of therapy presently used for MF, photochemotherapy seems to offer an alternative approach that is effective and safe. Continuous maintenance photochemotherapy in the plaque stage may keep mycosis fungoides in remission.

Keratinizing Dermatoses

Combined Data From Four Centers on Short-Term Topical Treatment With Tretinoin

Sigfrid A. Muller, MD; Richard W. Belcher, MD; Nancy B. Esterly, MD; Jon C. Lochner, MD; James S. Miller, MD; Henry Roenigk, Jr, MD; Lester Weissman, MD

• In four medical centers, 40 patients with keratinizing dermatoses were treated with topical tretinoin (vitamin A acid) 0.1% cream and salicylic acid 2% cream in a short-term, double-blind study. Tretinoin was the more effective treatment for several of the keratinizing dermatoses with the exception of palmar-plantar hyperkeratosis, for which it was not effective in the concentration and method of application used. The most striking clinical responses occurred in patients with lamellar ichthyosis and ichthyosis vulgaris. Local adverse reactions—chiefly pruritus, erythema, burning, excoriation, and irritation—were not severe and could be controlled by modification of the treatment regimen.

(*Arch Dermatol* 113:1052-1054, 1977)

Vitamin A preparations, both systemic and topical, have been administered for years for hyperkeratotic skin disorders. In the early 1960s, topical preparations of tretinoin (retinoic acid, vitamin A acid) were first reported effective in decreasing scale formation in the ichthyosiform dermatoses.[1,2] However, no further publications concerning their topical application appeared until 1968, when Frost and Weinstein[3] described the effects of various forms of vitamin A, including vitamin A acid cream in strengths ranging from 0.1% to 0.3%, in patients with ichthyosiform dermatoses or psoriasis. Fulton et al[4] reported the successful treatment of two patients with Darier's disease by application of a tretinoin 1% lotion under occlusion, and Schuppli and Ziegler[5] treated one patient with congenital ichthyosiform erythroderma and obtained good results. Subsequently, occasional papers, usually case reports, have appeared on the efficacy of tretinoin in the treatment of such chronic dermatoses as palmar-plantar hyperkeratosis, lamellar ichthyosis, psoriasis, ichthyosis vulgaris, and Darier's disease.[6-17] Considerable differences in formulation of medication, concentration of vitamin A acid, method and frequency of application, and duration of treatment can be noted in these reports.

A multiclinic study was initiated in which an identical protocol was used at four medical centers. In these double-blind studies, patients with hyperkeratotic skin disorders were treated with identically paired medications—a tretinoin 0.1% cream and a salicylic acid 2% cream, the latter being selected as a safe nonspecific irritant. The results were analyzed as a single, multiclinic study. The data from patients with the same disease were pooled and analyzed.

MATERIALS AND METHODS

A total of 44 patients with ichthyosis or bilateral and symmetric localized hyperkeratotic skin disease participated in these double-blind studies. Nineteen were male and 25 were female subjects; their ages ranged from 2 to 70 years (27 were less than 21 years old). Nine were black, the remainder white. For each patient, comparable sites of involvement were designated as site 1 and site 2. One site was treated with tretinoin 0.1% cream and the other with an identical-appearing salicylic acid 2% cream. Each tube also contained the following: distilled water, propylene glycol, stearyl alcohol, petrolatum, isopropyl palmitate, polyoxyl 40 stearate, cetyl alcohol, stearic acid, beeswax, methylparaben, (butylated hydroxyanisole) (BHA), (butylated hydroxytoluene) (BHT), propylparaben, and disodium sequestrene. Each medication, coded by patient number and site number, was applied to the designated area as a thin film once or twice daily for a period of 12 weeks, unless improvement suggested a reduced schedule, after which the code was broken. Patients were seen weekly by the principal investigator for evaluation, and overall improvement in scaling and erythema was recorded as none, slight, moderate, or good (scored 0 through 3).

Local or systemic side effects were detected by clinical examination and laboratory studies. Baseline values were established for routine hematologic studies, urinalysis, BUN, SGOT or SGPT, cholesterol, blood glucose, alkaline phosphatase, and serum bilirubin. These tests were repeated once every two weeks for the first four weeks and monthly thereafter.

For statistical tests of the results of therapy, each patient's daily improvement score for each treated area was recorded at every visit, and the average scores were calculated for the 12-week period by taking the sum of the daily scores and determining the mean. The mean improvement score of all patients was determined for

Fig 1.—Lamellar ichthyosis of upper extremities. Lesion has cleared on subject's left side after treatment with tretinoin. Salicylic acid cream (control), on subject's right side, was ineffective.

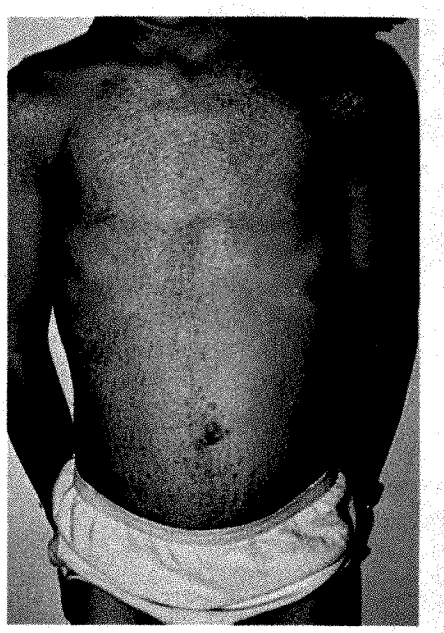

Fig 2.—Lamellar ichthyosis. Clearing has occurred on subject's left side after treatment with tretinoin. Control side patient's right was unimproved.

each medication, and the significance of the difference between the scores was obtained by the one-tailed Student's t-test.

RESULTS

Forty of the 44 patients completed 12 weeks of therapy. Four patients were dropped from the study and their data were not included in the results because the treatment period was too short for adequate evaluation of drug efficacy. Among the 12 patients with palmar-plantar hyperkeratosis, lesions of only three patients treated with tretinoin and only two treated with salicylic acid improved clinically even to a slight degree. The mean improvement score for each medication also indicated less than slight improvement, and no significant statistical difference between the two medications was detected.

For patients with ichthyosis vulgaris and lamellar ichthyosis (Table 1), the therapeutic effect of tretinoin 0.1% cream, represented by mean scores of 1.87 and 2.14, respectively, showed that tretinoin cream was definitely superior to salicylic acid 2% cream, which had mean scores of 0.61 and 0.80, respectively. The clinical difference in response of the paired treatment sites was particularly striking in the patients with lamellar ichthyosis, as shown in Fig 1 and 2.

Although all patients with lamellar ichthyosis responded most dramatically, there was also some response in patients with other ichthyosiform dermatoses, that is, ichthyosis vulgaris and X-linked ichthyosis.

Systemic reactions were absent in all 44 patients, and no significant abnormalities were detected by laboratory tests. Five patients in one clinic had elevated baseline levels of SGOT, but none of these values increased significantly during treatment, and in two patients, the values actually decreased.

Adverse reactions to therapy were restricted to local effects (Table 2) and occurred in all types of lesions treated with tretinoin 0.1% cream. The most common untoward effects were erythema, pruritus, and irritation. Fifty-nine reactions occurred in 29 of the 44 patients; 53 occurred in 26 of the 30 patients with a congenital ichthyosiform dermatosis. Local reactions were more frequently noted in sites treated with tretinoin (59 sites) than in those treated with salicylic acid (8 sites). The salicylic acid cream did not exacerbate any of the skin disorders treated.

Of the four patients dropped from the study, two did not complete the course of treatment because of exacerbation of a preexisting atopic dermatitis; they had been admitted to the study for treatment of concurrent ichthyosis vulgaris. The association of these two conditions is well documented.[18] Another patient had an impetiginized eczematous eruption at

both treatment sites. Therefore, the reaction could not be attributed to either tretinoin or salicylic acid. The fourth patient, who had mild acquired ichthyosis, was dropped from the study at his request after erythema developed, and he believed that treatment was making his skin condition worse.

COMMENT

Topical application of tretinoin 0.1% cream proved to be an effective short-term treatment for ichthyotic disorders, particularly lamellar ichthyosis and ichthyosis vulgaris. Too few patients with Darier's disease and pityriasis rubra pilaris were treated to permit any conclusions except that further trials should be done in these conditions. It did not improve palmar-plantar hyperkeratosis. (It is of interest that among the 12 patients with palmar-plantar hyperkeratosis who showed little or no response to tretinoin, only two topical irritative reactions were reported, both in the same patient.) This contrasts with the remarkable improvement reported in one case of keratoderma of the palms and soles by Heiss and Gross,[7] who used 0.3% tretinoin ointment on the palms and soles. It is possible that we would have observed a therapeutic effect if a stronger concentration of tretinoin had been used.

Statistical evaluation of the clinical responses demonstrated significant differences between the two medications that favored tretinoin in ichthyotic disorders. Improvement of all lesions treated with tretinoin was rated slight to good, whereas 17 of 28 sites (60%) treated with salicylic acid did not improve. These responses are reflected in the mean improvement score (Table 1).

Fifty-six local reactions occurred with tretinoin at treated sites and were regarded as probably attributable to the medication. The reactions were mild to moderate in degree and could be controlled easily by decreasing the frequency of application. Although described as adverse reactions, the irritant effects may be related to the pharmacologic action of tretinoin and may be contributing to the desired therapeutic response, as suggested by other studies.[4,13]

In this short-term study, tretinoin has been shown to be beneficial, and this confirms the data previously reported. It remains to be determined how useful tretinoin will be in the long-term management of patients with keratinizing disorders, because it is likely that the medication will usually need to be used indefinitely.

This investigation was supported by a grant from Hoffman-La Roche, Inc.

Defective Monocyte Chemotaxis in Mycosis Fungoides

Larry E. Seitz, MD; Loren E. Golitz, MD; William L. Weston, MD; John E. Aeling, MD; Roberta D. Dustin

• Monocyte-macrophage function was studied in 14 patients with histologically confirmed mycosis fungoides. Three component parts of the monocyte-macrophage system were examined. Monocyte bacterial phagocytosis and bacterial killing were normal. However, a defect in directional mobility (chemotaxis) was found in patients with mycosis fungoides ($P < .0025$) when compared to 35 healthy controls. Defective chemotaxis was present regardless of disease stage or therapy. This defect in monocyte chemotaxis represents a previously unrecognized immune deficiency and may help explain the frequent infections found in patients with mycosis fungoides.

(*Arch Dermatol* 113:1055-1057, 1977)

Mycosis fungoides is a lymphoma that is first manifest in the skin and later may invade visceral organs. It has a variable clinical course of one to many years and is characterized by its progression through three clinical stages. The last two stages, the plaque and tumor stage, are frequently complicated by cutaneous bacterial infections that may lead to septicemia, the major cause of death.[1-4]

This association with frequent infections led previous investigators to study immune responses such as lymphocyte function in patients with mycosis fungoides. Despite extensive studies, no consistent defect of the lymphocyte system was uncovered. Therefore, we chose to investigate another aspect of immunity, the function of the monocyte-macrophage system. We report the results of quantitative assays of monocyte-macrophage function in 14 patients with mycosis fungoides.

SUBJECTS AND METHODS

Fourteen patients were selected from the mycosis fungoides clinic at the University of Colorado Medical Center. All were registered with the National Mycosis Fungoides Cooperative Group and were diagnosed histologically as having mycosis fungoides by the national pathology panel. The patients were representative of all three stages of the disease and had their disease for periods of time ranging from a few months to 35 years. Seven of the patients had undergone x-ray therapy, including conventional and electron beam therapy, and six had received chemotherapy, either topically, systemically, or both. Five had received only topical steroids. Concomitant therapy did not exclude patients from this study. The two patients with stage 3 mycosis fungoides were lymphopenic (less than 1,000 lymphocytes/cu mm).[5] Two of the 14 patients (No. 1 and 11 on the Table) had cutaneous infections at the time of the study. Thirty-five controls (mean age, 35.2 years) were selected from healthy young adults. The majority of these were studied concomitantly with patients with mycosis fungoides. Three component parts of the monocyte-macrophage system were investigated. This included chemotaxis, bacterial phagocytosis, and bacterial-killing power. All assays were performed on suspensions of monocytes obtained from heparinized peripheral venous blood and separated on ficoll-hypaque gradients.[6] Monocyte phagocytosis and killing were measured as the ability to ingest and kill *Staphylococcus aureus* 502A using the modified methods of Tan et al.[7]

Chemotaxis was measured by the method described previously[8] using micro-

Summary of Data on Patients With Mycosis Fungoides

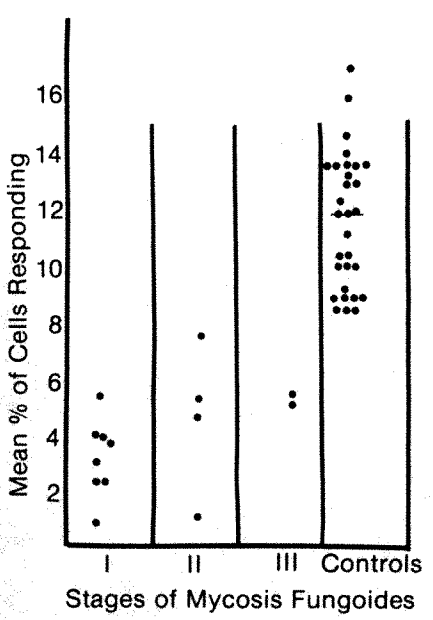
§ND indicates not done.



Scattergram of monocyte chemotaxis in patients with mycosis fungoides and controls. Mycosis fungoides, mean 4.3 ± 3.4 with control mean of 11.6 ± 6.0.

chemotaxis plastic chambers that were separated into two compartments by a sandwich of two Millipore filters. An 8.0-μ filter was placed on top and a 0.45-μ filter was placed below that permitted counting of any cells that passed completely through the upper filter and were, therefore, trapped by the lower filter. A standard chemotactic attractant used in this assay was a 10% solution of pooled AB negative human serum in RPMI-1640 tissue culture media activated with *Escherichia coli* lipopolysaccharide endotoxin type 0111:B4 at 200 μg/ml for 30 minutes at 37 C. This amount of endotoxin has been found to be the most effective in activating the C5a component of the complement system.[6] Aliquots of 0.5 ml of endotoxin-activated serum were stored and frozen at −70 C. Attractants were added to the lower chamber and 0.25 ml of a concentration of 1×10^6 monocytes/ml (250,000 monocytes) was added to the upper compartment. All assays were performed in triplicate. Chambers were incubated at 37 C with 5% carbon dioxide and 100% humidity for five hours. After incubation, the filters were removed and fixed in absolute methanol and rinsed in distilled water. Filters were stained using hematoxylin and bluing agents and then dehydrated in a standard fashion and cleared with xylene. After mounting on a slide and allowing to dry overnight, the filters were examined at ×430. Ten fields were counted. The cells on the upper surface of the 8.0-μ filter (cells that did not migrate) were compared to those migrating through the filter (including those within the filter) plus those that passed through the 8.0-μ filter and were entrapped on the surface of the 0.45-μ filter. The results were expressed as the percentage of total cells migrating using the formula: 100 × total number of cells migrating/total number of cells migrating and not migrating.

RESULTS

Monocyte phagocytosis and killing of *S aureus* 502A was normal in nine of the ten patients studied (Table). Phagocytosis expressed as percentage extracellular bacteria surviving (% EB) was 18.5 ± 6.2 (mean ± SD) for the control group and 33.3 ± 15.9 (mean ± SD) for patients with mycosis fungoides ($P = .20$). Bactericidal activity expressed as percentage intracellular bacteria surviving (% IB) was 2.0 ± 0.9 (mean ± SD) for the control group and 3.2 ± 1.5 (mean ± SD) for patients with myco-

sis fungoides ($P = .50$). One subject had evidence of poor bacterial phagocytosis (126% EB) (Table).

Thirteen of fourteen patients with mycosis fungoides demonstrated defective cellular chemotaxis of their mononuclear leukocytes. The mean of this group of patients was 4.3 ± 3.4 (mean $\pm$ SD) with a control of 11.6 ± 6.0 (mean ± 2 SD). This was significantly depressed ($P = .0025$) when compared to the 35 controls by χ^2 analysis (Figure). Only one of these 14 patients with mycosis fungoides demonstrated chemotaxis values within 2 SD of normal controls.

COMENT

Previous investigations of the immune system in mycosis fungoides have focused on lymphocyte number and function. Most recently, Tan et al[7] published their findings of B and T cell function in 19 patients. They found no evidence of immune suppression even in those who had the disease for many years. Their studies included quantitation of B cells in the peripheral blood and an attempt to find these cells in the skin tumors. Also normal were serum immunoglobulin levels, except for a slightly elevated IgE value. Serum complement components C3 and C4 were normal. T cell function as measured by lymphocyte transformation and reaction in mixed lymphocyte culture was normal.

Investigation of immune status in mycosis fungoides by Blaylock et al[8] also revealed relatively normal immunological responses. Evaluation of B cell function revealed a normal anamnestic response to an *E coli* antigen and normal levels of circulating immunoglobulins. Quantitative serum assays for IgM and IgG were normal, whereas the serum IgA level was frequently elevated. Delayed hypersensitivity as measured by a battery of nine skin test antigens and the ability to sensitize to dinitrochlorobenzene were similarly found to be normal. The development of contact sensitivity to topical nitrogen mustard in many patients with mycosis fungoides is additional evidence of the competence of this aspect of their cell-mediated immunity.[9,10] Clendenning[11] reported that all 14 of the patients he studied with mycosis fungoides retained the ability to reject a homograft and to accept autografts until the terminal stage of their disease. Conflicting evidence was reported by Rostenberg and Bluefarb[12] who found a decreased number of positive delayed skin tests in patients with mycosis fungoides and concluded that there was a general depression of delayed-type hypersensitivity.

The demonstration of normal immune response in the studies of Blaylock[8] and Tan et al[7] may reflect the selection of cases with patients with early mycosis fungoides because an absolute lymphopenia in the peripheral blood is a well-documented event in advanced mycosis fungoides. Lymphopenia was present in 45% of the 132 patients with tumor stage mycosis fungoides reported by Fuks et al,[13] in 76% of the 165 patients with mycosis fungoides reported by Cyr et al,[14] and in all four patients reported by Edelson et al.[15]

Despite the failure to detect an immunological defect in prior studies of patients with mycosis fungoides, there is considerable clinical evidence that infection is a major difficulty in these patients. All 34 patients in the study by Casazza et al[1] and all 17 patients in the study by Block et al[2] had skin infections. Infections of tissues other than skin were also common. Seventy-five percent of Casazza et al's[1] 34 patients, and 67% of the patients reported by Epstein et al[3] had extracutaneous infections, most notably bacterial pneumonia.[1-4] Although *Pseudomonas* and *S aureus* are the most frequently found pathogens, unusual organisms and opportunistic bacteria are also frequently found and accounted for eight of 21 cases of septecemia in one series.[9] Opportunistic pathogens, such as disseminated herpes simplex,[1] *Candida albicans*,[1-3] *Aspergillus*,[4] toxoplasmosis,[4] and the virus agent of multifocal leukoencephalopathy[16] have been demonstrated in mycosis fungoides as in other conditions with impaired host defenses.

Despite the apparent differences in immune response when comparing Tan et al's[7] patients with mycosis fungoides with those with Hodgkin[17] disease, the incidence of infection, the types of microorganisms involved, the time of onset of infections, the number of infectious episodes per patient, and the incidence of septicemia are virtually identical in both diseases. The same infection data are also found in patients with lymphosarcoma and reticulum cell sarcoma.[17] We speculated that a defect in the monocyte-macrophage system was a possible explanation for this contradiction. Our finding of depressed monocyte chemotaxis in 13 of 14 patients with mycosis fungoides represents a newly recognized in vitro immunologic defect in this disease. Since attraction of monocytes to tissue sites is an important host defense against invading microorganisms, faulty chemotaxis may partially explain the frequent infections in such patients.

Defective monocyte chemotaxis in mycosis fungoides occurs regardless of the stage of the disease, regardless of the presence or absence of therapy, and despite preservation of normal monocyte phagocytosis and bactericidal activity. A selective defect in directional mobility of monocyte-macrophages occurs in mycosis fungoides and may be a useful marker for this disease.

Allergic Contact Dermatitis to Topical Fluorouracil

Lt Col Detlef K. Goette, MC, USA, Lt Col Richard B. Odom, MC, USA

• We designed a prospective and retrospective study to determine the incidence of allergic contact dermatitis to topical application of fluorouracil. Intracutaneous and epicutaneous skin tests of various fluorouracil concentrations were given to patients who were to be treated with the drug for actinic keratoses (group A) and to patients who had previously been treated with fluorouracil for actinic keratoses (group B). Six patients in group B had allergic contact dermatitis to topical fluorouracil. The common clinical characteristic of the six patients was a severe pruritic eruption at the site of fluorouracil application. Allergic contact dermatitis should be suspected in the presence of severe pruritus or a severe eczematous response in patients treated with topical fluorouracil.

(*Arch Dermatol* 113:1058-1061, 1977)

Recently, we reported[1] two cases of allergic contact dermatitis to topical fluorouracil in patients treated for actinic keratoses of the face. Because a significant number of patients developed a vigorous reaction during this treatment, we wondered about the incidence of allergic contact dermatitis to fluorouracil. Such a reaction would be extremely difficult to differentiate from the well-known irritancy from topical application of fluorouracil. Therefore, we designed a prospective and retrospective study to determine the incidence of allergic contact dermatitis by means of intracutaneous and epicutaneous skin tests in patients who were to be treated and in those patients who had been previously treated with fluorouracil for actinic keratoses of the face, scalp, arms, and hands.

MATERIALS AND METHODS

Group A (Prospective Study)

Group A consisted of 35 patients who had never been treated with topical fluorouracil (fluorouracil virgins) for actinic keratoses. All of these patients were tested intracutaneously on the left forearm with the following concentrations of fluorouracil in sterile water: 50 mg/ml; 25 mg/ml; and 10 mg/ml. The intracutaneous injection consisted of 0.1 ml of each strength of fluorouracil. The test sites were read after 48 hours and observed for a period of six days. Only 12 of the 35 patients had epicutaneous skin tests before treatment. These tests were done on their backs or on the inner aspect of the upper arm with 1%, 5%, and 10% concentrations of fluorouracil in petrolatum. Forty-eight hours later, all 35 patients were questioned regarding any reactions at any test sites. They were questioned about erythema, papules, vesicles, itching, and burning. If any of these reactions were noted, the patient was seen by one of the physicians the same day. Patients were requested to observe the test sites for a total of six days for any other reactions.

If no reactions had occurred, the patient started applications of 1% fluorouracil in propylene glycol twice daily to the face or a 5% fluorouracil cream to the scalp, forearm and/or the hands for 3 to 5 weeks (4 weeks average). Posttreatment testing also was done intracutaneously and epicutaneously in all 35 patients. Within three to eight weeks after completion of the treatment, all patients were tested intracutaneously with the same concentrations of freshly prepared fluorouracil solutions that were made each week. Simultaneously, epicutaneous tests were performed with 1%, 5%, and 10% concentrations of fluorouracil. The intracutaneous and epicutaneous tests were read and recorded at 48 and 72 hours.

Group B (Retrospective Study)

Group B consisted of 35 patients who had been treated for actinic keratoses with topical fluorouracil (fluorouracil experienced) in the preceding three months to three years, on one or more occasions. All patients received intracutaneous tests as described for group A. Twenty of the 35 patients had epicutaneous skin tests done in addition to the intracutaneous tests. The procedure for reading the tests was the same as described for group A.

Five of the fluorouracil-experienced patients were retreated and at the conclusion of treatment were retested in the fashion described for group A.

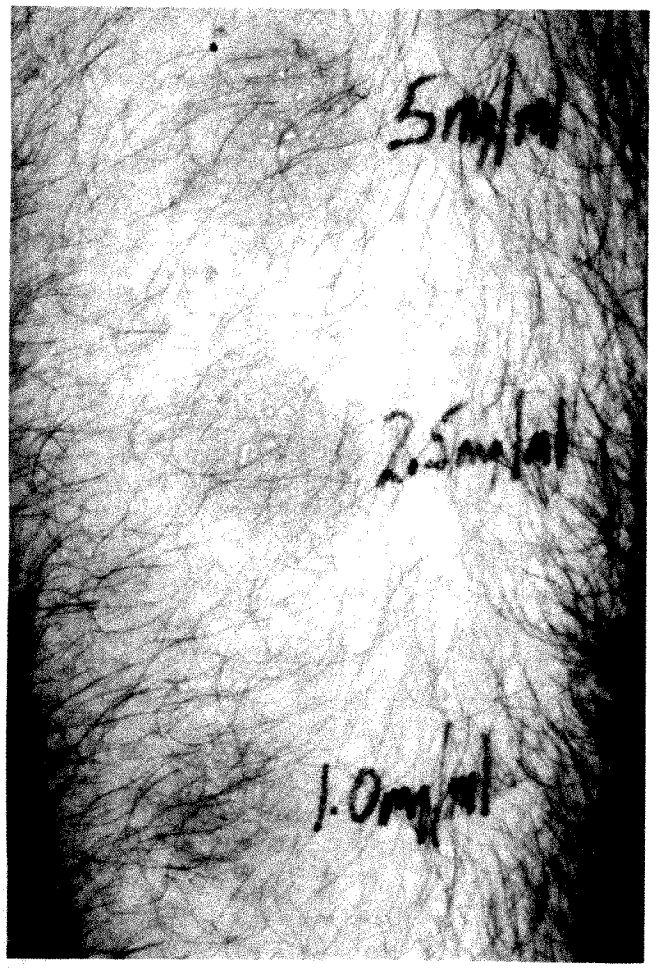

Fig 1.—Reaction 48 hours after intracutaneous injections of 0.1 ml of 50 mg/ml (top), 25 mg/ml (center), and 10 mg/ml (bottom) of fluorouracil in patient 6. (Skin markings at reaction sites are erroneous. Markings should read 5 mg/.1 ml, 2.5 mg/.1 ml, and 1 mg/.1 ml).

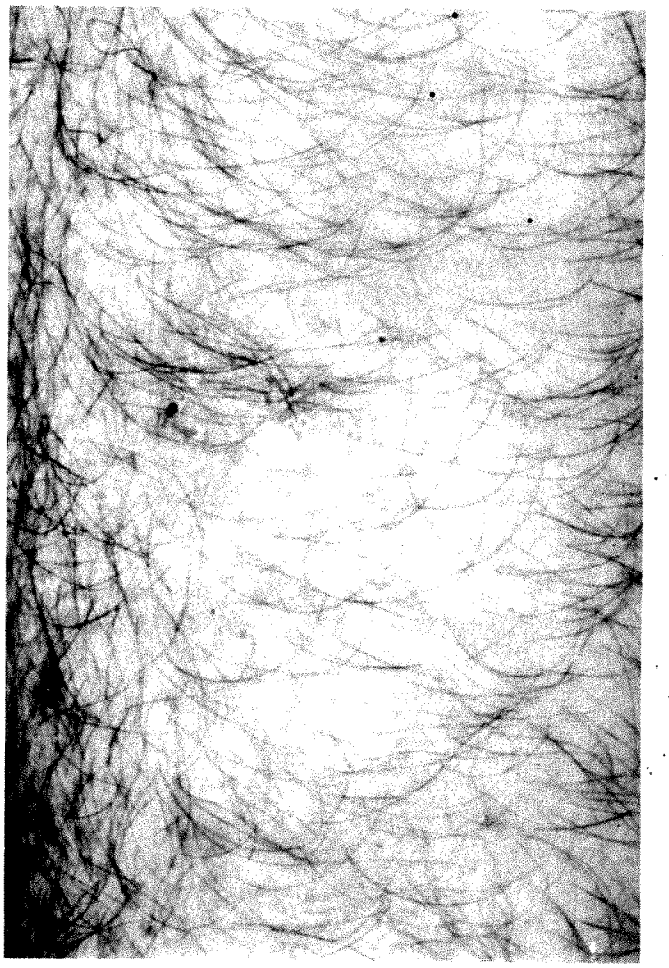

Fig 2.—Spontaneous flare of previously negative intracutaneous fluorouracil test sites two weeks after initiating a second course of topical fluorouracil for actinic keratoses of face (patient 5).

RESULTS

Group A

Of the 35 patients tested intracutaneously before fluorouracil treatment, one person reacted with asymptomatic, macular erythema at the testing sites. Of the 12 patients tested epicutaneously before treatment, none had any reactions to the patch tests.

Group B

Of the 35 patients tested intracutaneously, six reacted with patches of erythematous induration, papules, and minute vesicles (Fig 1). Pruritus was intense. All six patients reacting to intracutaneously injected fluorouracil had 3+ to 1+ epicutaneous reactions as outlined in the Table. Two patients (1 and 5 in the Table) experienced a moderate to severe pruritic, widespread dermatitis during fluorouracil treatment, while two other patients (2 and 6 in Table 1) noted a moderate local flare reaction. Patient 2 (Table) experienced similar reactions on the chin. The dermatitis was caused by the patient's nervous rubbing with her fluorouracil-treated hand on her chin. Patient 5 (Table), who developed fluorouracil sensitivity during a second course of treatment, had two to three intracutaneous test sites, initially negative, that flared two weeks after the onset of fluorouracil application to the face (Fig 2). The severity of the facial eruption necessitated interruption of therapy. Of the 29 remaining members of group B, two developed nonspecific, flat, asymptomatic, erythematous patches at the intracutaneous test sites not matched by any reaction at the epicutaneous level, while the rest of the sites were negative for both tests.

Histology

Biopsy specimens were taken from the intracutaneous test sites of patients 1 and 2 (Table), and in patient 1 (Table) a biopsy was done on an epicutaneous skin test specimen also. All three specimens demonstrated essentially similar findings; the epidermis showed mild spongiosis and round cell exocytosis. The papillary and upper dermal vessels revealed a mild to moderate perivascular infiltration with lymphocytes, histiocytes, and occasional eosinophils (Fig 3). These findings are consistent with allergic contact dermatitis but not compatible with an irritant dermatitis.

COMMENT

Topical fluorouracil therapy is considered the treatment of choice for diffuse actinic keratoses and erythroplasia of Queyrat[2] and has been used for the treatment of Bowen's disease,[3] actinic cheilitis, superficial basal cell carcinoma, and squamous cell carcinoma.[4]

Results of Intracutaneous and Epicutaneous Skin Tests With Fluorouracil, Group B (Six Patients)

Patient No.	Skin Tests: Intracutaneous Reaction, mm 5.0 mg	2.5 mg	1.0 mg	Epicutaneous Reaction, +s 10%	5%	1%	Reactions: Pruritus	Flare	Widespread	Biopsy	Courses of Fluorouracil

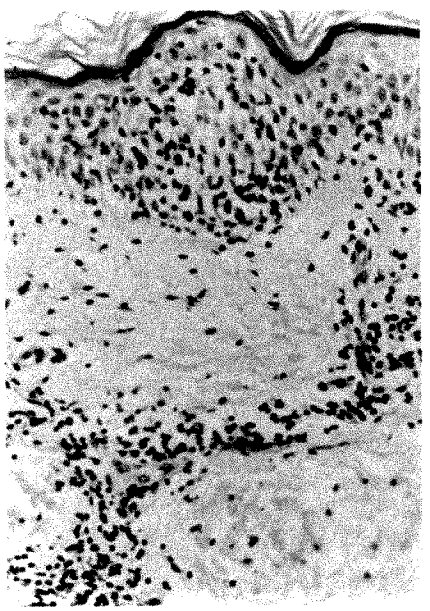

Fig 3.—Biopsy specimen of intracutaneous fluorouracil reaction site (patient 1) demonstrating epidermal spongiosis, exocytosis, papillary edema, and a moderately dense perivascular round cell inflammatory infiltrate (hematoxylin-eosin, original magnification ×100).

Topical fluorouracil usually elicits a moderate to severe irritation at the diseased site with symptoms and signs of burning, itching, stinging, erythema, and scaling often aggravated by exposure to direct sunlight. Disease-free fluorouracil-treated skin usually remains clinically normal, although Zelickson et al[5] have discovered mild histological and ultramicroscopical changes. Side effects to topical fluorouracil other than irritancy are rare, but allergic contact dermatitis to fluorouracil, or its vehicle, or preservatives therein, has been noted. Sams,[6] in 1968, reported four cases of contact dermatitis to fluorouracil preparations. In two of his cases, he elicited a positive reaction to the vehicle; in one case, to propylene glycol, and in the other to both the wool wax and to alcohol esters of the aquaphor base. In the remaining two cases, he obtained eczematous reactions to fluorouracil and not to the vehicles in the patch tests. Sams'[6] article seems to be the first to point out the possibility of allergic sensitization to topically applied fluorouracil preparations.

In 1975, Mansell et al[7] described the development of delayed hypersensitivity reactions in patients treated with topical fluorouracil (5% to 20% creams) for cutaneous malignancies. They studied 25 patients retrospectively and were able to elicit positive responses in 17 patients (68%) after intracutaneous testing with serially diluted concentrations of fluorouracil (50 mg/ml to 0.4 mg/ml of sterile preservative-free water). In a prospective series of 15 patients tested in like manner, they found that 11 patients (73%) developed sensitization to fluorouracil during the treatment. They eliminated the possibility of an irritancy reaction to fluorouracil mostly on a histological basis. Epicutaneous skin tests were not done in their series.

Comparing the incidence of induction of delayed hypersensitivity to fluorouracil of approximately 70% in Mansell's series[7] to that of 0.6% in Sams' series,[6] a marked discrepancy becomes apparent. While Mansell et al[7] relied exclusively on intracutaneous skin tests, Sams[6] performed only epicutaneous skin tests to fluorouracil.

We believed that the combination of intracutaneous and epicutaneous tests in varying strengths of fluorouracil to fluorouracil-virgin and fluorouracil-experienced groups might allow a more accurate evaluation of the subject of allergic contact dermatitis to fluorouracil.

The absence of any reactions in group A (fluorouracil virgins) on challenge after initial intracutaneous injections and after three to five weeks of 1% or 5% fluorouracil topical preparations rules out any possibility of allergic sensitization or irritant reaction. The asymptomatic, macular patches of erythema at the sites of the initial injections of fluorouracil in four patients in groups A and B were interpreted as irritant phenomena. However, the preceding erythema was not necessary for the development of hyperpigmentation; it was observed in several individuals in whom erythema did not develop at intracutaneous injection sites. Similar erythema and subsequent hyperpigmentation had been observed previously, especially after administration of fluorouracil and bleomycin[8] given for systemic effect.

The fact that none of the patients in group A showed any reactions to intracutaneous and epicutaneous skin tests after three to five weeks of topical fluorouracil therapy is in stark contrast to the report of Mansell et al[7] of development of sensitivity to fluorouracil in 73% of their group of prospective patients. An explanation for the obvious discrepancy may be found in the fact that Mansell et al[7] were treating their patients for precancerous conditions and basal cell and squamous cell carcinomas with 5% to 20% topical fluorouracil. The patients may have been treated for longer periods with higher concentrations of fluorouracil that caused greater absorption and probably higher sensitization. This observation may account for the fact that five of our six cases of fluorouracil sensitivity occurred in patients who had received two courses of fluorouracil (group B). The repetitive insult led to further antigen exposure, thus enhancing the chance of development of sensitization. All six patients in our group B had a severe irritant reaction to fluorouracil before the signs of allergic contact dermatitis became prominent.

Despite the allergic reaction, all patients had excellent therapeutic results from topical fluorouracil. In view of the high incidence of allergic contact dermatitis in the Mansell et al[7] series, one could consider immunological mechanisms a factor in the therapeutic response of premalignant conditions. However, the overall incidence of 8.6% allergic contact dermatitis in our study indicates that the development of delayed hypersensitivity is not a prerequisite for an adequate therapeutic response.

Additionally, the occurrence of a widespread pruritic dermatitis in nontreated areas of the skin in two patients supports the hypothesis of increased absorption and hematogenous dissemination of the allergen with elicitation of allergic contact dermatitis in distant sites. This allergic dermatitis differs from the dermatitis confined to mostly sun-exposed areas in patients receiving fluorouracil therapy for systemic effect for carcinomatosis. The systemically administered fluorouracil apparently eradicates actinic keratoses in these patients with the appearance of an irritant dermatitis similar to that seen after topical application of fluorouracil. Such an observation was initially reported by Falkson and Schulz[8] in 1962 and later by Omura and Torre[9] in 1969.

The following criteria may be useful for the differentiation of an allergic from an irritant contact dermatitis to topical fluorouracil: (*a*) development of a severely pruritic eczematous eruption at the site of contact with a topical fluorouracil preparation; (*b*) development of a widespread pruritic dermatitis away from the treated area during fluorouracil treatment or the occurrence of a flare phenomenon at a site previously exposed to the drug; (*c*) development of a positive epicutaneous skin test reaction to preservative-free test materials of fluorouracil in concentrations of 5% or 10%; (*d*) development of a pruritic indurated erythema with papules or vesicles at the site of the intracutaneous injections (0.1 ml injections of 50 mg/ml, 25 mg/ml, and 10 mg/ml of fluorouracil in sterile water); (*e*) excellent correlation of the intracutaneous and epicutaneous reactions; and (*f*) compatible histological findings.

The development of a severely pruritic eczematous dermatitis at the site of fluorouracil application in a fluorouracil-experienced patient, should alert the clinician to the possibility of an acute allergic contact dermatitis to the drug. The simple testing methods outlined in this article will readily confirm or negate this diagnosis.

Since acceptance of this article, we have seen an additional patient who developed widespread allergic contact dermatitis to fluorouracil during his third course of treatment over a five-year period. Also, he experienced a flare phenomenon of his dermatitis when skin-tested in the above-described fashion.

Utilization of Physician Services for Dermatologic Complaints

The United States, 1974

Robert S. Stern, MD; Marie-Louise Johnson, MD, PhD; James DeLozier, MD

• The National Ambulatory Medical Care Survey provides data on the "who," "for what complaint," and "to whom" for office visits to office-based physicians. In 1974, complaints referable to the skin accounted for 44 million physicians visits. This represents 7% of the 634 million visits to physician offices made during this period. Dermatologists accounted for 34% of all visits for skin complaints. General and family practitioners accounted for 40% of such encounters. Office visits prompted by dermatologic complaints were frequently less than 16 minutes long. Each office-based dermatologist accounted for an average of 5,600 patient visits per year. According to the dermatologist's diagnosis, 31% of these visits were prompted by acne; warts accounted for an additional 8%.

(*Arch Dermatol* 113:1062-1066, 1977)

This report presents data about office visits for dermatologic complaints in the United States in 1974. It is based on provisional data generated by the National Ambulatory Medical Care Survey (NAMCS) and provides information of the characteristics of patients coming to physicians' offices for care of dermatologic complaints. In addition, the survey provides comparisons of the type of patients seen by various specialists, the direction of physician visits, and physician follow-up plans. This information gives a clearer picture of the "who," "for what," and "to whom" with respect to physician visits motivated by dermatologic illness in this country. When analyzed with information on the prevalence of dermatologic disease that will be available as a result of the National Center for Health Statistics Health and Nutrition Examination Survey, better determination of the magnitude of unmet needs for dermatologic services will be possible.

Accepted for publication Nov 10, 1976.

METHODS

The NAMCS, described in detail elsewhere, is an ongoing effort to collect information relating to ambulatory visits to a national sample of office-based physicians.[1] A randomly selected, geographically proportional sample of physicians in "office-based, patient care practices" was selected for monitoring. A total of 3,581 such physicians drawn from a universe of 184,386 physicians identified as being office-based cooperated in the 1974 data collection.

Each participating physician was visited prior to the period of data collection by NAMCS staff for thorough instruction in the use of data forms. During a randomly assigned seven-day period, each physician maintained a log of all office visits and completed encounter forms (Figure) on a systematic sample of patients.

The 3,581 participating physicians completed encounter forms for a total of 61,158 visits during 1974. These NAMCS data allowed an estimate of total 1974 physician office visits in the United States of 634 million. The analysis of data where dermatologic complaints were the principal stated reason for physician visits to any practitioner and all visits to a dermatologist provided a clearer picture of the "who," "for what," and "to whom" of the demand for medical care for dermatologic complaints. This analysis has been carried out with the full cooperation of the National Center for Health Statistics. To facilitate this analysis we developed a dermatologically oriented grouped classification for the NAMCS Symptom Classification (Table 1).[1]

RESULTS: VISITS FOR DERMATOLOGIC COMPLAINTS

Total

During 1974, a total of 44 million visits were made to office-based physicians for complaints referable to the skin. This represents 7% of the estimated 634 million visits to office-based physicians during this time. Visits for dermatologic complaints exceeded the number of visits prompted by the most common symptomatic problems seen in office practice, including "problems of the lower extremity" (26 million visits, 1973 and 1974) and throat soreness (21 million visits in 1973 and 1974), as well as the combined total of visits for pregnancy and routine gynecologic examinations (39 million in 1973 and 1974).[2]

Sex Distribution

Women accounted for 60% (26 million) of all visits for skin complaints. This percentage was the same as the proportion of all ambulatory visits made by women. To correct for the greater female population in the United States, age- and sex-specific rates of visits per year were calculated (Table 2). Except for the group under 15 years old, women more frequently attended a physician for a dermatologic complaint than did men. For

Encounter form.

dermatologic complaints, the difference in the sex-specific rate of visits is greatest in the adolescent-early adult group (15-24 years old). In this age group, females attended a physician 45% more frequently than men. Among patients 25 years old and over, the women's rate of visits for dermatologic complaints was less than 10% greater than that for men. This can be compared to the substantially higher rates of total physician visits by women in the adult years (Table 2).

Age

The percentage of total physician visits accounted for by dermatologic complaints was greatest in younger patients. The rate varied from a high of 11% in the group aged 15 to 24 years to only 5% of all visits to a physician among patients 45 years old and over being for a dermatologic complaint.

In addition to having its greatest relative importance as a reason for a physician visit in the 15- to 24-year-old age group, the absolute rate of visits for such complaints was also greatest in this group. Women in this age group were more than half-again as likely to seek advice for a dermatologic complaint than were women in any other age group. While the rate for males was also highest in the adolescent group, it never exceeded by more than 25% the visit rate by men in other age groups.

Complaint Category

When grouped according to our complaint classification scheme, individual complaint (Table 1) categories accounted for 15% to 34% of all visits for dermatologic complaints. There was substantial variation in the sex ratio of visits for each complaint (Table 3). For example, while men comprised 59% of visits for allergic and irritant conditions affecting the skin (category 2, Table 1), men accounted for only 24% of acne visits. Substantial variation between males and females in frequency of physician visits was confined to three age and complaint categories: (1) adolescent (age 15 to 24) acne, (2) childhood (less than age 15) injury and infection, and (3) adolescent (age 15 to 24) allergic and irritant skin complaints. Visit rates for remaining categories are similar between men and women.

While male and female visit rates per thousand population are similar for patients age 45 and over, the number of women in this age group is larger. As a result, women were seen in 56% of the 13.2 million visits by patients 45 and over who had dermatologic complaints.

UNIVERSITY OF MICHIGAN LIBRARY

Table 1.—Dermatologic Complaint Classification

Complaint Categories	NAMCS Code	Partial Listing of Component Complaints
Acne	100	
Infectious disorders and wounds	106,116	Athlete's foot, boils, ringworm, bites, blisters, bruises
Allergic and irritant	112,113	Hives, photosensitivity, poison ivy, diaper rash, itching, pain, ulcers, sores
Morphologic changes	104,109,110, 115,120	Discoloration of pigmentation, wrinkles, bumps, nodules, lesions, moles
All other	108,111,122, 124,126,130	Warts, calluses, corns, symptoms referable to hair and nails including brittleness, breaking, falling out

Table 2.—Annual Rate of Office Visits* by Age According to Type of Complaint

	No. of Visits per Thousand Persons per Year								
	Total Patients	Male	Female	Male	Female	Male	Female	Male	Female
Complaint All visits	Patients 3,072	2,272 (under 15 yr)	2,107	1,762 (15-24 yr)	3,348	2,252 (24-44 yr)	4,024	3,568 (45+ yr)	4,478
All visits for dermatologic complaints	214	218	183	226	327	181	200	203	215
Acne	21	†	†	47	99	†	†	†	†
Allergy	73	86	90	63	92	53	62	66	72

*Quantity indicated by percentage distribution.

Specific Complaints

The most frequent patient skin complaint leading to a physician visit was "allergic skin reaction" (10.2 million visits). Other specific complaints leading to large numbers of encounters included acne (4.4 million), warts (2.6 million), and skin moles (1.0 million).

Physicians diagnosed warts as the principal reason for the visit in 3.5 million encounters. Thus, more than one third of patients coming for wart treatment did not indicate specific knowledge of the nature of their skin growth.

Duration of Visits

Visits for dermatologic complaints were, on the average, shorter than visits for all medical complaints. Dermatologic visits lasted 15 minutes or less in 85% of cases, and 21% of dermatologic visits lasted five minutes or less. Only 76% of visits for all complaints took 15 minutes or less. Notable for frequent short visits (as defined by actual physician contact time with patients) were visits prompted by allergic and irritant dermatoses (Table 4).

Procedures and Drugs

Visits for dermatologic complaints frequently involved surgical procedures and the use of drugs, both prescription and over-the-counter preparations. For instance, 70% of visits for acne involved prescription of a drug and 20% of such visits over-the-counter medications. With the exception of visits related to warts, 75% which were treated surgically, on the average the rate of writing a prescription was approximately 70%. This was a substantially higher prescription-writing rate than the 55% rate for all visits to general practitioners and internists.

Visits by Physician Specialty

General and family practitioners, internists, and pediatricians together accounted for 52% of the visits for dermatologic complaints, which numbered 44 million or 7% of all office-based physician visits (Table 5). Of the 4.2 million visits for acne, 85% were seen by dermatologists. Dermatologists saw 47% of patients with complaints referable to morphologic changes of the skin. Acute conditions, such as allergic skin reactions, irritation, and swelling of the skin, were seen more often by physicians other than dermatologists (Table 6).

Practitioners other than dermatologists who see a large number of patients with specific skin complaints were general and family practitioners, pediatricians, and internists. The percentage of total visits to each of these specialties that were initiated for skin complaints is 6.8%, 5.8%, and 3.2%, respectively.

Visits to Dermatologists

Of the 18 million office visits to dermatologists in 1974, 85% were prompted by specific dermatologic

complaints. The remaining visits were for administrative reasons, routine follow-up examinations, or for nondermatologic complaints, which, in the NAMCS classification, included visits for venereal diseases not accompanied by skin findings.

Based on NAMCS data and the American Medical Association *Distribution of Physicians* in office-based practice, it appeared that dermatologists averaged about 5,600 patient visits in 1974, a number equal to that of general practitioners (Table 7).

Other data available from the NAMCS survey showed that 65% of visits to dermatologists were follow-up visits, a proportion close to that found for all physicians (62%). However, dermatologists followed up a higher proportion of patients with allergic and irritant complaints and with morphologic changes (53% and 56%) than did other physicians (31% and 38%). In general, dermatologists scheduled return visits more frequently (72%) than did other physicians (60%). Dermatologists' highest rate of return visits was for patients with acne; 85% were given appointments to return.

Thirty-five percent of visits to dermatologists were first visits to that physician for a particular complaint. This percentage parallels the 38% of all visits that are the first contact with a given physician for the presenting problem. Dermatologists have a higher percentage of visits made by new patients (26%) than do general and family practitioners (12%), internists (13%), or pediatricians (9%).

Table 5.—Number and Percentage Distribution of Office Visits by Physician Specialty

Complaint	No. of Visits, Millions	Physician Specialty*		
		Dermatologists	General Family Practice	All Other Physicians
All visits	634.0	2.8	41.5	55.7
All dermatologic complaints	44.1	34	40	25

COMMENT

The profile of the "average" dermatologist provided by the NAMCS was that of a busy practitioner who in a 48-week working year of five days per week saw 23 to 30 patients daily in his office.[3] The actual time that the dermatologist spent with patients—on the average, 19 to 20 hours per week—is comparable to that spent by the general practitioner with his patients. The most frequent complaints handled by the dermatologist, in descending order of frequency, were acne, chronic lesions and tumefactions of the skin, allergic dermatitis, and contact dermatitis. Approximately seven of ten patients were given a written prescription; some surgical procedure was performed on three of ten patients. The NAMCS study documented that primary care physicians were major providers of dermatologic care. Curiously, acne, a ubiquitous condition, was not as frequently a precipitating reason for visits to these physicians as were other conditions and diseases of the skin.

The profiles of the dermatologist and the primary care practitioner in reference to providing care for patients with skin complaints were intuitively reasonable. The quantitative estimates provided in this study were subject to limitations of interpretation. Errors due to variations occurring by chance ascribable to the size of the sample can be estimated, and when reasonable confidence limits were exceeded, no data inferences have been made.[3] Other limitations, such as the nonresponse rate (26% of all physicians, 16% of dermatologists contacted) due to physicians' refusal to cooperate in the study or the noninclusion of some office-based physicians in the AMA and American Osteopathic Association listings were

not considered to have seriously distorted the data.[2] The larger sample of physicians and the greater number of patient encounters that will become available as the survey continues will provide more reliable and detailed estimates. The NAMCS data conformed in general, by diagnosis and type of physician seen, to data provided by the National Disease and Therapeutic Index (1968 and 1969) cited by the National Program for Dermatology study.[3]

However impressive the reported volume of visits due to complaints of the skin may be, the present demand for care is moderated by financial factors. For example, the percentage of adolescents consulting a physician for acne is at least three times greater for individuals from families with an income exceeding $15,000 than for members of low-income families.[4] Diminishing financial barriers with extended third-party coverage, as in a program of national health insurance, will increase demand substantially. For example, only 1.4 million patients are accounted for in the NAMCS study by the conservative estimate of three visits per year by a patient with acne. This in only one fifth of the nine million Americans with acne, according to preliminary survey information.[5] Estimates in the range of an increase of 75% in the overall utilization of health services with full insurance coverage have been made.[6] Further, with full coverage, patients with skin complaints may choose to consult dermatologists directly. With demand potentially exceeding supply, some rationing of the dermatologist's services coupled with increased utilization of primary care physicians and other substitute skills may become necessary.

The present study does not provide information on the quality of care given to patients with skin complaints by dermatologists and other physicians. The minimal dermatologic preparation of medical students and residents in other specialties poses serious questions about their level of diagnostic and therapeutic adequacy. A major task for the discipline of dermatology is to augment the education of other physicians so they can recognize and treat common dermatologic conditions and, where indicated, recognize the need for dermatologic consultation. Within the field of dermatology itself there is a need to determine more precisely what knowledge and skills are crucial and to ensure that dermatologists maintain a satisfactory level of performance.

Another unanswered question is the extent to which dermatologists' practices are oriented toward cosmetic care such as hair transplants and dermabrasion. A determination of the extent and appropriateness of such practices is needed for specialty planning manpower needs.[7]

The NAMCS study provides useful estimates of present demand for the relief of dermatologic complaints. In its present stage, it is not comprehensive enough to identify populations at high risk, such as occupational groups, and it does not analyze differences in the efficiency or outcome of different practitioner's treatment of skin disease. The NAMCS does, however, complement other efforts, most notably the Health and Nutrition Examination Survey, which will describe with some precision the extent and nature of skin disease in the US population and the individual variation in the utilization of medical service for its relief.

As an ongoing data collection effort, the NAMCS data base is constantly expanding. In addition, proposed revisions of the encounter forms should provide more specific information on chronicity of disease, physician diagnostic and treatment services, and prescribing habits. When available, this information will provide a basis for comparison of the actual services rendered by physicians with different specialties for discrete dermatologic conditions.

This investigation was supported in part by a Fellowship Grant by the Dermatology Foundation to Dr Stern.

Todd M. Frazier, MS, pointed out the availability of the data used in this paper and reviewed the manuscript. These data were made available by the National Center for Health Statistics, which, acting on the recommendations of the NAMCS Advisory Committee, has encouraged users of survey data to request special tabulations addressed to specific problems as we have.

Editorial Comment

The largest and, I hope, insurmountable obstacle to the prompt government ownership of the medical care system in the United States is the expectation that our government bureaucracy would surely bungle the job. An even worse disaster for elected politicians than bungling the postal service or the welfare administration or the auto safety legislation or the energy crisis or the Department of Defense purchasing would be fouling the voluntary health care system. Most knowledgeable men of power, in and out of government, will never risk supporting federal ownership or direction of medicine *unless* the private physicians hopelessly bungle the job themselves. Our principal defense against the major intrusion of government into dermatology is to manage our specialty not merely well, but in a sophisticated, progressive, and very humane fashion. The first rule is this: All citizens with any skin diseases are our responsibility ultimately.

To manage our specialty expertly, we need to know precisely what our task is and what resources we can and cannot use. Stern et al have done a fine preliminary study of some of these problems. They have described where our patients go for their care and for which disorders. Because less than one third of dermatology is done by specialists, we see the importance of our members' participating in continuing education programs in every state of the nation. Many skin disorders are not medically complex, apparently not requiring the care of a specialist, but to assure the best results some supervision is appropriate. How is that to be achieved in private practice? In the same way, what is the best and most economical means for all patients to receive high-quality care for their acne? As Stern et al show, all patients with skin complaints cannot see the dermatologist; he is already working a 48-hour week. Furthermore, that highly trained dermatologist is needed to diagnose and treat more complex disorders, and use special technical facilities, such as for minor surgery or for patch testing. We alone can solve this problem properly.

Many other crucial questions raised by this communication are yet to be answered, concerning the quality of care, proper pricing, rehabilitation, disease prevention, and more. The more detailed data from the National Health Survey may solve some problems and raise some more. We can say that although we are now far superior to the federal bunglers, we have only started on the difficult road to managing our specialty properly and serving our patients expertly.

Mycobacterium marinum Infections Treated With Tetracycline

Allan K. Izumi, MD; C. William Hanke, MD; Michiko Higaki, MT (ASCP)

• Five cases of *Mycobacterium marinum* skin infections were successfully treated with 2 gm of tetracycline hydrochloride daily for periods from four to 12 weeks. In each case, the isolated *M marinum* was sensitive in vitro to tetracycline at levels from 25 to 50 μg/ml. Tetracycline is recommended as treatment for extensive or sporotrichoid *M marinum* infections.

(*Arch Dermatol* 113:1067-1068, 1977)

Treatment for *Mycobacterium marinum* infections are numerous. Surgical curettement and electrodesiccation and excision are the most popular methods of treatment, since the majority of these infections are small and localized. Chemotherapeutic measures are usually reserved for the more extensive and sporotrichoid varieties but are hampered because of the known resistance of this bacillus to antituberculous drugs. However, a variety of chemotherapeutic measures are described. Johnson[1] reported his success with streptomycin sulfate and potassium iodide. Barrow and Hewitt[2] successfully treated a case with co-trimoxazole and sulfamethoxazole. Wolinsky et al[3] and Van Dyke and Lake[4] used a combination of ethambutol, isoniazid, and rifampin. Kim[5] briefly reported his success with tetracycline hydrochloride. Loria[6] recently described his success with minocycline hydrochloride.

Thus far, the results of chemotherapy have been difficult to evaluate because of the natural tendency of this infection to spontaneously heal, usually within one to two years. The purpose of this study was to present our experience with the use of tetracycline and to correlate this with in vitro sensitivity studies.

SUBJECTS AND METHODS

Five male patients were examined from 1972 to 1975 (Table 1). Three had localized tuberculoid granulomas over the finger or hand. One patient had a sporotrichoid granuloma involving his hand and elbow. One patient had an extensive granuloma over the entire knee and upper thigh. Each patient had been aware of his lesion ranging from three months to 20 years. Four of these patients had not received prior treatment. A 4-mm punch biopsy was obtained from each patient. The biopsy specimen was immediately bisected. One half of the specimen was sent to pathology (hematoxylin-eosin and acid-fast stains) and the other one half placed in 1 ml of sterile water and sent to Leahi Hospital for culture. In vitro sensitivity studies were set up against streptomycin isoniazid, *p*-aminosalicylic acid, ethambutol, rifampin, and tetracycline (Table 2).

For comparision several atypical *Mycobacterium* strains (group I-IV), obtained from Hawaii's State Department of Health, were also tested against tetracycline in vitro (Table 3).

Each patient was placed on regimens of tetracycline at a dose of 2 gm daily. This dose was maintained for an average of 8.5 weeks, with a range of 4 to 12 weeks. The criteria for resolution was complete flattening and clearing of the granuloma. In case 4, a repeat biopsy specimen and culture were obtained to confirm the granuloma's resolution. Four-month to eight-month follow-up studies on each patient were done to confirm that the granuloma had not recurred.

RESULTS OF IN VITRO TESTING

The results of the in vitro sensitivity studies of the *M marinum* isolates from these five patients are summarized in Table 2. All isolates were resistant to *p*-aminosalicylic acid at levels of 10 to 100 μg/ml. These isolates were also resistant to isoniazid, showing only growth suppression at levels of 5 and 10 μg/ml in one isolate each. There was a modest growth suppression to streptomycin at 100 μg/ml in three isolates, ethambutol at 2 to 8 μg/ml, and rifampin at 0.1 to 1.0 μg/ml. The isolates were not suppressed by tetracycline until levels of 25 μg/cc were reached. All isolates were suppressed at levels of tetracycline from 25 to 50 μg/ml.

Results of in vitro sensitivity studies against other atypical *Mycobacterium* strains are also summarized in Table 3. Except for *M flavescens*, *M smegmatis*, and *M phlei*, all other strains were resistant to tetracycline.

COMMENT

Mycobacterium marinum (*balnei*) is a Runyon group I photochromogen *Mycobacterium*. Linell and Norden[7] originally described the bacteriologic characteristics of this bacillus as the following: (1) growth on Lowenstein-Jensen media at 31 C, but not at 37 C; (2) conversion from cream-colored colonies to yellow-orange colonies in 10 to 21 days after light exposure; and (3) failure to grow in guinea pigs.

In vitro antimicrobial sensitivity

Table 1.—Patient Summary

Patient No.	Age, yr/ Sex	Duration of Lesion	Clinical Site	Treatment Period, Weeks	Follow-up Period, mo

studies against *M marinum* have consistently shown that it is relatively resistant to isoniazid, streptomycin, neomycin sulfate, *p*-aminosalicylic acid, penicillin, chloramphenicol (Chloromycetin), and thiosemicarbazone.[3,4,7-9] However, it is partially sensitive to rifampin, ethionamide, vancomycin hydrochloride, ethambutol, streptomycin, cycloserine, and tyrothricin.[3,4,7,8]

There have been relatively few reports concerning the in vitro antimicrobial effects of tetracycline on *M marinum*. Linell and Norden[7] reported that *M marinum* was resistant to "physiologic doses" of chlortetracycline hydrochloride (Aureomycin/all forms) and oxytetracycline (Terramycin), but they did not define the concentration. Knox et al[10] briefly commented that the isolated *M marinum* organism was resistant to tetracycline in vitro, but again, they did not define that level. Kim[5] noted that two out of six cases were resistant to tetracycline in vitro at 100 μg/cc. All of his cases, however, did respond to tetracycline.

All of our isolates of *M marinum* were sensitive to tetracycline in vitro at levels of 25 to 50 μg/ml. A limited survey of other atypical mycobacteria indicated that all were resistant to tetracycline, except for *M flavescens, M smegmatus,* and *M phlei.* We are unable to explain the in vitro resistance of *M marinum* to tetracycline reported by Kim.[5]

Tetracycline and minocycline, a semisynthetic derivative of tetracycline, have both been reported to be clinically effective against *M marinum* infections.[5,6] Based on our correlated in vitro antimicrobial studies, we believe that this is a direct antimicrobial effect.

Tetracycline is recommended as the treatment of choice for extensive or sporotrichoid varieties of *M marinum* infections. Small localized *M marinum* infections should probably be treated locally by surgical excision, curettement, electrodesiccation, or cryosurgery. Our treatment program consisted of 2 gm of tetracycline daily for at least two to four months.

James T. Swift, MD, provided clinical data and laboratory material for case 5.

Immunopathologic Study of Herpes Gestationis in Mother and Infant

Allan Katz, MD; Joe O. Minta, PhD; John W.P. Toole, MD; Walter Medwidsky, MD, FRCP(C)

• In vivo bound C3 was demonstrated by immunofluorescence in lesions of both maternal and infant skin in an immunopathologic study of herpes gestationis. Immunoglobulins and other complement components of both classical and alternative pathways were not found. The serum was also negative for circulating antibody to basement membrane of skin. Maternal serum had a factor present that was able to deposit C3 from fresh normal serum onto the basement membrane zone of skin.

Hemolytic complement titrations showed a decrease of CH_{50} levels in serum of both classical and alternative pathways in the mother and the classical pathway in the infant, with a decrease of C2 and C4 in both.

To our knowledge, this is the first report of a decrease in serum complement components in herpes gestationis and indicates that complement may not be activated locally.

(*Arch Dermatol* 113:1069-1072, 1977)

Herpes gestationis (HG) is a rare vesiculobullous dermatitis of pregnancy first described by Bunel in 1811[1] and named by Milton in 1872.[2] Russell and Thorne[3] estimated the incidence to be 1 in 3,000 to 4,000 deliveries; however, Kolodny[4] stated the incidence was closer to 1 in 10,000 deliveries.

In recent years an immunologic mechanism has been implicated in the pathogenesis of HG. Provost and Tomasi demonstrated in vivo bound C3, C5, and properdin in the basement membrane zone of skin by immunofluorescence.[5] Also, a factor was detected in the serum (HG factor) that was capable of depositing C3 along the basement membrane zone of normal human skin. This factor has recently been shown to be a thermostable IgG.[6,7] Bushkell et al demonstrated in vivo bound IgG as well as Clq, C3, and properdin in a patient with an IgG basement membrane antibody in both serum and blister fluid.[8] There have been several reports of in vivo bound IgA as well.[9,10]

With respect to HG occurring in the infant, Rimbaud et al found IgG fixation in the basal layer of skin without circulating antibodies in serum.[11] There was no mention, however, of complement staining. In vivo fixation of C3 and C4 without IgG has been reported in both normal skin of an infant who did not have the lesions of HG,[6] as well as in lesional skin.[12] In several recent studies the HG factor was also shown to be present in cord serum.[6,7]

The following report of HG occurring in a mother and infant describes studies on skin and serum and documents a decrease in serum complement activity of both the classical and alternative pathways.

REPORT OF A CASE

A 39-year-old, para 4, gravida 8, Rh-positive woman was hospitalized Nov 20, 1975, at 37 weeks' gestation with hypertension, edema, and proteinuria.

At three months' gestation the patient developed a widespread pruritic urticarial vesiculobullous eruption. Biopsy results showed subepidermal bullae consistent with herpes gestationis. She was treated with prednisone, 20 mg/day, which was maintained throughout pregnancy. This controlled the pruritus, however, scattered bullae confined to the distal extremities still persisted.

A similar eruption appeared in the last trimester of her preceding full-term pregnancy in 1969. This had been treated with orally given dexamethasone, but a biopsy was not carried out. The healthy infant was noted to have a transient erythematous rash that was not further investigated.

Past history included a spontaneous abortion in the first trimester in February 1975, a full-term delivery in 1963, a spontaneous abortion in the first trimester in 1962, full-term normal deliveries in 1961 and 1960, and a first trimester abortion in 1959.

A diagnosis of chronic persistent hepatitis confirmed by liver biopsy was made in 1973.

The patient was delivered of a full-term female infant on Nov 21, 1975. She was maintained on a regimen of prednisone, 20 mg/day, until Nov 27, when the dose was reduced to 15 mg/day. Two days later an exacerbation of her skin condition developed with erythematous papules, vesicles, and bullae most severe in the periumbilical region, back, and limbs. This responded to an increase in the dose of prednisone to 30 mg/day started on Dec 3. Results of a second biopsy showed subepidermal bullae

Accepted for publication Dec 15, 1976.

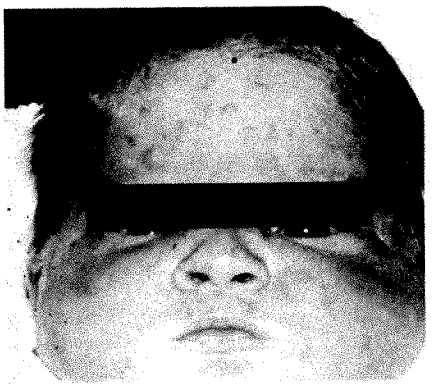

Fig 1.—Papulovesicular rash on forehead of infant.

consistent with HG. Pertinent laboratory findings were as follows: peripheral blood eosinophilia, 1,152/cu mm; erythrocyte sedimentation rate, 108 mm/hr; and albumin/globulin ratio, 3.8/3.5 gm/100 ml in serum.

The baby was noted to have an erythematous rash at birth that involved the face, abdomen, and distal extremities by 6 days of age. It consisted of polycyclic erythematous papules studded with vesicles (Fig 1). Biopsy results showed subepidermal bullae with numerous eosinophils, consistent with HG (Fig 2). The eruption subsided throughout a period of one week.

METHODS

Four-millimeter punch biopsies of bullous lesions and adjacent skin were performed on mother and baby. One portion of tissue was fixed in 10% buffered formaldehyde solution followed by Brazil solution.[14]

The rest of the tissue was snap frozen in liquid nitrogen and stored at −70 C until used. Four-micron sections were cut in a cryostat at −20 C and immunofluorescent staining was done on both unfixed tissue and tissue fixed in acetone for ten minutes. Fluorescein conjugates were prepared from purified antibodies to rabbit antihuman IgG (RAHIgG), sheep antihuman IgM (SAHIgM), and sheep antihuman IgA (SAHIgA) by previously described methods[14] for direct immunofluorescent staining[15] of skin biopsy specimens. All conjugates gave single lines when tested with normal human serum and monoclonal proteins by immunoelectrophoresis and double diffusion in agar. For the demonstration of C3, conjugated antiserum to human C3 produced in goats (GAHC3) was purchased (Meloy Laboratories, Springfield, Mass). Controls for C3 staining included the following: (1) the use of surgical specimens of normal human skin; (2) blocking of specific staining by incubation of sections with unconjugated antihuman C3 (purchased from Meloy Laboratories) followed by conjugated antihuman C3; and (3) prior absorption of the conjugate by purified human C3 prepared by the method of Müller-Eberhard et al.[16] A detailed description of these conjugates is given in Table 1.

The indirect immunofluorescent method[15] was used in an attempt to demonstrate Clq, C5, properdin, and factor B in biopsy specimens of mother's and baby's skin. The details of the methods used to prepare rabbit antisera to human Clq, properdin, and factor B have been reported elsewhere.[17-19] Goat antiserum to human C5 was purchased from Kent Laboratories, Vancouver, BC (lot 1100Dl). Fluorescein-conjugated sheep antirabbit IgG (SARIgG) and rabbit antigoat IgG (RAGIgG) were prepared by the above methods[14] for the staining of biopsy specimens by the indirect immunofluorescent method with the corresponding rabbit and goat antisera to human complement components. Details of these conjugates are also given in Table 1.

The sera of both mother and baby were tested by the indirect method for the presence of a circulating IgG antibody localized to the basement membrane zone of normal human group O skin obtained at surgery. Serum was used undiluted and at dilutions of 1/5 and 1/10 followed by the application of RAHIgG conjugated globulin.

The in vitro complement binding test[20] was performed in an attempt to demonstrate HG factor in the serum of mother and baby. Briefly, sera were applied undiluted and diluted 1/4 and 1/8 to cryostat sections of unfixed normal human group O skin. Following washing, the sections were incubated with a 1/10 dilution of fresh

Table 2.—Complement Titrations on Serum-CH_{50} Units*

Specimen	Classical Pathway	Alternative Pathway	C2	C4
Normal adult serum	72	14	1,150	14,000
Mother's serum A (Dec 1)	18	4.5	398	1,160
Mother's serum B (Dec 3)	51	8.8	767	12,000
Normal cord serum	35	6.7	610	5,210
Baby's serum (Dec 5)	10	5.1	354	1,820

*Normal range in our laboratory; classical pathway, 60 to 90 CH_{50} units; alternative pathway, 12 to 18 CH_{50} units.

normal human group O serum (which was a source of complement), rinsed again, then followed by the application of fluorescein-conjugated antihuman C3 or C4 at dilutions of 1/4 and 1/8. Controls included the use of conjugates alone, substitution of buffer in place of mother's and baby's sera, and the use of sera from two pregnant women who did not have skin disease.

For in vitro properdin binding, rabbit antihuman properdin serum was used undiluted followed by conjugated SARIgG.

Complement Assays

All serum samples were stored at −75 C until used. Total hemolytic complement activity (CH_{50}) was determined, according to the method of Kabat and Mayer,[21] using sensitized sheep erythrocytes. The integrity of the alternative pathway in serum was assayed by measuring its ability to hemolyse unsensitized rabbit red blood cells as described by Platts-Mills and Ishizaka.[22]

The hemolytic assay of C2 was performed by a one-step method using C2 deficient human serum.[23] The C4 hemolytic titrations were carried out by a modification of the one-step functional assay of C4 using C4-deficient guinea pig serum, as described by Gaither et al.[24] Essentially, 0.25 ml of normal or patient's serum diluted from 1/400 to 1/32,000 in veronal-buffered dextrose saline (0.084 μ) containing calcium ions, magnesium ions, and gelatin[25] was added to 0.25 ml of C4-deficient guinea pig serum (diluted 1/40) and 0.5 ml of sensitized erythrocytes (5×10^8 cells/ml). After incubation at 37 C for 60 minutes, the unlysed cells were sedimented and the serum dilution required for 50% lysis determined.[21]

RESULTS

Immunofluorescence

Direct immunofluorescent staining showed in vivo bound C3 in a continuous pattern along the basement membrane zone of the epidermis in both mother's and baby's skin (Fig 3) at conjugate dilutions of 1/10 and 1/15. The intensity of staining was decreased by blocking with unconjugated anti-C3 and staining was abolished by prior absorption of the conjugate with purified human C3. Negative results were obtained for IgG, IgM, IgA, Clq, C4, C5, properdin, and factor B in both maternal and infant skin.

Circulating antibodies of the IgG class to the basement membrane zone of normal human skin were not detected in either mother's or baby's serum by the indirect immunofluorescent method.

The in vitro complement-binding test disclosed the presence of a factor in two samples of maternal serum (sample A taken Dec 1 and B Dec 3) to a dilution of 1/8 that bound C3 from fresh normal human serum along the basement membrane zone of normal human skin. No C3 binding was observed with a single sample of infant's serum taken Dec 5. Negative results were also noted for C4 and properdin binding with both samples of maternal serum as well as with infant's serum.

Complement Studies

Table 2 summarizes the results of selected complement titrations on patients' and normal serum. As shown in the Table, mother's serum A had a substantially depressed total hemolytic complement activity. Both C2 and C4 titres determined by functional assays were also correspondingly decreased. Whereas the classical total hemolytic activity and C4 titre in serum B approached normal levels, the C2 titre was subnormal. To evaluate the integrity of the alternative complement pathway, the efficiency of patients' serum in hemolysing unsensitized rabbit erythrocytes in the presence of magnesium ion ethylene glycol bis tetraacetic acid was compared to that of normal serum. The results show that the alternative pathway hemolytic activity in mother's serum A was remarkably lower than in serum B and normal serum. The titre in serum B was about 63% of normal.

The classic and alternative pathways of hemolysis, the C2 and C4 titres of normal cord serum, were

about 30% to 50% of normal adult values. The alternative pathway hemolytic activity in the baby's serum was comparable to that of normal cord serum. However, the C2 and C4 titres as well as the classic pathway hemolytic activity were appreciably lower than in normal cord serum.

COMMENT

The finding of in vivo bound C3 in skin of both mother and infant in the present study and in a previous one,[12] as well as the demonstration of HG factor in cord blood,[6,7] is suggestive of passive transfer of the disease from mother to infant.

We were unable to demonstrate in vivo deposition of other complement components apart from C3 of either the classical or alternative pathways as reported by others.[5,6,8] Reasons for this difference may be related to variable concentrations of complement components, their transient presence in the basement membrane zone, or to the relative insensitivity of the method used.

This study clearly demonstrates a decrease in serum complement activity of both classical and alternative pathways and suggests that complement activation may not be occurring only locally at the site of blister formation. The decrease would appear to be real, as both the classical and alternative pathways as well as C2 and C4 activity were affected. Our results are at variance with previous reports[6,9] that failed to demonstrate decrease in CH_{50} levels and C3 concentration in serum. Although the technique of radial immunodiffusion used to measure C3 concentration does not indicate functional activity, unlike the method used in this study, the reason for this discrepancy is not known. As maternal complement levels were lowest when the dose of steroids was reduced, it is unlikely that complement depression was merely a nonspecific effect of steroid therapy.

The in vivo fixation of IgG as well as Clq, C3, C5, properdin, and factor B in skin in HG[6,8] is also consistent with activation of both the classical and alternative complement pathways. The circulating (HG) factor that is able to deposit C3 and other components of the classical complement system from fresh serum along the basement membrane zone has recently been shown to be IgG.[6,7] When C2-deficient serum or magnesium ion EGTA-treated serum was used as a complement source, no in vitro binding of C3 was seen, suggesting complement activation via the classical pathway.[7] A possible explanation for the above findings is that the alternative pathway is being activated secondarily to classical pathway activation through the C3b amplification mechanism.[26]

Circulating IgG antibody to skin has also been detected in bullous pemphigoid. This together with in vivo fixation of IgG, Clq, C3, C4, C5, properdin, and factor B in the skin in bullous pemphigoid[5] is suggestive of a relationship to HG. Also, HG factor inhibited the staining of basement membrane zone of normal human skin by fluorescein-conjugated globulin from a bullous pemphigoid serum.[7]

The importance of immunoglobulin and complement deposition in the skin in HG together with the demonstration of a circulating antibody to basement membrane is not known. Such antibodies have not as yet been shown to be pathogenic and may arise secondarily to tissue damage. Similarly, the possible role of changes in pregnancy, such as hormonal alterations, in the pathogenesis of HG is not known.

Dr Minta is a research scholar of the Canadian Heart Foundation, Toronto.

The C4-deficient guinea pigs were provided by Michael Frank, MD, National Institutes of Health.

Leukocytoclastic Angiitis in Subacute Bacterial Endocarditis

Sheldon Rubenfeld, MD, Kyung-Whan Min, MD

• The case of a patient who had palpable purpura on his lower extremities due to *Lactobacillus*-caused subacute bacterial endocarditis is reported. Histologic examination of the purpuric lesions demonstrated a leukocytoclastic angiitis. It is postulated that purpuric and other cutaneous lesions of subacute bacterial endocarditis are related to circulating immune complexes.

***(Arch Dermatol* 113:1073-1074, 1977)**

Skin lesions are often very helpful in making the diagnosis of subacute bacterial endocarditis (SBE). Petechiae, splinter hemorrhages, Osler nodes, and Janeway lesions are commonly described, but purpura has rarely been noted.

The pathogenesis of the cutaneous manifestations of SBE has been attributed to embolic phenomenon, altered capillary permeability, and immunologic or hypersensitivity reactions. We describe a patient with leukocytoclastic angiitis caused by SBE.

REPORT OF A CASE

A 40-year-old man was admitted to the Houston Veteran's Administration Hospital because of red spots on his legs. Two-and-one-half months prior to admission he had noted migratory polyarthralgias and weakness. Five weeks prior to admission, red spots appeared on the patient's legs that cleared in ten days but reappeared on the day of admission. During the previous two weeks he had noted daily fevers, drenching night sweats, dyspnea on walking three blocks, and paroxysmal nocturnal dyspnea without orthopnea, edema, or chest pain.

Physical examination revealed a pale, nervous, and slightly obese man in no acute distress. His temperature was 37.6 C; pulse rate, 110 beats per minute and regular; blood pressure, 146/90 mm Hg; and his respirations were 22/min. The skin showed multiple palpable purpuric lesions (Fig 1) on the anterior and posterior aspects of the legs. Funduscopic examination revealed three white exudates partially surrounded by hemorrhage. A systolic thrill was felt at the apex, and auscultation revealed a grade 4/6 holosystolic murmur and a third heart sound. The spleen was palpated 6 cm below the left costal margin.

Pertinent laboratory data included the following values: hematocrit, 25%, hemoglobin, 8.3 gm/100 ml, and a leukocyte count of 7,800/cu mm. The reticulocyte count was 0.8% and the platelet count was 302,000/cu mm. The RBCs were normochromic and normocytic with a rare fragmented RBC. Prothrombin time was 12 seconds with control of 12.3 seconds; partial thromboplastin time was 28.3 seconds with control of 28.1 seconds. The template bleeding time was 6.5 minutes (normal is less than 7 minutes), and the whole blood clot retraction was 74% (normal is 40% to 94%). Fibrinolysin and cryoglobulin tests were negative, as were direct and indirect Coombs tests; the plasma fibrinogen value was 370 mg/100 ml (normal is 160 to 415 mg/100 ml). The antistreptolysin 0 titer and antinuclear antibody titers were negative. Rheumatoid factor was positive 1:2,560 and the C3 level was 59 mg/100 ml (normal is 70 to 150 mg/100 ml). The BUN level was 21 mg/100 ml, serum creatinine clearance was 63 ml/min, and urinalysis results revealed proteinuria with RBCs too numerous to count. Chest film showed marked cardiomegaly; an echocardiogram demonstrated abnormal motion of the anterior and posterior leaflets of the mitral valve, with smudging of the anterior leaflet suggestive of vegetations.

The patient spiked fevers up to 39.1 C. One week after admission, six of 12 blood cultures grew a pleomorphic Gram-variable rod that was sensitive to penicillin and was later identified as *Lactobacillus*. Each day 24 million units of aqueous penicillin G potassium were administered intravenously, and the patient defervesced with resolution of the purpuric lesions during the next eight to ten days.

A biopsy specimen of the purpuric skin lesions showed small, dermal arterioles infiltrated by polymorphonuclear leukocytes with generalized disruption of the arterial walls and scattered nuclear debris (nuclear dust) within the exudate (Fig 2). Extravasated erythrocytes were also present. Gram stains of the skin biopsy sections failed to reveal any microbiological agents in the vascular lesions. Immunofluorescent staining on the fresh-frozen section of the skin biopsy specimen for human IgG and C were not revealing.

COMMENT

Purpuric lesions have only rarely been noted in patients with SBE. Weber[1] reported the first such case in 1910, in a patient who had a bleeding tendency manifested by bleeding gums and epistaxis. A causative organism was neither isolated in the blood nor found at autopsy. In 1912, Osler[2] described a patient with streptococcal SBE, purpuric skin lesions, and bleeding gums. Libman and Friedberg[3] noted seven such cases in their 1941 monograph, but many large reviews[4,5] of SBE since that time have failed to mention purpura as a manifestation of SBE.

Horwitz and Silbert[6] in 1968, however, reported two cases of streptococcal SBE with purpura, normal bleeding and coagulation times, normal platelet counts, and a negative tourniquet test. This report clearly ruled out coagulopathy as the cause of the purpura, but the pathogenesis of these as well as other cutaneous lesions in SBE remains obscure.

Merklen[7] considered damage to blood vessels rather than septic emboli as the mechanism for purpura in SBE. In 1936, Cornil et al[8] suggested that Osler nodes were a local response to protein from bacteria in the heart valve. In 1960, Howard[9] noted biopsy studies of Osler nodes which demonstrated perivasculitis in many tiny vessels beneath the Malpighian layers without evidence of emboli or bacteria. He considered these lesions to be allergic reactions to the causative organisms. In 1974, Weinstein and Schlesinger[10] attributed the classic peripheral signs of SBE to an allergic

vasculitis involving small arteries.

Williams and Kunkel[11,12] and others[13-15] have demonstrated various immunologic phenomena in endocarditis such as IgM anti-IgG antibodies (Rheumatoid factor), hypocomplementemia and high titers of agglutinating, complement-fixing, and opsonizing antibodies specific for the causative organism. Gutman et al[16] demonstrated γ-globulin and C in the glomerular basement membrane of patients with endocarditis, and concluded that the diffuse proliferative glomerulonephritis associated with SBE is probably caused by circulating antigen-antibody complexes.

The typical patient with leukocytoclastic angiitis[17] has palpable purpura that persist for one to four weeks and are localized to the lower extremities, and a compatible histological picture on biopsy specimens. In several large-scale studies on leukocytoclastic angiitis[18,19] an association with endocarditis was not found. The lesion of leukocytoclastic angiitis is identical to that of the Arthus reaction and to experimental serum-sickness produced by the trapping of antigen-antibody complexes within vessel walls. Although IgG and C have been seen in the skin lesions of many patients with leukocytoclastic angiitis,[20] failure to demonstrate immune complexes in the purpuric lesions of our patient does not detract from the hypothesis of an immunologic origin since removal of immune complexes occurs within 18 hours in the cutaneous vessels of guinea pigs in which an Arthus reaction was produced.[21] Biopsies of the skin lesions of our patient were performed several days after admission.

The depressed serum level of C3 and the evidence of renal involvement further suggest that our patient had an immune-complex disease, and that the purpuric lesions were a manifestation of trapping of antigen-antibody complexes arising as a consequence of his SBE. This lends support to the concept of an immunologic phase of SBE.[22] Further immunologic investigations of other cutaneous manifestations of SBE are warranted.

Cutaneous Infarction

Manifestation of Disseminated Mucormycosis

Barnett S. Kramer, MD; Alfred D. Hernandez, MD; Robert L. Reddick, MD; Arthur S. Levine, MD

• We describe the second reported case of cutaneous infarction as a manifestation of disseminated mucormycosis. The lesion, which closely resembled ecthyma gangrenosum, occurred in a leukemic patient who was on a regimen of broad-spectrum antibiotics. In this case as in the only other reported case, *Mucor pusillus* was the cause.

***(Arch Dermatol* 113:1075-1076, 1977)**

With the routine use of potent cytotoxic agents and broad-spectrum antibiotics in the practice of oncology, fatal deep mycoses have become increasingly frequent.[1,2] Laboratory confirmation of a deep mycosis is often difficult,[3] and physical signs may therefore be of particular value. Cutaneous infarction is not well known as a component of a disseminated mucormycosis.

REPORT OF A CASE

A 20-year-old, nondiabetic woman was admitted to the National Cancer Institute (NCI) in August 1975 for treatment of the third relapse of acute lymphoblastic leukemia (first diagnosed in September 1973). Reinduction therapy was initially attempted with asparaginase (L-asparaginase), vincristine sulfate, daunorubicin, and prednisone. The treatment was complicated by a bacterial, upper respiratory tract infection and by otitis media, which were treated successfully with oral sulfisoxazole and erythromycin stearate. The leukemia did not respond to the reinduction attempt, and the patient was then admitted to the Institute for one week of treatment with high-dose thioguanine, cyclophosphamide (Cytoxan), cytarabine, and methyl-CCNU (semustine) (TEAM). Her peripheral granulocyte count was less than 500 cu mm on days 4 to 28 following the inception of the TEAM regimen. Because of persistent fever of unknown origin, she was given cephalothin sodium, gentamicin sulfate, disodium carbenicillin, and daily WBC transfusions on days 8 to 26. By day 35 granulocytopenia and fever had remitted, but the patient remained in relapse, and a second course of TEAM at higher dosage was administered. Profound granulocytopenia and recurrent fever were present from day 50 until death. During this time, she received continuous broad-spectrum antibiotics and, on days 65 to 80, she received daily WBC transfusions for an apparent infection of the left cheek. The latter resolved, but spiking fevers persisted.

On day 117, an exquisitely painful 2 × 2.5-cm macular erythematous lesion appeared on the upper-abdomen without antecedent skin trauma. A chest film (normal one week earlier) showed infiltrates in the right lung with a small area of cavitation. The purpuric skin lesion enlarged to 9 × 8 cm during the next four days, with a nonblanching ring of surrounding erythema and a central area of vesiculation and necrosis (Fig 1). Biopsy specimens taken of the advancing erythematous ring and purpuric edge were culture-negative, although a few hyphae were noted on wet-crush preparations. The cavitary pneumonia progressed, and the patient died on day 121, 24 hours after she developed a left hemiparesis. All premortem and postmortem blood cultures were negative for bacteria and fungus.

At autopsy, leukemia was found in the bone marrow, liver, and spleen. Hemorrhagic infarction of the lungs, liver, right kidney, and brain was evident. Total occlusion of many vessels throughout these organs (including the superior saggital sinus) by broad, irregularly walled, nonseptate fungal hyphae of the type that are consistent with mucor, was evident on histologic sections (Fig 2). Culture of pulmonary tissue revealed *Mucor pusillus*.

Results of histopathologic examination of the skin lesion revealed thromboses of dermal blood vessels by mucor and necrosis of the overlying epidermis. Fungi were also present in the necrotic epidermis, morphologically similar to those found in other tissues.

COMMENT

Mucormycosis is almost uniformly fatal in the compromised host, and is usually diagnosed using postmortem material. It has been reported to involve nearly every organ, but premortem diagnosis is often difficult because of the inaccessibility of tissue necessary for biopsy or culture.[1] Isolation from blood is rare, positive CSF cultures have never been reported, and current serologic tests are of no value in diagnosis.[2] Skin lesions, although rare, may be of considerable importance since they might permit early recognition and treatment of disseminated infection. In patients who may achieve a remission of their underlying cancer, early treatment of the complicating mycosis would be of obvious value.

Localized subcutaneous phycomycosis is seen almost exclusively in cases in Indonesia and Africa; it is a well-described, self-limited, painless, mycetoma that occurs in noncompromised hosts; and it may resolve without definitive therapy.[4,5] How-

ever, there has been only one previous report of cutaneous infarction as a manifestation of disseminated mucormycosis.[6] Both in our case and in the earlier one, skin infarction and pain were prominent manifestations; and the lesion was very similar in appearance to ecthyma gangremosum.

Veliath et al have recently reported a case of disseminated mucormycosis in which the portal of entry was presumed to be a skin ulcer.[7] In that case, the ulcer was present for at least 15 days before the clinical and roentgenographic signs indicated pulmonary dissemination and infarction. In addition, there is a question as to whether the fungus found in the skin ulcer was a superinfection of a preexisting ulcer. However, it was believed certain that the skin manifestations did not arise as a result of a disseminated pulmonary lesion.

It is interesting that cutaneous infarction as a manifestation of disseminated mucormycosis is rare, especially in view of the marked propensity of this organism to cause widespread thromboses. The skin may be relatively uninvolved in phycomycetes infections. Large inocula of *Absidia* spores have been injected intravenously in more than 600 mice.[8,9] Although fungal lesions and thromboses were found in multiple organs, only one skin lesion was described—a subcutaneous granuloma with no cutaneous infarction. It is also of note that in the only previously reported case of cutaneous infarction in disseminated mucormycosis, *M pusillus* was identified, as it was in our case.[6] It may be that this particular species of phycomycetes has a propensity to produce cutaneous lesions.

Systemic Argyria Secondary to Topical Silver Nitrate

Jay P. Marshall II, MD, Richard P. Schneider, MD

• **A case of generalized argyria secondary to topical silver nitrate use on the oral mucosa is described, and the nature and history of argyria reviewed. The patient has extreme pigmentation of her skin and abdominal viscera, as seen on physical examination, gastroduodenoscopy, and laparotomy. Her use of silver nitrate applicators was uncontrolled by her dentist and pharmacist, and the diagnosis of argyria was not made until 2½ years of heavy usage had passed. Avoidance of similar cases requires the careful scrutiny of silver-containing medicinal usage by all health practitioners and pharmacists. Although the systemic distribution of silver in both elemental and ionic forms can be linked with no systemic toxicity, the resultant pigmentation can be devastating to the patient.**

(*Arch Dermatol* 113:1077-1079, 1977)

Argyria results from exposure to silver salts or silver protein colloids and can closely mimick cyanosis, methemoglobinemia, metastatic melanoma with melanogenuria, and hemochromatosis.[1-3] This paper describes a patient with generalized argyria secondary to mucosal absorption of topically-applied silver nitrate and presents a brief review of the history of argyria.

REPORT OF A CASE

A 46 year-old white woman presented to St Thomas Hospital in December 1975 for evaluation of chronic abdominal pain. The patient was extremely pigmented and has been told in 1972 that she had argyria. She had first used silver-containing medications in 1970 when her dentist suggested the use of topical silver nitrate for bleeding gingiva secondary to poorly fitting dentures. In April 1970, she began using the applicators at the rate of three weekly without a prescription. In November 1971, a bluish discoloration appeared about the patient's nasal and glabellar areas. She continued to use the silver nitrate applicators and referred herself to a physician for evaluation of the pigmentation in July 1972. She was strikingly pigmented at that time and was originally felt to have cardiac cyanosis. That diagnosis proved false, and other studies, including porphyrin levels, serum iron studies, hemoglobin electrophoresis, and serum cortisol levels were normal. The only drug that could be implicated was silver nitrate. Skin biopsy specimens revealed a large amount of intracellular and extracellular pigment with the distribution and staining properties of silver. She was advised to discontinue her use of silver nitrate sticks.

In 1973, she had had an exploratory laparotomy with excision of a cystic duct remnant and an intraoperative liver biopsy. The biopsy specimen revealed silver pigment deposited in portal areas and around central veins (Fig 1). During the following two years, no substantive decrease in the skin pigment was noted. The

patient continued to experience the abdominal pain noted prior to her first usage of silver nitrate and was referred to us for evaluation of this problem in December 1975.

On examination, she was a very deeply pigmented white woman with a slate grey hue to her skin (Fig 2 and 3). The pigmentation was most striking in the sun exposed areas, although present over the entire body. The nail lunulae were bluish with the rest of the nailbed a light grey. The pigment was totally confluent, giving the patient a noncaucasian appearance. The sclerae were grey, and the corneas revealed perilimbic brownish rings.

Due to her abdominal complaints, gastroscopy was performed. The entire esophagus, stomach, and duodenum had a faint greyish cast, and the stomach was inflammed secondary to poor gastric emptying as a sequella to previous gastric surgery. Reconstructive surgery was therefore performed with formation of a gastrojejunostomy and Roux-en-Y drainage. At operation, the patient's pancreas, stomach, hepatic capsule, spleen, intestines, and peritoneum were all discolored in a manner similar to the skin. The pancreas was by far the most pigmented and actually appeared "silver." Gastric biopsy (Fig 4) revealed deposition of silver granules in the connective tissue. Postoperatively, the patient improved and was discharged with only mild abdominal complaints.

COMMENT

In ancient medicine, silver compounds were used largely for diseases of the nervous system due to the proposed relation between silver and the moon, and the belief that the insane were under the influence of the lunar deities. Angelus Sola, in 1647,[3] advocated internal use of silver nitrate in epilepsy, tabes, and chorea minor. De Fourcroy[4] reported the first case of argyria in 1791 in a Protestant minister in Hamburg with obstructive jaundice who had taken a solution of silver nitrate for several months and had eventually become "almost wholly black."[4] The prevalence of argyria increased until the late 19th century when the fear of silver toxicity decreased its use. Although Potter[5] attributed numerous maladies to argyria, present understanding is, however, that the systemic toxicity of silver is limited to pigmentation, except in acute silver poisoning where hemorrhagic, erosive intestinal lesions occur.[6] Systemic toxicity of silver is limited by its rapid binding to various active groups of proteins and the precipitation of silver chloride. Damage to the tissues only occurs when its ability to bind the silver locally is overwhelmed acutely by massive doses. The fatal oral dose is approximately 10 gm, although recovery has occurred after much larger doses.[7] Slow administration can result in huge amounts of the metal being stored in the body. The minimal oral dosage ingested to yield systemic argyria has been estimated to be 25 to 30 gm over a six-month period.[8] As is graphically demonstrated in this patient, the silver is diffusely distributed throughout the body with the highest concentrations occurring in the skin and connective tissues. The pigment may be silver sulfide, silver chloride, or the metallic silver, which results from the reduction of the silver salt within the tissues. This reduction is photoactivated, causing the skin to function in a manner similar to photographic film.[7] Silver also has a stimulatory effect on melanocytes, therefore adding to the increased pigmentation of the sun-exposed areas.[9]

The pigmentation of argyria is permanent. Local injections with 6% sodium thiosulfate solution and 1% potassium ferrocyanide intradermally can decrease silver concentrations in small areas.[10] The use of this is cumbersome and uncomfortable. Because the pigment is elemental silver, chelating agents such as dimercaprol and ethylenediaminetetracetic acid are ineffective.[7]

Localized argyria results from topical silver salts via either medicinal or occupational exposure. Buckley[9] reports a case of a duplicating machine operator who developed localized argyria of her hands from daily immersion in photographic developing solutions. Handling of silver metal by silversmiths and the oral suctioning of silver nitrate solutions in the preparation of silver beads are other causes of reported occupational argyria.[8,9]

As in this case, cyanotic heart disease is often an early consideration.[11,12] This diagnosis should be rapidly dispelled by history and laboratory evaluation. Corneal pigmentation resembling Kayser-Fleischer rings and azure lunulae, both present in this patient, were originally described by Whelton and Pope.[13] The extreme pigmentation of both skin and the abdominal organs seen in this patient has been described,[2,8,14] but no case of severe systemic argyria could be found that had been attributed solely to topical silver nitrate usage. Although argyria is listed as a complication of prolonged use of topical silver nitrate applicators, some manufacturers characterize this as "localized" argyria.

All silver-containing preparations are controlled and must be prescribed. Despite this, as demonstrated in this patient, the possible toxic effects of long-term silver use may be overlooked and indiscriminate use allowed.

Use of colloidal silver compounds such as mild silver protein (Argyrol) strong silver protein and (Protargol) for such varied indications as bladder irrigation, urethritis, nasal drops for cold prevention, mucosal ulcerations, cervicovaginitis, and conjunctivitis has been practiced. The use of silver arsphenamine in the early 20th century for the treatment of syphilis was associated with a significant incidence of at least localized argyria. In 1935, Gaul and Staud[15] reported 70 cases of argyria secondary to oral, intranasal, or pharyngeal use of organic and colloidal silver compounds. It appears that his series marked the end of widespread use of the silver colloid solutions as no subsequent reports have rivaled his in number of cases or frequency of detection. The current use of silver sulfadiazine in the treatment of burns must be carefully scrutinized to avoid excessive systemic absorption of silver from the wounds.

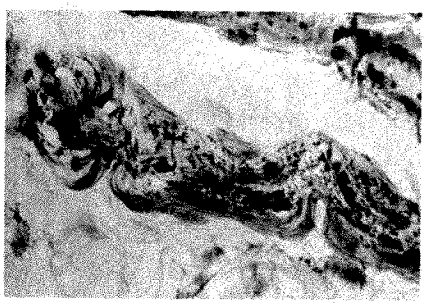

Fig 4.—Gastric biopsy with pigmented granules in connective tissue (hematoxylin-eosin, original magnification ×400).

In patients who ingest silver nitrate, marked argyremia may persist for months as demonstrated by spectography. This can be used diagnostically in the evaluation of possible argyria.[16] Histologically, the silver granules appear as small dark granules deposited diffusely in the tissue, with largest concentrations being in elastin, basal laminar areas of sweat glands, the epidermal membrane, and in connective tissue stroma throughout the body.[8,9,14] The particles average 300 A units in size with a calculated mass of 1.035×10^{-16} grams.[17] Spectroscopic examination of the biopsied tissue may be necessary to differentiate bismuth and silver in the skin.[10]

The impact of argyria on this patient is very significant. Her pigmentation, like that of the "blue man" of the Barnum and Bailey circus,[8] is extremely noticeable. Its presence causes her a great deal of embarrassment and anguish, and because of this, she has severely restricted her social activities and contacts with those outside her family.

Eruptive Nevocytic Nevi After Severe Bullous Disease

Alfred W. Kopf, MD; Charles Grupper, MD; Rudolf L. Baer, MD; John C. Mitchell, MD

• In two patients, hundreds of nevocytic nevi (melanocytic nevi) appeared in sites of severe bullous dermatoses that were considered to be toxic epidermal necrolysis and erythema multiforme exudativum, respectively. This phenomenon may result from benign melanocytic hyperplasia accompanying keratinocytic hyperplasia during the healing process of some of the denuded areas of the skin.

(*Arch Dermatol* 113:1080-1084, 1977)

About 1% to 4% of newborn white infants possess one or more pigmented nevi at birth.[1] During the first three decades of life, the average number of such moles increases to 30 or 40 per person.[2,3] Sometimes nevocytic nevi can be very numerous, very large (giant nevocytic nevi) or in zosteriform distribution. Usually, nevocytic nevi appear gradually in the early years of life as hyperpigmented and macular lentigines or as junction nevi; they are rather symmetrically distributed over the cutaneous surface.[4] In contrast to this usual course, the two patients presented in this report abruptly developed hundreds of nevocytic nevi in sites that had been previously involved by bullous dermatoses.

REPORT OF CASES

Case 1.—In June 1971, this 8-year-old white girl developed a severe eruption involving the skin, eyes, and nails (Color Fig 1). A diagnosis of Lyell's syndrome (toxic epidermal necrolysis) was made. The Stevens-Johnson type of erythema multiforme was considered in differential diagnosis. After subsidence of the acute manifestations, in January 1972, the patient had the following skin changes: mottled, faint, brownish, erythematous, coalescing patches over her trunk; an erosion in the right nostril; thinned finger nail plates; and an area of peculiar brownish-black hyperpigmentation on the anterior part of her left shoulder, within which were darker, buckshot-like macules as well as circinate and gyrate, dark brown lesions.

A biopsy, taken from a hyperpigmented area in her left axilla, showed nests of nevus cells at the dermal-epidermal junction. A histologic diagnosis of "junction nevus" was made.

Examination by an ophthalmologist in July 1971, showed severe photophobia and fibrosis of the conjunctivae and eyelids. Vision was 20/20 in the right eye and 20/50 in the left. The right lids exhibited trichiasis and marked keratinization of the margins extending onto the palpebral conjunctivae. A keratinized plaque was seen in the right lower fornix. There was developing symblepharon with filamentary bands between the lids at the canthi. The lower fornix was shrinking. The cornea was clear and the fundus negative. The left eye showed more severe symblepharon and conjunctival shrinkage. The cornea exhibited diffuse superficial punctate keratitis with filaments. The diagnosis was cicatricial phase of Lyell's syndrome with possible continuing activity.

The patient was again seen in April 1972, at which time she had many more pigmented lesions. Over the anterior aspect of her right shoulder, she had patches of brown, speckled, macular lesions. On the anterior aspect of her left shoulder, there were very many pinhead-sized, barely elevated, brownish papules (Color Fig 2). In her right axilla were numerous, deeply pigmented macular and slightly papular lesions (Color Fig 3). On the trunk, faint hyperpigmentation remained in the areas that had been involved during the acute phase of the bullous disease. There was very superficial scarring in a few of these areas. Both thumb and middle finger nail plates were thinned and dystrophic.

The patient was seen again in August 1972, April 1973, and November 1973, with only a very slight increase in the number of pigmented lesions (Color Fig 4). Light microscopy of specimens revealed nests of typical benign nevus cells at the dermal-epidermal junction and in the dermis (Color Fig 5). Junctional and intradermal nevus cells were readily demonstrated on plastic embedded (1-μ thick) sections (Color Fig 6).

Additional studies included electron microscopy (EM) of two punch biopsy specimens obtained under local anesthesia and fixed immediately for EM processing. One-micron thick sections were studied. Some melanocytes overlying intradermal nevocytes exhibited normal features, having long dendrites and normal melanosome synthesis with respect to number, size, and keratinocytic delivery. In the area of nevocytic hyperplasia (Figure), the epidermal melanocytes had few dendrites and were round in shape. Their melanosomal content was reduced. In the dermis, the nevus cells had short cytoplasmic processes. Macrophages were dispersed throughout the papillary and reticular dermis. Melanosomes resembled those seen in type B nevus cells or were round and contained dense vesicles and electron opaque structures. The nevus cells in the deep dermis had few melanosomes and some of these were round and irregularly stained.

Urinary melanogens were determined by the method of Rorsman-Rosengren.[5-7] Determinations of dihydroxyphenylalanine (DOPA), cysteinyl-DOPA, dopamine, and creatinine were made on two separate morning specimens. All these metabolites were within normal limits (Table).

When last examined elsewhere in February 1976, the eruptive nevocytic nevi remained virtually unchanged and rebiopsy of one of the axillary lesions again showed a benign compound nevocytic nevus.

Case 2.—In 1969, an 8-year-old white boy developed measles, followed by a widespread bullous eruption diagnosed as Stevens-Johnson syndrome (erythema multiforme exudativum). He was very ill at the time of the bullous eruption and had a stormy course in the hospital. Subsequently, he lost his hair and nails. Approximately six to eight weeks after this illness, multiple pigmented lesions were noted on the trunk in areas that had been involved by the bullous lesions. Virtually all of the lesions developed within a few months

Patient 1. Electron photomicrograph of nest of junction nevus cells. Only a few keratinocytes (darker cells) remain in this area.

after the illness. Since their onset, the pigmented lesions have more or less remained stationary. When examined in August 1974, five years after the acute illness, he presented with corneal scarring, nail dystrophy, and eruptive nevi over a large area of his back (Color Fig 7).

Two biopsies of the pigmented lesions were performed. Biopsy 1 specimen had the features of a typical compound nevus (Fig 8). Except for some hyperpigmentation of the keratinocytes in the epidermis and an apparent increase in the number of clear cells (melanocytes) at the dermal-epidermal junction, the epidermis between the clusters of nevus cells was normal. The nevus cells at the dermal-epidermal junction formed classic theques of varying sizes. The nevus cells in the dermis were present in nests and cords of varying sizes and shapes. A considerable amount of pigment was present in these intradermal clusters of nevus cells. No mitoses were noted in the nevus cells, and their size and shape were typical of benign moles. No features of benign juvenile melanoma were noted. There was no inflammatory reaction surrounding the nests of nevus cells nor in any portions of the cutaneous biopsy. In summary, the findings were those of uncomplicated typical compound nevi.

The findings in biopsy 2 specimens were identical to those of biopsy 1 except that there was somewhat more pigment in the nevus-cell nests at the dermal-epidermal junction and that there was a sparse perivascular inflammatory infiltrate in patchy fashion in the dermis. Again, the histologic findings were those of a benign, compound nevocytic nevus.

COMMENT

The following constellation of findings seems to set apart these two patients from those with other types of nevocytic nevi: (1) hundreds of nevocytic nevi erupted over a relatively short period of time in an asymmetric fashion; (2) both patients were children (age 8); (3) both patients had developed a severe bullous dermatosis prior to the appearance of the eruptive nevus-cell nevi; (4) in both cases, histologic examination of more than one pigmented lesion showed benign, compound nevi; and (5) in both patients relatively long-term follow-up (four and six years) showed the condition to have reached a point of stability in terms of the number of lesions without tendency for spontaneous involution.

Several possibilities were considered in order to explain these unusual lesions. First, we considered the possibility that they represented disseminated benign juvenile melanoma[5]; but the histopathologic findings did not meet the criteria set forth for this type of neoplasm.[5] Secondly, the abrupt onset, number, and clinical appearance of the lesions made us consider malignant melanoma in a phase of satellite metastases. This

diagnosis was ruled out by the findings that the lesions were benign compound nevi and by the subsequent course that showed no further dissemination in four-year and six-year follow-ups, respectively.

To explain the phenomenon of eruptive nevocytic nevi in these two patients, we postulate that, during the re-epithelialization entailed in the healing process of the bullous eruptions, there was stimulation of widely disseminated melanocytes, each one of which had the potential for producing nevus cells. The fact that this condition was observed in young patients during their prime years of life for developing pigmented nevi[2] would favor this conjecture.

It is also known that nevus-cells or their precursors can be involved in the healing process after partial removal of moles. For example, after partial removal of giant nevus-cell nevi, it is not unusual to see hyperpigmented streaks coursing over the surface of the scars produced by the surgical procedures. Melanocytes can migrate along with epithelium as has been demonstrated in a number of studies.[10-12] Such melanocyte migration is associated with melanocyte multiplication.[13]

It is generally held that nevus cells are derived from dermal-epidermal melanocytes.[14] Thus, a failure of the usual control mechanisms regulating melanocytic proliferation (eg, by a melanocyte chalone)[15] could be considered as a possible explanation for the tremendous, albeit, temporary proliferation of nevus cells in our patients. Benign nevocytic nevi, after partial removal, can recur with clinical hyperpigmentation. Though some of the original lesions so treated were histologically shown to be intradermal nevi, the recurrent hyperpigmentations took on the histologic aspects of junction or compound nevi.[14,16] Such lesions can sometimes simulate malignant melanomas and the neologism "pseudomelanoma" has been proposed.[17] A concept of "seeded nevus cells" to explain recurrences of nevi after partial removal was suggested by Gougerot in 1947.[18] Schoenfeld and Pinkus[14] reported that in some instances, the melanocytes that produced recurrence of pigmentation in nevocytic nevi after incomplete removal appeared to be derived from nevus cells around hair roots. Since hair root melanocytes can migrate during wound healing,[13] an adnexal (pilar) source of melanocytes could have been responsible for the spotty "buckshot" distribution of nevi in our two patients.

Very little is known about the rapidity of the process of maturation of nevocytic nevi. We know that most such nevi removed in the first few decades of life have a significant component of junctional theques or nests; but that in nevi removed later in life, the cells are mostly intradermal in location.[4,19,20] Since this process of dropping off or "Abtropfung" is usually incomplete, most clinically typical intradermal nevi have some few remaining junctional theques.[21] The biopsies in our patients were done 6, 31, and 60 months after the abrupt onset of the nevi. All already showed intradermal elements; thus, at least under some circumstances, nevocytic nevi can develop a combination of junctional and intradermal elements in a relatively short time.

Since juvenile lentigines are considered to be precursors of nevocytic nevi, the eruptive nevocytic nevi reported here may be related to various syndromes of lentiginosis.[22] This similarity is especially true for the syndrome of lentiginosis profusa in which large numbers of lentigines develop in a short period of time in adolescents and young adults.[23-27] Crops of pigmented nevi can develop rapidly in adolescence and during pregnancy. They can also appear without any apparent hormonal influence as reported by Coskey[28] who collected and documented three cases of eruptive pigmented lesions (nevus and lentigo) in a two-year period. In clinical practice, it is not unusual to be consulted by patients who report a sudden appearance of numerous moles, but in our review of the literature, we were unable to find previous reports of eruptive, pigmented, nevocytic nevi following bullous dermatoses, as occurred in the patients reported here. In some cases of lentiginosis profusa[29] which were actually examples of widespread nevocytic nevi, partial or complete spontaneous disappearance of the pigmented lesions seems to have ensued. Such disappearance of lesions did not occur in our patients during the observation periods noted.

The precise pathogenesis of nevo-

cytic nevi is not known. The hypothesis suggested above, melanocytic seeding of some healing sites following bullous dermatoses, remains unproven. Perhaps the precursors of nevus cells are nevoblasts that are special melanocytes destined to give rise to a broad spectrum of morphologic types of nevocytic nevi,[30] including those of the eruptive variety. One has to explain further proliferation of the melanocytes by invoking theories such as those of clonal selection, pathogenic induction, and accidental mutation.[31] A local abundance of a nerve-growth factor from dermal neural structures could provide a local stimulus for melanocytic proliferation.[32] However, the seeding hypothesis leaves many questions unanswered, such as the following: Why is this phenomenon not observed more often? Why does it not occur after extensive cutaneous burns, after dermabrasions, or even after bullous *Rhus* dermatitis? Why has it not been reported following other types of bullous dermatoses such as epidermolysis bullosa? Why are the eruptive nevi localized to only a portion of the skin affected by the bullous disease?

The phenomenon of eruptive nevocytic nevi following bullous disease may result from the profound epidermal necrosis that occurred as a consequence of bulla formation and that called forth a burst of mitoses of epidermal keratinocytes. The ratio of keratinocytes to melanocytes is approximately 36 to 1,[33] and melanocytes must presumably proliferate along with keratinocytes to maintain this ratio of cells. Such orchestration must require very precise mechanisms to result in a perfect balance of recreated normal epidermal-melanin units. It is possible that the control mechanisms concerned with melanocytic proliferation went astray during the wound healing process so that an overabundance of pigment cells resulted leading to the formation of numerous nevocytic nevi.

Since these patients have been followed for only four and six years, respectively, the potential for malignancy in such cases is not known. In instances of giant nevocytic nevi, which also cover large areas of the skin, the possibility for malignant transformation is substantial.[34-36] Our patients have numerous nevocytic nevi, but the lesions are small and widely scattered rather than concentrated in the large plaques as occurs in giant nevocytic nevi.

We hope to continue to follow these patients and report at a later date any further developments.

Goodwin Breinin, MD, Chairman of the Department of Ophthalmology, New York University School of Medicine, performed the ophthalmic examinations on patient 1; J. P. Cesarini, MD, Laboratoire de Recherches sur les Tumeurs de la Peau Humaine, Foundation Ophtalmologique A de Rothschild, performed the electron microscopic examinations and interpretations; Dr Hewes, of the American Hospital in Paris, treated patient 1 in collaboration with C. Grupper, MD, when she presented with the acute phase of toxic epidermal necrolysis; Beltzer Garelly, MD, performed the light microscopy of patient 1; and William S. Wood, MD, examined the histologic material by light microscopy on patient 2.

The Rudolf L. Baer Foundation for Skin Diseases, Inc, aided in defraying the costs of preparation of the manuscript and publishing the color illustrations.

Eczema Herpeticum Caused by Herpesvirus Type 2

A Case in a Patient With Darier Disease

Paul G. Hazen, MD, R. Bennett Eppes, MD

• This, to our knowledge, is the first documented report of eczema herpeticum due to infection with herpesvirus hominis type 2. The virus was isolated from a patient with known Darier disease who developed Kaposi varicelliform eruption. Recent increases in the incidence of infection with type 2 herpes simplex as well as the high frequency of recurrence with this virus make this infection of potential significance in patients with preexisting cutaneous disease.

(*Arch Dermatol* 113:1085-1086, 1977)

Darier disease (hyperkeratosis follicularis) has been reported to be among the dermatoses susceptible to the sudden onset of a widespread vesicular eruption accompanied by high fever known as Kaposi varicelliform eruption. Both the vaccinia virus and the herpes simplex virus have been implicated, and the infections are referred to respectively as eczema vaccinatum and eczema herpeticum.

There are two types of herpes simplex virus that can be distinguished by clinical and laboratory criteria. Herpesvirus hominis type 1 is the virus most often responsible for perioral herpes infections, although other anatomic regions may be involved. Herpesvirus type 2 is frequently implicated in genital infections, eruptions of the hands, thighs, and buttocks and in infants with neonatal herpes infections, although it also can be found in other sites.[1] Type 1 and type 2 herpesvirus can be distinguished in vitro by their different growth patterns on chorioallantoic membrane of the chick embryo, by their different biochemical composition, and by specific serologic responses in the host.[2]

The purpose of this report is to present a patient with known Darier disease who developed Kaposi varicelliform eruption caused by the herpes simplex type 2 virus. To the best of our knowledge, this is the first report of eczema herpeticum in which the herpesvirus hominis type 2 virus has been isolated as the causative agent.

REPORT OF A CASE

A 26-year-old man with known Darier disease since age 6 was admitted to University Hospitals of Cleveland in August 1974, with a widespread vesicular eruption and high fever.

For many years the patient had had persistent hyperkeratotic papules on the mid-chest, back, upper arms, and legs. Previous skin biopsies had confirmed the diagnosis of Darier disease. The patient's father also had Darier disease.

Extensive vesiculation and crusting of forehead, neck, and ears due to infection with herpes simplex virus type 2.

One week before admission the patient noted a cluster of small blisters on the shaft of the penis. The lesions became pustular, and the patient developed moist and tender fissuring with crusting in the intertriginous areas of the groin. Four days later, multiple exudative and crusted lesions appeared on the ears, forehead, and chest. The patient developed chills, fever, and malaise and became toxic.

On admission, the patient appeared acutely ill. The temperature was 40 C. There were clusters of umbilicated vesicles on an erythematous base and extensive crusting on the neck, back, and forehead (Figure). Both pinnae showed a vesiculopustular eruption with crusting and marked edema. There were multiple superficial erosions of the penis and severe maceration and crusting of the genitocrural folds and presternal region. Multiple "dirty-brown," scaly papules were noted on the arms and legs.

The patient's past medical history included varicella in childhood and smallpox vaccinations without complication at the ages of 1, 5, and 12. The patient denied a history of "cold sores," herpes zoster, or previous genital lesions.

Results of laboratory studies were as follows: white blood cell count, 7,000/cu mm, with 72% polymorphonuclear leukocytes, 15% lymphocytes, 9% monocytes, and 4% eosinophils. The hematocrit value was 42%, and the erythrocyte sedimentation rate, 42 mm/hr. Serum glutamic oxaloacetic transaminase was 42 Henry units/100 ml (normal, > 25 units). Results of other liver function tests were within normal limits. Serum protein electrophoresis showed an increase in the α_2-globulin fraction. Chest roentgenogram was within normal limits. Skin, throat, and urine cultures demonstrated normal flora. VDRL was nonreactive.

Skin tests for *Trichophyton*, *Candida*, purified protein derivative, and mumps were negative at 48 hours. A Tzank smear of a chest vesicle demonstrated several multinucleated giant cells. Culture of an adjacent vesicle yielded a virus characterized as herpes simplex and subsequently identified as type 2 by the Communicable

Disease Center in Atlanta. A biopsy specimen of an arm papule demonstrated suprabasilar separation with corps ronds and grains typical of Darier disease.

The axillae and groin remained moist and fissured after discharge. Skin biopsy specimens from the forearm, groin, and chest in July 1975 again demonstrated changes consistent with Darier disease.

The patient has continued to have approximately monthly episodes of grouped vesicles on an erythematous base occurring in clusters on the trunk. Another skin culture in May 1975 has again demonstrated herpes simplex virus type 2.

COMMENT

Eczema herpeticum, by definition, appears in patients with preexisting cutaneous disease. It generally appears as tiny umbilicated vesicles, often in an area of previous dermatitis, that gradually enlarge, coalesce, and progress to pustular and crusted stages. Erosions and fissuring accompanied by edema and purulent exudate are common. The patient's temperature is usually elevated and may remain so for several weeks. The patient may appear toxic, and involvement of internal organs including the liver, brain, gastrointestinal tract, lungs, and adrenals may occur. The mortality has been reported to be as high as 10% to 50%.[3]

Several groups of patients are more susceptible to severe herpetic infections. These include those patients with preexisting cutaneous disease; newborn infants, particularly if premature[4]; patients with severe malnutrition[5]; certain patients with associated infections such as measles[6]; those with underlying defects in cell-mediated immunity such as patients receiving immunosuppressive agents[7-9] and patients with congenital thymic defects such as thymic dysplasia or the Wiskott-Aldrich syndrome[10]; and those patients with underlying lymphomas.[7] In considering herpetic infections in patients with preexisting cutaneous disease, those patients with atopic dermatitis or neurodermatitis are most often affected, although eczema herpeticum has been reported as a complication of a variety of other cutaneous diseases including Darier disease, congenital ichthyosiform erythroderma, seborrheic eczema, and pemphigus.[3]

In all previous reports of eczema herpeticum in patients with Darier disease or other dermatoses, either herpes simplex type 1 was isolated or typing was not carried out. In 1961, Hitselberger and Burns[11] reported a patient with Darier disease who developed a generalized vesicular eruption after contact with a neighbor with a "cold sore" ten days previously. Although no virus was isolated, the skin biopsy specimen was consistent with a cutaneous viral infection and a Tzank smear demonstrated numerous multinucleated giant cells.

Fisher and Kibrick,[12] Doeglas and Moolhuysen,[13] von Weiss et al,[14] and Bleiberg and Klosk[15] have reported cases of Kaposi varicelliform eruption in which herpes simplex type 1 was suspected to be the causative agent. Von Weiss was able to culture herpes simplex, but typing was not done. Izumi and Goldschmidt[16] and Higgins and Crow[17] were also able to culture the herpes simplex virus from their patients; they were further able to identify it as type 1. Carney et al[18] reported a patient with Darier disease who recovered from eczema vaccinatum only to experience numerous vesicles over the anterior portion of the trunk nine months later. The eruption had been preceded ten days earlier by a blister in the genital region. The patient was otherwise asymptomatic and the vital signs were normal. Herpes simplex virus was cultured from one of the trunk vesicles. Typing was not performed.

Our patient is similar to the patient reported by Carney et al in that a vesicular eruption in the genital area preceded the onset of the more generalized process. Our patient, however, was febrile, appeared toxic, and had more extensive involvement.

Recent epidemiologic studies indicate a high incidence of genital herpes in the population and a significant risk of recurrence. Several reports indicate that herpes genitalis has become the predominate cause of vesiculoulcerative disease of the genitalia.[19,20] Herpes simplex virus type 2 has been isolated from the genitourinary tract of 15% of 190 asymptomatic males.[21] Moreover, 9% of private patients and 22% of public clinic patients have serologic evidence of prior herpesvirus type 2 infection.[20] This represents at least a several-fold increase in occurrence in the last 20 years.[19]

The increasing incidence of infection with herpesvirus type 2 and the tendency of this eruption to recur suggests that physicians should be alert for the complication of eczema herpeticum due to herpes simplex virus type 2 in any patient with preexisting cutaneous disease.

Graft-Versus-Host Reaction

Cutaneous Manifestations Following Bone Marrow Transplantation

Antoinette F. Hood, MD; Nicholas A. Soter, MD; Joel Rappeport, MD; Irma Gigli, MD

• The distinctive cutaneous changes that occur in both the acute and chronic forms of the graft-vs-host reaction (GVHR) are described in two living patients in whom the GVHR developed after bone marrow transplantation for aplastic anemia. In the skin, the mild form of the acute GVHR is recognized as a subtle macular erythema, and the severe form appears as erythematous papules and violaceous macules with scale. Skin biopsy specimens in both of the acute forms show vacuolar alterations of the epidermal basal-cell layer with a perivenular infiltrate of lymphocytes. The chronic GVHR evolves from generalized scaling to diffuse areas of sclerotic and atrophic skin with a curious reticulated hyperpigmentation, ulcerations, and alopecia. Histopathologic study shows collagenization of the dermis that can be correlated with the clinical sclerodermoid changes. Owing to its visibility, the skin offers a unique opportunity for the early recognition of the GVHR.

(*Arch Dermatol* 113:1087-1091, 1977)

Lymphocytic cells that are administered to an immunodeficient or immunosuppressed individual possess the capacity to react against recipient tissue antigens that are absent in the donor and that are not linked to the histocompatibility (HLA) or mixed leukocyte culture (MLC) loci. The immunologic competence of these cells forms the basis for the development of the graft-vs-host reaction (GVHR).[1,2] Although the GVHR has been described in immunodeficient patients who have received unirradiated blood products,[3,4] it is seen most frequently in patients that have received bone marrow transplants.[5] The GVHR has become one of the major impediments limiting the success of this therapeutic maneuver. The principal organs involved in the GVHR are the intestinal tract, the liver, and the skin; clinically distinguishable acute and chronic forms of the GVHR are recognized. The acute GVHR develops one to seven weeks after bone marrow transplantation and is characterized by fever, eosinophilia, diarrhea, hepatic dysfunction, and distinctive cutaneous changes. Mortality in the acute GVHR ranges from 44% to 90% and results from end organ failure, or, more commonly, associated infection.[6,7] The use of antithymocyte globulin (ATG) and sterile environments has reduced appreciably the mortality in an acute GVHR.[8] The chronic GVHR occurs months after bone marrow transplantation and may or may not be preceded by a clinically recognizable acute GVHR; the skin and the intestinal tract are commonly affected, and the liver is less frequently involved. Although the chronic GVHR is less frequent than the acute GVHR, it may become more frequent as patients receiving bone marrow transplants survive for longer time intervals. Morbidity and mortality of the chronic GVHR are uncertain at the present time.

Of the three organs commonly affected in a GVHR, the skin offers unique opportunities for observation and study of the emergence and progression of both gross and microscopic changes. Although the histopathologic changes of the GVHR have been documented,[7-11] detailed descriptions of the gross morphological findings of the lesions are lacking. In this report, the evolution of the distinctive cutaneous lesions in two living patients in whom GVHR developed following bone marrow transplantation is described and correlated with histopathologic features. In the first patient, an acute GVHR occurred that resolved after the administration of antithymocyte serum (ATS). In the second patient, a chronic GVHR developed that was characterized by evolution into striking generalized sclerodermoid changes with ulcerations and alopecia.

MATERIALS AND METHODS

Grafting Procedure

The donor in each instance was a sibling who was HLA identical and MCL nonreactive when compared with the patient. The patients were maintained in a protected environment with strict reverse isolation. Skin sterilization was obtained with daily applications of topically applied povidone-iodine (Betadine) ointment; gastrointestinal sterilization was obtained by means of a diet low in bacteria and a bowel preparation containing nystatin (Mycostatin), gentamicin sulfate, and vancomycin hydrochloride. Prior to bone marrow transplantation, the following immunosuppressive agents were administered: cyclophosphamide, 50 mg/kg/day for four days; procarbazine hydrochloride, 12.5 mg/kg/day for three days; and three doses of ATS. Thirty-six hours after the last administration of cyclophosphamide, the patients received an intravenous infusion of donor marrow with the day of infusion designated as day 0. In an attempt to prevent GVHR following bone marrow transplantation, methotrexate, 10 mg/sq m, was administered orally on days 1, 3, 6, 11, and weekly thereafter to day 62 in patient 1 and day 102 in patient 2.

Biopsy Specimens

Skin trephine biopsy specimens measuring 4 mm were obtained with use of lidocaine, fixed in 10% formaldehyde solution,

embedded in paraffin, stained with hematoxylin-eosin, and examined with a light microscope.

RESULTS
Report of Patients

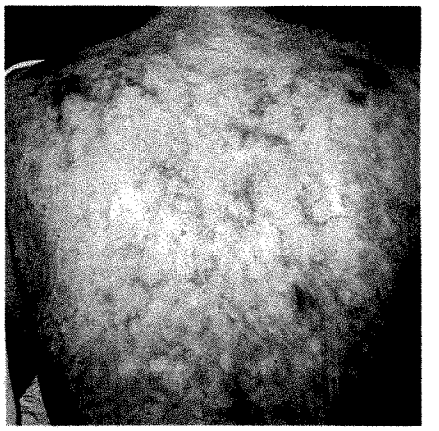
CASE 1.—A 28-year-old woman with idiopathic aplastic anemia of one month's duration had the following laboratory values on admission: hemoglobin, 8.9 gm/100 ml; hematocrit, 26.5%; WBC, 2,600/cu mm, with 28% neutrophils, 65% lymphocytes, 6% monocytes, and 1% eosinophils; platelet count, 4,000/cu mm; and reticulocytes, 0.4% (uncorrected). A bone marrow biopsy specimen showed an acellular marrow. After immunosuppression, 1.9×10^8 marrow cells per kilogram body weight obtained from the patient's histocompatible brother were administered intravenously on day 0. A bone marrow biopsy specimen obtained on day 16 showed an increase in all hematopoietic elements, and allogeneic engraftment was further documented by the demonstration of donor RBC markers and sex chromosome. The patient developed clinical and laboratory evidence of the GVHR in the following three organ systems: the gastrointestinal tract, liver, and skin. Diarrhea was noted on day 7; liver function test (LFT) results were abnormal between days 22 and 29 with increased bilirubin, alkaline phosphatase, and SGOT; and there were skin lesions on day 30.

The initial eruption was recognized as a faint, mottled macular erythema that blanched with the application of external pressure and that was noted initially on the upper portions of the trunk with gradual spread to include the entire trunk, face, and upper extremities. Between days 42 and 48, numerous nonblanching erythematous papules were observed on the upper and lower extremities accompanied by erythematous macules on the trunk; these lesions were replaced by discrete violaceous papules with evolution into macules with scale (Fig 1). The progression of the cutaneous eruption from the sixth to the ninth week following diarrhea was accompanied by continued nausea and vomiting, weight loss, and hepatomegaly with persistent elevation of the LFTs. Regimens of ATS (0.1 ml/kg of body weight) were administered on days 65, 68, and 70 following transplantation. After the first dose of ATS, the patient experienced fever, arthralgias, and hypocomplementemia with a low CH50 level, presumably the result of serum sickness. The ATS was discontinued after three doses; the diarrhea subsided, and the skin lesions faded, leaving residual postinflammation hyperpigmentation. The LFTs failed to improve after the administration of ATS; however, with continued elevation of her total bilirubin and alkaline phosphatase; an atypical cytomegalovirus was cultured from the urine, suggesting that the persistent liver disease was the result of viral hepatitis rather than the GVHR. The patient was discharged from the hospital on day 91 and has been followed up as an outpatient. Despite persistently abnormal LFTs, she remains clinically well with a good appetite, stable weight, and no recurrence of either diarrhea or skin lesions.

CASE 2.—A 25-year-old woman was hospitalized with a two-month history of aplastic anemia following exposure to benzene. Laboratory studies revealed the following values: hemoglobin, 10.4 gm/100 ml; hematocrit, 30.3%; reticulocytes, 0%; platelet count, 2,500/cu mm; and WBC, 2,600/cu mm with 2% neutrophils, 1% band forms, 88% lymphocytes, 5% atypical lymphocytes, 2% monocytes, and 2% metamyelocytes. A bone marrow biopsy specimen showed severe hypoplasia with depletion of all hematopoietic elements. After immunosuppression, 2.6×10^8 marrow cells per kilogram body weight, obtained from the patient's histocompatible sister were administered intravenously on day 0. Twelve days after transplantation, there was evidence of successful engraftment in the peripheral blood with the appearance of myeloid cells and nucleated erythrocytes. A bone marrow aspirate and biopsy specimen obtained on day 31 showed marked erythroid activity, normal myeloid activity, and adequate megakaryocytes. A RBC marker further substantiated successful engraftment. On day 35, the patient experienced evanescent pruritic skin lesions that were ascribed to the administration of ampicillin sodium for cystitis. The eruption persisted after the antibiotic was discontinued, and the patient developed fever and abnormal LFTs on day 45. These signs and symptoms subsided after the dose of methotrexate was increased from 10 to 15 mg/sq m weekly. When discharged on day 81, the patient was clinically well with good appetite, stable weight, and no diarrhea or skin lesions.

Over the next few months, however, the patient developed an inexorably progressive GVHR of the skin that appeared as generalized scaling, follicular hyperkeratosis, and patchy hyperpigmentation (Table). On day 133, several erythematous macules with scale were observed on the midback (Fig 2), and subsequently similar lesions appeared on the face and extremities. The individual lesions resolved, leaving a localized area of sclerotic, atrophic skin with a curious reticulated erythema and hyperpigmentation (Fig 3, right). The palms and soles appeared diffusely violaceous with scale; periungual erythema and telangiectases were observed. As the eruption progressed, the patient experienced increas-

Fig 1.—Severe acute GVHR (patient 1, day 52). Violaceous macules over an upper extremity.



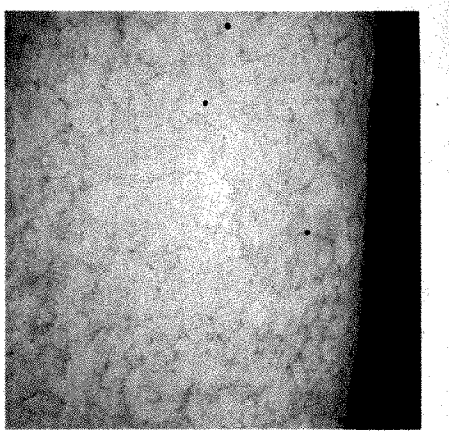


Fig 3.—Chronic GVHR (patient 2, day 326). Left, Extensive atrophy of skin with erythema and ulceration. Right, Detail of lower extremity showing curious reticulated hyperpigmentation.

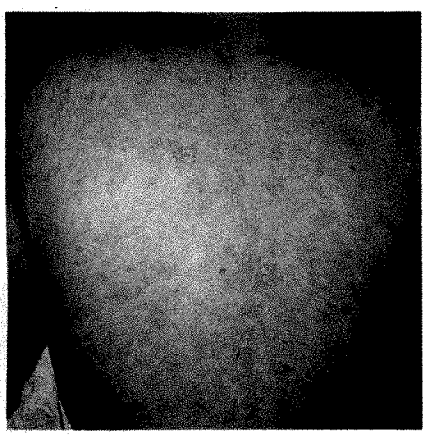

Fig 2.—Chronic GVHR (patient 2, day 155). Erythematous macules with scale are present lateral to midline.

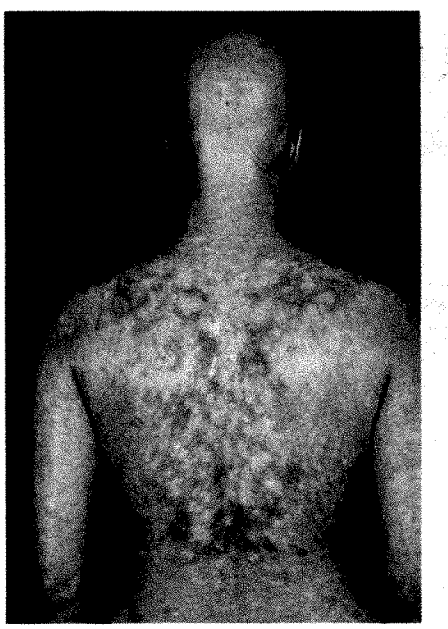

Fig 4.—Chronic GVHR (patient 2, day 398). Alopecia of scalp with extensive cutaneous ulceration.

ing "tightness" of her skin and decreased range of motion at the elbows, knees, and mouth. There was patchy erythema, reticulated hyperpigmentation, and superficial parchment-like wrinkling. Six months after transplantation, multiple superficial erosions with honey-colored crusts appeared over the trunk; these lesions, interpreted as impetigo, resolved after the administration of erythromycin for ten days. Several weeks later, focal areas of erythema were noted in previously altered skin of the back that evolved into large ulcerations (Fig 3, left). Antinuclear factor and lupus erythematosus (LE) cell preparations were negative on multiple occasions, and the patient denied a history of Raynaud's phenomenon, dysphagia, or constipation.

Neither the administration of prednisone and methotrexate nor the topical application of 0.1% betamethasone valerate cream was effective in altering the progression of the skin lesions. When the eruption became symptomatic enough to interfere with her normal activities, the patient was hospitalized, and ATS (0.1 ml/kg of body weight) was administered beginning on day 313. After the third dose of ATS, she experienced fever and arthralgias interpreted as serum sickness; the treatment was discontinued. Although there was a transient decrease in the erythema following the administration of ATS, the inexorable progression of the process remained unaltered. Thirteen months after the marrow transplantation, the patient's skin disease remained as the major clinical feature and therapeutic problem (Fig 4).

Histologic Findings

The faint macular erythematous lesions that appeared early in patient 1 were characterized by focal vacuolation of the epidermal basal-cell layer, focal extension of lymphocytes into the epidermis, and a sparse perivenular infiltrate of lymphocytes and histocytes in the upper portions of the dermis. The nonblanching papules in patient 1, violaceous macules with scale in both patients, and the erythematous macules appearing in previously affected skin in patient 2 showed intercellular edema of the epidermis, marked vacuolation of the basal-cell layer, dyskeratosis and necrosis of individual epidermal cells, so-called mummified cells,[1] a perivenular infiltrate of lymphocytes with focal extension into the epidermis, edema with fibrosis of the papillary dermis, and occasional focal extravasation of RBCs about venules (Fig 5). As the chronic cutaneous disease progressed in patient 2 to include atrophy, reticulated hyperpigmentation, and ulceration, a skin biopsy specimen exhibited thickening of the dermis with hypertrophic and closely packed collagen bundles that appeared hyalinized and brightly eosinophilic with fibrosis and with loss of hair follicles and persistence of sweat glands surrounded by collagen. There was hyperkeratosis, thinning of the epidermis, and a paucity of lymphocytes in the epidermis and about venules (Fig 6).

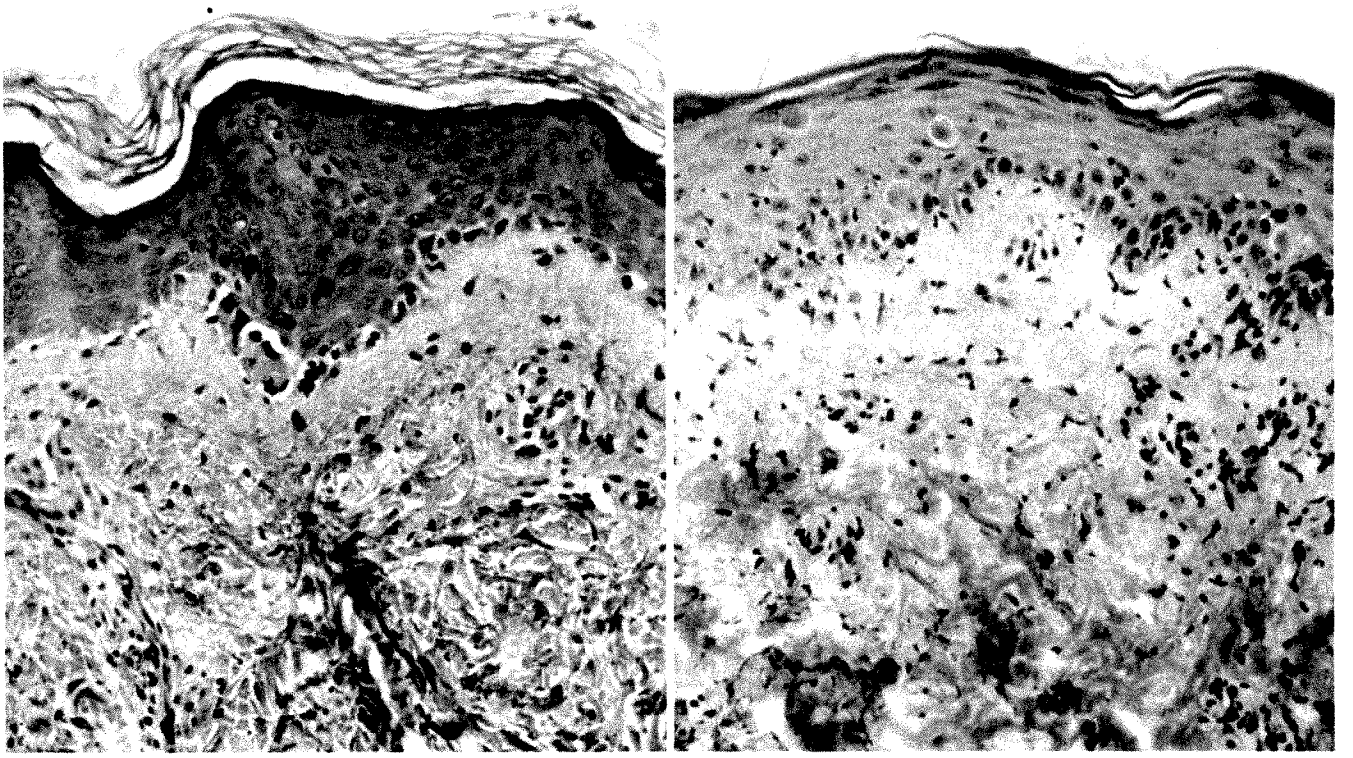

Fig 5.—Acute GVHR (patient 1, day 48). Left, Focal dyskeratosis and vacuolation of basal-cell layer of epidermis. Right, Epidermal intercellular edema; lymphocytic infiltration of both epidermis and dermis (left and right, hematoxylin-eosin, original magnification ×125).

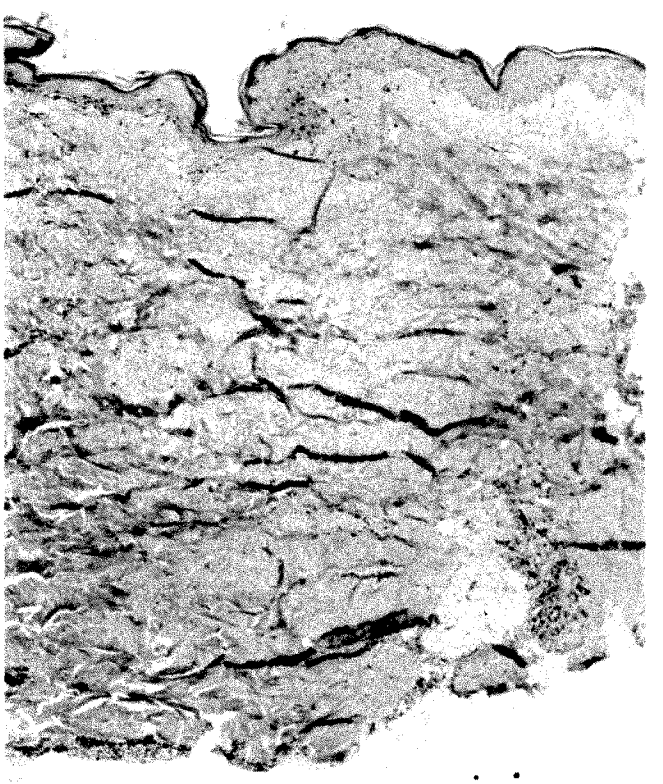

Fig 6.—Chronic GVHR (patient 2, day 302). Atrophic epidermis, collagenization of dermis with persistence of eccrine sweat gland, and paucity of infiltrate of lymphocytes (hematoxylin-eosin, original magnification, ×12.5).

COMMENT

Distinctive skin changes may be observed in the GVHR both in the acute and chronic forms, and the cutaneous changes associated with acute GVHR can be subdivided as mild and severe (florid) with respect to clinical description and course. The mild acute GVHR is characterized by an easily overlooked macular erythema that appears on the upper portion of the trunk, head, and neck and histologically shows focal vacuolar degeneration of the epidermal basal-cell layer with a sparse perivenular infiltrate of lymphocytes. This reaction corresponds to the grade I GVHR described in the Seattle classification (≦ 25% body surface involved, little or no visceral involvement).[6] Inasmuch as this form of the GVHR is observed in transplantation patients without sustained engraftment as well as in immunodeficient patients that have received nonirradiated blood products, the cells participating in the reaction are presumed to be the mature circulating lymphocytes administered in the marrow infusion. Mortality in a mild acute GVHR is similar to that in patients without a GVHR.[6] This form of the GVHR should be considered in the differential diagnosis of any cutaneous eruption developing in immunosuppressed patients receiving transfusions of blood rich in lymphocytes. Since the skin lesions are subtle and not all eruptions occurring in these patients are manifestations of the GVHR, drug-induced eruptions and viral exanthems should also be considered. Histopathologic examination of a skin biopsy specimen may be helpful in resolving the dilemma.

The severe or florid form of an acute GVHR was noted in patient 1 as nonblanching, erythematous papules and violaceous macules with scale that appeared on the extremities and trunk. On histologic examination, these lesions showed intercellular epidermal edema, vacuolar degeneration of the basal-cell layer, dyskeratosis and necrosis of epidermal cells, and a perivenular infiltrate of lymphocytes with extension into the epidermis. These observations correspond to the Seattle classification of grade II to III GVHR (≧ 25% body surface involved, mild to moderate visceral involvement).[6] Although the pathogenesis of the severe acute GVHR is unknown, since it occurs only in patients with successful bone marrow engraftment and can be terminated by ATS, it is probable that the process results from established and proliferating lymphocytes in the recipient. The mortality associated with severe GVHR (grade II-IV) is high (85%), owing to the patients' increased susceptibility to infections.[6] Although certain of the violaceous papules may clinically and histopathologically resemble lichen planus,[12,13] the lesions in the severe acute GVHR can be distinguished by their characteristic histopathologic features. In lichen planus, there is characteristically a dense infiltrate of mononuclear cells in the upper portion of the dermis; these cells may obscure the dermoepidermal junction. In the GVHR, the infiltrate in the dermis is sparse and disposed about venules. In addition to lichen planus, the histologic differential diagnosis includes LE, fixed-drug eruptions, and erythema dyschromicum perstans.[14]

The evolution of a chronic cutaneous GVHR in patient 2 was characterized by a progression from generalized scaling to diffuse sclerotic, atrophic skin with widespread ulcerations. The most striking histopathologic change was the progressive collagenization of the dermis that correlated clinically with the sclerodermoid changes; in addition there was a paucity of lymphocytes, and the epidermal changes were similar to those observed in the acute severe GVHR. The possibility of coexistent collagen-vascular diseases such as scleroderma and LE were considered but eliminated, owing to the absence of the criteria requisite for diagnosis. The similarity between the skin lesions of the chronic GVHR and those observed after external administration of electron-beam therapy and poikiloderma atrophicans vasculare, a premalignant harbinger of mycosis fungoides, is considerable.[7]

The incidence of a chronic GVHR following bone marrow transplantation is as yet unknown inasmuch as a substantial population of patients that are long-term survivors has not yet been accumulated. In reported patients, three of 20 individuals[5] that survived more than 100 days after engraftment developed a chronic GVHR. The pathogenesis of the chronic GVHR is unclear; owing to the delayed onset of the disease, it seems likely that the immunocompetent cells participating in the reaction are derived from the engrafted marrow and have differentiated within the recipient. The paucity of lymphocytes observed in the skin compared with the extensive changes of the epidermis and the dermis suggest that additional factors may be implicated.

Eosinophilic Fasciitis

Ronald E. Krauser, MD, Ralph J. Tuthill, MD

• A detailed evaluation of the clinical and histologic manifestations of eosinophilic fasciitis is described in a 22-year-old woman. Scleroderma-like skin involvement is associated with eosinophilia and hypergammaglobulinemia. Visceral and serologic manifestations of a generalized scleroderma are lacking. Results of a biopsy showed severe thickening of the deep fascia accompanied by an infiltration of lymphocytes and plasma cells. This syndrome must be differentiated from generalized scleroderma because eosinophilic fasciitis has a benign course and may benefit from systemic corticosteroid therapy.

(*Arch Dermatol* 113:1092-1093, 1977)

In 1974 Shulman reported an unusual scleroderma-like syndrome associated with hypergammaglobulinemia and eosinophilia.[1] Since then three additional articles have described similar patients.[2-4] Cutaneous involvement seems to occur mainly on the arms and legs, with a relative sparing of the face and hands. Visceral involvement is uniformly lacking and serologic evaluations are usually negative. We describe a patient with similar clinical features and provide a detailed analysis of the histopathologic changes that accompany this disorder.

REPORT OF A CASE

A 22-year-old woman was in good health until December 1974 when she developed intermittent swelling of her left hand, particularly on the volar aspect. Within the next month she noticed an inability to completely straighten the left elbow and the fingers of the left hand. No other extremities were affected. She specifically denied morning stiffness, fever, rashes, dysphagia, cough, shortness of breath, or symptoms suggestive of Raynaud phenomenon.

Results of the physical examination were unremarkable except for the left arm and hand. The skin from the shoulder to the wrist appeared tight and slightly thickened. Puckering or dimpling of the skin was noted on the medial aspect of the proximal forearm. There was no telangiectasia or palpable calcinosis. The left elbow lacked full extension by 10°. The left wrist was warm with mild swelling and tenderness. There was swelling of the tendon sheaths on the dorsum of the left hand. The metacarpophalangeal and proximal interphalangeal joints lacked full extension by 15°.

On laboratory evaluation, complete blood counts repeatedly showed 15% to 20% eosinophils. The total eosinophil count was 1,050/cu mm. A Wintrobe sedimentation rate was 10 mm/hr. Urinalysis, muscle enzyme test and biochemical screen determinations were normal. Fluorescent antinuclear antibody, latex fixation, and anti-DNA antibodies were negative on three occasions. Serum protein electrophoresis disclosed a mild hypergammaglobulinemia, which on quantitation proved to be of the IgG class. Roentgenograms of the hands, wrists, and chest, as well as esophageal manometric and pulmonary function test results were within normal limits.

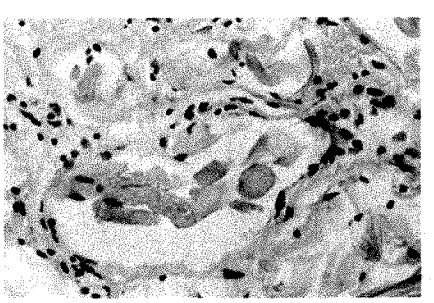

Fig 1.—Altered collagenous bundles of reticular dermis are more intensely eosinophilic, have crumpled appearance, and seem to lie in small lacuna with basophilic substance at periphery (hematoxylin-eosin stain, original magnification ×400).

An open biopsy of the skin and deep fascia of the proximal forearm was performed. On histologic examination the epidermis and papillary dermis were unremarkable. The mid-dermis showed spotty perivascular lymphocytic infiltrates. The deep reticular dermis disclosed discrete foci of fibrillation with both swelling and shrinking of collagenous bundles accompanied by increased basophilic ground substance and a mild lymphocytic infiltrate. Some of the altered collagenous bundles appeared to lie in lacunae or small cystic spaces (Fig 1). It was in the deep fascia, however, that the changes were most striking. This tissue showed centrally located foci of pale basophilic change that were so extensive that cystic changes were noted in one area (Fig 2). There were perivascular lymphocytic infiltrates and mild degenerative changes in the fat cells adjacent to the fascia. Evidence of new collagen formation, as shown by entrapment of lipocytes, was also present (Fig 3). In the areas of less involved deep fascia there were scattered, small blood vessels with plump endothelial cells and mild perivascular infiltrates. In other areas in which there was less myxomatous change, there were numerous plump spindle-shaped cells. No eosinophils and only rare plasma cells and mast cells (Giemsa stain) were seen. Alcian blue stain at pH 4.5 was strongly positive in the myxomatous areas but was negative at pH 0.5 in the same sites.

COMMENT

The presence of fascial inflammation and peripheral eosinophilia has led Rodnan and associates to suggest the term "eosinophilic fasciitis" be used to describe this syndrome.[2] As was the case in prior reports, our patient lacked telangiectasia, calcinosis, Raynaud phenomenon, and visceral manifestations associated with generalized scleroderma. Esophageal manometric findings, which are abnormal in almost 90% of patients with

generalized scleroderma,[3] have been uniformly normal in individuals with eosinophilic fasciitis. However, joint involvement with synovitis and early contractures of shoulders, elbows, and hands is a common feature of this syndrome. Not only are the clinical patterns of skin involvement unusual for both generalized and localized forms of scleroderma, but a relationship to strenuous exertion or trauma has been suggested in some patients. Our patient was a left-handed barber, and repeated microtrauma to her left arm could have possible etiologic implications. The natural course of the disease may lead to severe skin hardness and tightness in 6 to 12 months. In some instances dramatic improvement, including reversal of the cutaneous lesion, has been observed following systemic corticosteroid therapy.

The biopsy findings of eosinophilic fasciitis have been relatively consistent in all published cases. The predominant changes are deep with striking thickening of the deep fascia. Inflammation, often perivascular, is present in the deeper layers of the subcutaneous tissue and extends into the tendons and superficial muscle bundles. The inflammatory response is composed mostly of lymphocytes and plasma cells. Eosinophils are usually not present in significant numbers. Immunohistologic studies by Rodnan et al[2] in two cases have disclosed deposits of IgG and C_3 in the deep fascia and septa of underlying muscle.

The biopsy changes are difficult to correlate into a specific histologic diagnosis that relates to any well-recognized clinicopathologic entity. It appears that there is a primary change in collagen fibers with a multitude of secondary changes. The myxomatous change in the deep fascia is reminiscent of two other lesions: early ganglion formation in periarticular connective tissue[6-8] and cutaneous myxomas.[9] Both of these lesions have high correlation with minor trauma[9,10] such as might be suspected in our patient. Also, the earliest changes in cutaneous myxomas[9] show some similarities to the early changes in the deep reticular dermis of our patient. Excluded on clinical and histologic grounds are entities such as eosinophilic collagenosis, which shows foci of necrotic collagen surrounded by histiocytes, eosinophils, and extruded granules from the eosinophils.[11] Distinguishing eosinophilic fasciitis from linear scleroderma and morphea is difficult because these other disorders may also involve underlying structures such as deep fascia and skeletal muscle.[12-14] The early dermal changes in our patient and those described in early morphea[11,15] are similar, as was the case with early cutaneous myxomas. Eosinophilic fasciitis might be separated from localized scleroderma by the rather extreme degeneration of small collagen bundles associated with a microcystic myxomatous change. However, it is probably inappropriate to do so upon the examination of only a single clinical case.

Thus, eosinophilic fasciitis seems to possess some clinical, serologic, and histologic changes that may differentiate it from generalized and localized sclerodermas. It remains to be determined if this new disease is just part of the spectrum of scleroderma or in truth merits consideration as a distinct clinical entity.

Xanthoma Disseminatum

Clinical, Metabolic, Pathologic, and Radiologic Aspects

Maurice A. Mishkel, MD; W. Peter Cockshott, MD; Darius J. Nazir, PhD;
Donald Rosenthal, MD; William P. Spaulding, MD; Alun Wynn-Williams, MD

• A 55-year-old man with the classical mucocutaneous lesions of xanthoma disseminatum has been followed up for a period of 13 years. The special features of this case, which make it unique, are as follows: (1) the availability of histologic data on multiple lesions for more than a ten-year period; (2) the progressive nature of the multiple osseous lesions; (3) the metabolic studies that show no evidence for accumulation of abnormal sterols in a xanthoma, the blood, or intestinal aspirate; (4) the development of hypothyroidism and symptoms or signs, or both, of an intracerebral and an intraspinal lesion; (5) the partial regression of the cutaneous symptoms and lesions while receiving clofibrate, in spite of progression of the mucous membrane and osseous lesions; and (6) the failure to develop diabetes insipidus to date.

(*Arch Dermatol* 113:1094-1100, 1977)

Xanthoma disseminatum (XD) is a rare dermatologic disorder of unknown cause that may be accompanied by systemic manifestations. Although the clinical picture may be very distinctive, there is still controversy about how many reported cases are examples of this disorder and whether or not there is an overlap with Hand-Schüller-Christian disease. A textbook of dermatology[1] states that there are fewer than 30 reported cases of XD.

Our patient has had a clinical follow-up for a period of 13 years with biopsies performed on skin and bone lesions. Information is given concerning the sterol composition of a xanthoma. We have shown that the disease is not characterized by an accumulation of cholestanol, as seen in cerebrotendinous xanthomatosis,[2] another normolipidemic disorder. This case is classic in most of its features in that the patient is a man who has no family history of the disorder, which commenced in his middle life. The cutaneous lesions are typical in their widespread nature, with particular emphasis on flexural involvement. The color of the lesions varies from yellow to mahogany-brown to purple. Mucous membrane involvement of the mouth and nose is a prominent feature but the patient has not developed diabetes insipidus to date. An unusual feature has been the slowly progressive involvement of bone, reminiscent of a reticuloendotheliosis, but the histology is similar to a case reported by Halprin and Lorincz.[3] Although the patient has been normolipidemic throughout the course of the disease, clofibrate (Atromid-S) therapy led to a definite decrease in size of the cutaneous lesions throughout a period of three years. The progressive nature of the mucous membrane and osseous lesions by contrast has not been affected. Subsequently, the patient became hypothyroid and developed a spastic paraparesis, but no cause for the latter has yet been found.

REPORT OF A CASE

A 55-year-old Yugoslavian man came to the HGH-McMaster Lipid Research Clinic on Aug 18, 1969. Previously he had been seen by one of us (D.R.) in 1966 and a diagnosis of XD was made. The patient noted the appearance of orange-brown lesions on the face and neck in 1954. Initially, the lesions had waxed and waned, but particularly in the last few years, they had spread to other sites and increased in size and number. The lesions caused him concern because of the disfigurement, the tendency for the lesions to itch when he ate certain foods, and because of obstruction to passage of feces.

No family member had similar lesions. His father had died at 72 years from a heart attack, and his mother at 85 years of natural causes. Three sisters had died from infectious diseases and one brother was still alive in Yugoslavia. Except for the mucocutaneous lesions, the patient's only other complaints were of depression and early morning stiffness and aching in the shoulders and hips. In particular, he had no symptoms of vascular insufficiency (angina of effort or intermittent claudication), polyuria nor polydipsia, and no bone pain. His past history included recurrent urinary tract infections, cystoscopy, and subsequent prostatectomy. During a urologic investigation in 1962, some of the perineal lesions were removed, but these quickly recurred. The 13-year follow-up period dates from this time, for microscopic examination disclosed a polypoid xanthoma showing lipid-containing macrophages.

Prior to his first clinic visit he had been shown to be essentially normolipidemic. The laboratory values were as follows: plasma cholesterol, 190 mg/dl; triglyceride, 162 mg/dl (upper limit of normal, 250 and 150 mg/dl, respectively); and phospholipids, 180 mg/dl (normal range, 175 to 305 mg/dl). Results of an oral glucose tolerance test had been abnormal, with a fasting blood glucose level of 116 mg/dl, and blood glucose levels at one-half, one, and two hours of 158, 200, and 110 mg/dl, respectively. Another test performed a year later gave similar results. There was no glycosuria during either test. A routine roentgenogram of his pelvis (1969) showed cystic lesions in the region of the acetabulum but his serum alkaline phosphatase level was normal.

The physical examination showed a middle-aged man in a good state of nutrition. He weighed 61.2 kg (136 lb) and was 160 cm tall. His blood pressure was 110/70, and no abnormality was found in the cardiovascular system including the peripheral pulses. The liver and spleen were not palpable, there was no lymph node enlargement, and no bone tenderness. The only abnormalities found were restricted to mucocutaneous lesions. There was a minor bilateral corneal arc and a single red-brown pinguecula at the outer aspect of the right corneoscleral junction. Otherwise, the eyes were unaffected. There was a smooth, fleshy, yellow-red nodule approximately 1 cm in diameter at the lateral aspect of the right naris, and a smaller lesion on the left. Similar fleshy nodules were seen at the lateral aspects of the mouth, and these extended into the mouth, heaping up the mucous membranes (Fig 1). The nodules were pink or yellow and there were similar smaller lesions scattered over the face and forehead. The entire neck was surrounded by a collar of bosselated mahogany-brown elevated plaques, stretching from below the clavicles and the upper back to below the mandible and the hairline (Fig 2). Two butterfly-shaped areas, extending down the back into the axilla, the lateral chest wall, and up over the anterolateral aspects of the chest, were extensively involved with purple-brown macules. The axillary flexures were diffusely infiltrated with orange-yellow papules and plaques (Fig 3). The antecubital fossae were extensively involved with purple-brown papules and the umbilicus was encircled by a few similar lesions. Pigmented papular lesions were found in the groins, over the scrotum, and in the

popliteal fossa. The anal orifice was partially obstructed by large, sessile, yellow-brown masses (Fig 4).

The extensor surfaces, elbows, knees, and buttocks were spared. There were no tendon xanthomas on the dorsum of the hands and the Achilles tendons were not thickened. The palms of the hands showed no planar xanthomas or diffuse yellowing. The ocular fundi were normal.

Fasting plasma lipid tests showed a cholesterol level of 166 mg/dl and triglycerides, 74 mg/dl; lipoprotein electrophoresis was normal. Other normal biochemical findings included a BUN of 16 mg/dl; fasting blood glucose, 108 mg/dl; and serum uric acid, 6.0 mg/dl.

It was learned from the patient that his family physician had previously placed him on a regimen of clofibrate capsules, which had caused partial regression of his lesions and relieved the pruritic response to certain foods. Clofibrate had been stopped after one year, some six months prior to his clinic visit, because of the cost. The patient was given clofibrate again, 1 gm twice daily. This was continued for three years with one month's break to allow for metabolic studies.

RESULTS

Progress

The patient tolerated clofibrate very well. Within two months he put on 13.5 kg (30 lb) in weight, reached a maximum weight of 74.7 kg (166 lb), and then stabilized at 72 kg (160 lb). Within two months he stated that the pruritic response to pork, sugar, beer, and whisky had been greatly reduced. This symptom returned on temporary cessation of the drug. Within ten weeks of drug therapy, the patient noted a decrease in size of the lesions around the neck. This could not be verified with any certainty until at four months when the yellowing of the axilla was reduced, and more strikingly, the lesions around the neck were flattened considerably from a "cobblestone" appearance to a diffuse thickening of the skin. There was no change in the red-brown pigmentation. There was, however, actual progression of the mucosal lesions in the nose and at the angles of the mouth.

The fasting plasma lipid determinations and lipoprotein electrophoresis (on paper and agarose gel) were repeated more than ten times throughout the next three years, and results were always normal. The majority of cholesterol and triglyceride values were below 200 and 100 mg/dl, respectively.

Subsequent Investigations

The patient was admitted to the hospital July 1972 for removal of the lesions in the nose and mouth. Roentgenograms of the skull showed no abnormality, and in particular, the sella turcica was normal. Multiple cystic lesions in both acetabula, femoral necks, and the proximal phalanx of the right middle finger were essentially as seen in 1969. In addition, there were new cystic lesions in both ischial tuberosities and the left scaphoid bone. The results of serum calcium, phosphorus, alkaline phosphatase, BUN, electrolytes, and oral glucose tolerance test were normal. A complete blood cell count, including platelet count and sedimentation rate, was normal. An iliac crest aspiration showed a normal bone marrow, and in particular, there was no increase in plasma cells and no lipid-laden histiocytes seen. The determinations for serum total proteins, albumin, protein electrophoresis, and immunoelectrophoresis were normal.

The patient declined a bone biopsy of a cystic lesion, but in March 1973 he fell and dislocated his right shoulder. Roentgenograms showed cystic areas in the humerus, clavicle, coracoid process, and acromion. The shoulder was reduced while the patient was under general anesthesia, and an open biopsy of the acromion performed. The bursal tissue was yellow; this specimen and bone curettings from the acromion were examined histologically.

In August 1974 he was seen by another internist (W. B. S.). He was receiving no medication for the xanthomas but followed a low-fat diet and avoided alcohol (to prevent itchiness of the lesions). For the past several years pain in the shoulders, wrists, arms, and legs together with generalized weakness had forced him to stop working and he was limited to walking with a cane. For six weeks he had often complained of increasing difficulty with his balance, for he often felt dizzy. Physical examination was as before with the same cutaneous, buccal mucosal, and perineal lesions; however, in addition, the tongue was large, furrowed, and contained firm deposits. The legs were cold and no arterial pulses were palpable below the femoral arteries.

Laboratory investigations, including urinalysis, hemoglobin, white blood count, and blood film, sedimentation rate, serum electrolytes, BUN, creatinine, blood glucose, bilirubin, SGOT, SGPT, serum albumin, alkaline phosphatase, calcium, phosphorus, and uric acid were all normal. Fasting serum cholesterol level was 220 mg/dl and triglycerides, 67 mg/dl.

A skeletal roentgenographic survey showed widespread lesions. In summary, these were juxta-articular, marginal erosions combined with destructive lesions in trabecular bone, most severe at the hips and shoulders but seen to a lesser degree in the hands and elbows. A chest roentgenogram showed a nodule posteriorly overlying dorsal vertebrae 6 and 7 on the right side. The nodule appeared to be a soft tissue mass closely related to pleura. A bone scan was negative.

In November 1974 a diagnosis of hypothyroidism was made. The patient had noted increasing intolerance to cold for six months and for two years his voice had been lower-pitched and his skin felt drier. The thyroid gland was not enlarged and the serum thyroxine level was 2.0 μgm/dl (normal, 4 to 11 μgm/dl) and serum thyroid-stimulating hormone value, 140 μU/ml (normal, < 10 μU/ml). Cytoplasmic and colloid antibody test results were negative but the thyroglobulin tanned RBC antibodies were present in a titre of 1:40. Replacement treatment was given using levothyroxine sodium.

In December 1974 his wife described an episode of stiffening with tonic and clonic movements of the limbs, associated with unconsciousness, and lasting "all night." An EEG disclosed "mild and diffuse excess of slow activity . . . some minimal paroxysmal features during photo flash stimulation. No features to suggest the presence of a localized cortical lesion." Neurologic examination yielded signs of bilateral pyramidal tract disease with equal hyperactive

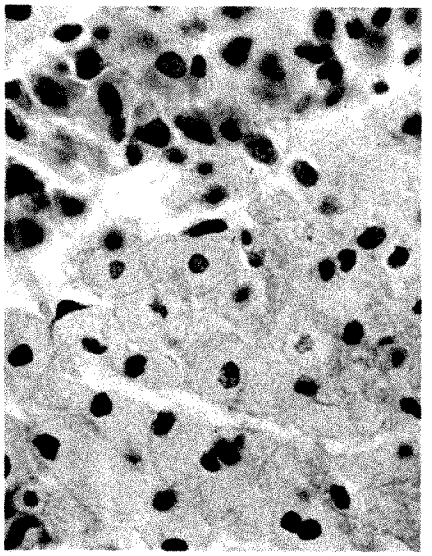

Fig 5.—Pale and denser histiocytes in skin biopsy section (hematoxylin-eosin, original magnification ×400).

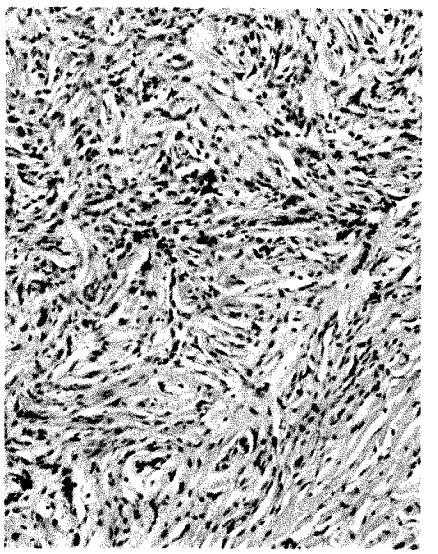

Fig 6.—Dermatofibromatous appearance (hematoxylin-eosin, original magnification ×150).

Fig 7.—Hemosiderin deposits in skin biopsy section. (Prussian blue stain, and hematoxylin-eosin, original magnification ×30).

tendon reflexes, bilateral Babinski responses, and generalized weakness of the limbs, more severe proximally.

A neurologic consultation confirmed bilateral pyramidal tract disease with increased deep reflexes, spasticity in the legs, and bilateral plantar extensor responses. In addition, there was a sensory level to pinprick and light touch at roughly T 11-12, and there was also diminished vibration and joint position sense in the lower limbs. An intramedullary lesion was suggested as the likely cause and a myelogram was performed but showed no significant abnormality. Examination of the CSF showed a protein level of 21 mg/dl, a glucose value of 60 mg/dl, and lymphocyte, 1/cu mm. A serum B_{12} level was normal, and a serum VDRL result was negative.

In order to explain the patient's paraparesis, in February 1975 a radioiodinated serum albumin brain scan and a computerized transaxial tomographic scan of the head were done; both were normal, there being no suggestion of a parasagittal lesion. He was treated symptomatically with diazepam, 2 mg three times a day, which significantly relieved the flexor spasms and spasticity. He was seen by Prof P. K. Thomas (London) who considered that an intraspinal xanthoma[4] had not been ruled out. The patient was last seen in December 1975 and there had been no significant change in his general or neurologic condition.

Biopsy Findings

Infiltrative xanthomatous lesions were prominent in all the biopsy material from skin, mucous membranes, bone, and bursal tissue. There were numerous histiocytes in the connective tissues (Fig 5). Many of these were pale, swollen cells containing doubly refractile lipid and a small central nucleus. Other histiocytes, however, had a denser, eosinophilic cytoplasm and varied in size and shape; their nuclei were larger and a few of these cells were large and multinucleate. Actual Touton cells were very rare. Mitotic activity was not a feature. Mingled with the histiocytes were fibrocytes and small blood vessels in variable numbers; some fields were richly collagenous (Fig 6). A minority of histiocytes contained iron and there were small extracellular deposits of iron (Fig 7). No recent hemorrhage was evident. There were no features of malignancy. The bony infiltrates resembled those seen in the skin and other tissues and did not present the characteristics of eosinophilic granuloma. The microscopic appearances are in best accordance with the very rare condition described as disseminated xanthosiderohistiocytosis by Halprin and Lorincz,[3] and alternatively described as XD. Lipid accumulations are associated with accumulations of histiocytes, which may also contain iron, and the condition is distinct from either hypercholesterolemic or hyperlipemic xanthomatoses.

Radiologic Aspects

The skeletal lesions were para-articular in distribution and intramedullary, affecting particularly the hips, shoulders, elbows, knees, and wrists. The bone foci were discrete, well-demarcated, usually rounded areas of bone destruction varying in size from 0.5 cm to as much as 2.5 cm (Fig 8). In the femoral necks, the oval foci were larger, being as much as 4 cm in length (Fig 9). In the hands, carpal deposits as well as an enchondroma in the proximal phalanx of the middle finger were present. A series of examinations were carried out in several institutions for a period of three years. These studies indicated a slight progression in size of deposits during this period of time. The skull and sella were normal.

This type of bone lesion is vaguely suggestive of deposits in bone such as are seen in amyloidosis and Gaucher's disease, but the severity is far greater than one expects. The lesions in the

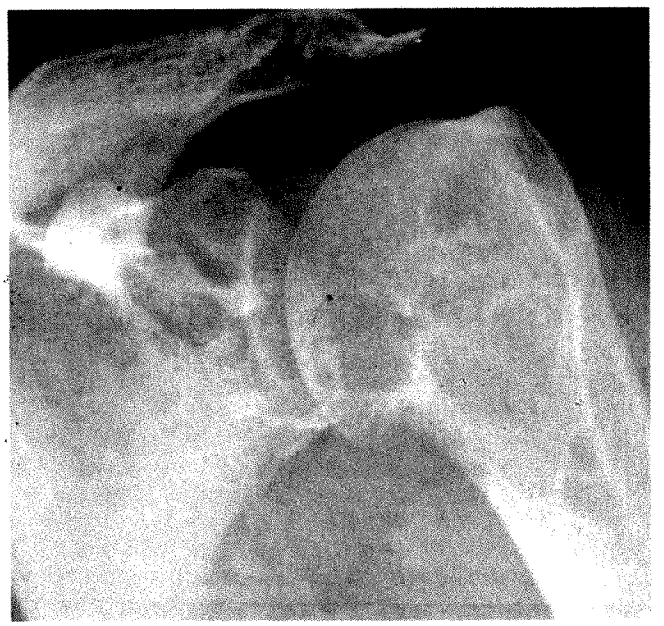

Fig 8.—Left shoulder showing cystic lesions, particularly in head of humerus.

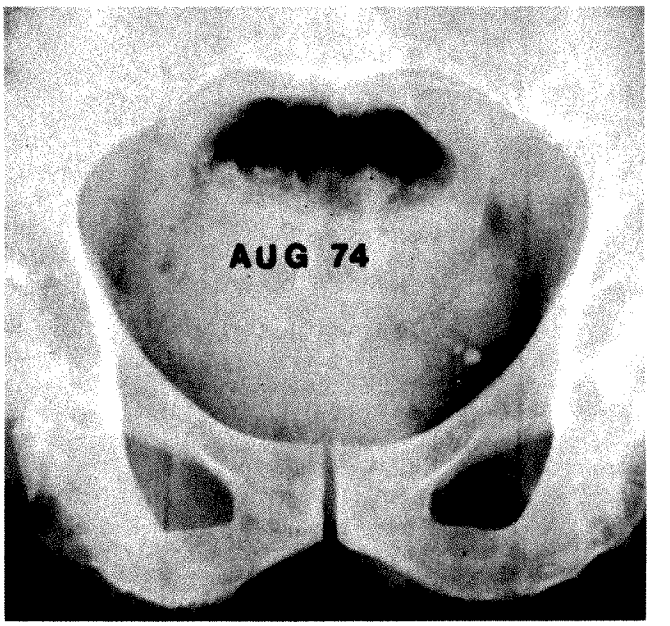

Fig 9.—Cystic lesions in pelvis and femoral necks.

shoulders and hips have features very similar to those recorded in reticulohistiocytosis (lipid arthropathy), but the lack of destructive lesions in the hand around the metacarpophalangeal joints and the interphalangeal joints excludes this possibility. If a single joint had been affected, villonodular synovitis would have to be considered.

These XD lesions are difficult to fit into a conventional diagnosis. In Hand-Schüller-Christian disease the lesions in tubular bones are usually in the shaft, and skull and rib lesions are common. The hands are rarely affected in contradistinction to this case. The well-defined edges, multiplicity of lesions, and chronicity are unlikely features of eosinophilic granuloma.

The parasynovial foci in bone is a different distribution pattern from that one normally sees in eosinophilic granuloma. There the lesions, in a person of the age of this patient, are related to the remaining sites of red marrow in bone. These naturally tend to be in the cancellous intramedullary bone at the proximal and distal ends of the long bones, flat bones, and in the spine. The histiocytic lesions of intramedullary origin extend toward the cortical margin from within. In this patient the lesions seem to be arising from the region of synovial attachment to bone in the para-articular areas; others are however intramedullary in the cancellous bone. Obviously by roentgenographic criteria alone, separation between XD and eosinophilic granuloma cannot be absolute. Lipoid granulomatosis, an entity described by Jaffe,[3] produces a sclerotic endosteal and medullary reaction to the cholesterol-laden cells.

Metabolic Studies

Hepatic cholesterol synthesis was studied while the patient received clofibrate and for a period without (performed in conjunction with H. Sodhi, MD, of Saskatoon). Approximately 100 μCi of acetate labeled with radioactive carbon 14 and 10 μCi of tritium-labeled mevalonate were injected intravenously and blood was taken at zero and two hours, and then every half hour for four hours total. The patient fasted for 12 hours prior to and throughout the test, and ten subjects with hyperlipoproteinemia (HLP) were simultaneously studied under the same conditions. Three had type IIA HLP, three type IIB HLP, three type III HLP, and one type IV HLP. All 11 patients were studied on two separate occasions, by the same technique. On the first occasion all had been receiving clofibrate, 2 gm/day, for a minimum of three months, while on the second occasion they had stopped the drug therapy for a minimum of two weeks. Measurement of incorporation of the two radioactive labels into plasma cholesterol showed that clofibrate inhibited cholesterol synthesis in the patient with XD to a degree (33%) comparable to that found in hyperlipidemic subjects (mean of 42% for ten patients, range 0% to 93%). The results indicate that clofibrate was effective in suppressing hepatic cholesterol synthesis in the patient with XD.

One of the yellow skin lesions was analyzed for its sterol content and this was compared with the composition of a tuberous xanthoma from a patient with hyperlipidemic xanthomatosis (type IIB hyperlipoproteinemia). The tuberous xanthoma had 50% more sterol content, but the major difference was that the sterol in XD was predominantly esterified (Table 1). Only a small percentage of the sterol in both biopsy specimens was in the form of cholestanol.

A recently well-delineated form of normolipidemic xanthomatosis is known as cerebrotendinous xanthomatosis (CTX). It is characterized by

the accumulation of a sterol, cholestanol, which is normally found in tissues in low concentrations. No increase in cholestanol was found in plasma, intestinal aspirate of bile, or a xanthoma from this patient (Table 2). Another metabolic abnormality found in CTX is a reduction in the primary bile acid, chenodeoxycholic acid in the biliary aspirate, but this abnormality was not found in the patient with XD (Table 3). Actually, the percentage of chenodeoxycholic acid was raised by more than 30% in this patient when compared to values for normal subjects, while the secondary bile acid, deoxycholic acid (formed from cholic acid), was considerably lower than in normal subjects.[2]

COMMENT

The term XD has been used loosely in the world literature so that confusion abounds. Most authors regard XD as a primary disorder of histiocytic proliferation with secondary accumulation of lipid, both intracellularly and extracellularly. The major point of disagreement is whether XD is a specific entity or if there is a consistent overlap with histiocytosis X, especially the Hand-Schüller-Christian (H-S-C) variant.

A composite picture is that of an adult man without a family history of the disease, who has multiple xanthomatous papules, nodules, and plaques, which are progressive in nature, distributed particularly in the flexor areas of the body, including axillae, antecubital fossae, periumbilical area, perineum, and genitalia. Mucosal lesions in the mouth and of the upper respiratory tract are characteristic and may lead to respiratory embarrassment.[1-6] Lesions in the perineum may interfere with defecation. Except for severe laryngeal involvement, the disease tends to run a chronic course and the lesions have been seen to regress spontaneously. Conjunctival or corneal involvement, or both, are not uncommon. If diabetes insipidus occurs, it usually is mild and may be transient so that continued therapy with vasopressin injection (Pitressin) becomes unnecessary.[7] Diabetes insipidus is thought to be due to the presence of meningeal xanthomas involving the hypothalamic-posterior pituitary axis. No reports of the use of clofibrate in this disease have been found, and a low-fat diet, radiotherapy, and steroid treatment do not have a convincing effect on the course of the disease.

In the typical case, no true differential diagnosis exists. Domonkos[7] believes that XD is not a manifestation of histiocytosis X and Beare,[8] and Allen[9] consider the histology of the two lesions to be different, but Allen considers them to be related.

Thannhauser and Magendantz[10] consider the first case of XD to be the one reported by Virchow[10] in 1871, entitled "Xanthelasma multiplex." Turner[6] in 1925 was the first to differentiate XD from other xanthomatous eruptions. The case described by Horsfall and Smith[1] was considered to be one of XD but it better fits H-S-C disease in a child. The cutaneous lesions were those of XD with involvement of bone, dura of the brain, pituitary, spinal cord, and the lungs. In view of the epileptic fit and the spastic paresis in our case, the xanthomatous lesion of the pons in the cases of Weidman and Schaffer[11] and Chiari[10] are relevant.

Altman and Winkelmann[12] described seven cases of XD and reviewed an additional 46 cases. They quoted Fleischmajer[13] in differentiating between XD and the H-S-C syndrome, as follows.

1. Xanthoma disseminatum usually occurs in adults, while the H-S-C syndrome primarily affects children.

2. Diabetes insipidus may be absent, mild, or transient in XD while it is one of the classic triad of the H-S-C syndrome.

3. Bone lesions are rarely associated with XD but our case bridges this very basic difference between the two syndromes. Involvement of the upper respiratory tract is frequently associated with XD.

4. Xanthoma disseminatum is

usually self-limited with a good prognosis, while the H-S-C syndrome usually is progressive and has a poor prognosis.

5. The histology of XD reveals a xanthomatous picture from the beginning, progressing in some areas to fibrosis. The histology of the H-S-C syndrome is that of a granuloma, although xanthomatous features frequently occur.

Altman and Winkelmann[12] noted that iron deposition was not a feature of their cases. When present, iron was found within histiocytes and giant cells. The case of Halprin and Lorincz[3] showed considerable accumulation of iron pigment granules within the histiocytes, and they proposed the new term xanthosiderohistiocytosis.

Little information is available about the sterol content of the xanthomas. Thannhauser and Magendantz[10] found that a lesion contained cholesterol, 4.6 mg/100 gm (dry weight) of which 80% was esterified. (This probably should have been expressed as 4.6 gm/100 gm). In three cases analyzed by Altman and Winkelmann,[12] the total cholesterol level was 4.6, 3.4, and 7.0 gm/100 gm (wet weight) as compared to 1.6 gm/100 gm (wet weight), with 87% esterified cholesterol in our case (Table 1). To our knowledge, this was the first attempt to find an accumulation of cholestanol.

Kalz et al[14] followed up a patient with XD for ten years and reported that orally taken steroid treatment did not stop the progression of the cutaneous lesions. Combined oral steroids and electrocoagulation prevented the lesions from relapsing once they were removed. Altman and Winkelmann[12] showed cases undergoing spontaneous remission, and they considered that there was no effective treatment for XD. The response to clofibrate in our case (by regression of cutaneous lesions once and cessation of pruritus on both occasions) might have been fortuitous. However, we have shown that clofibrate suppressed hepatic cholesterogenesis and local suppression of cholesterol synthesis may have been the mechanism involved. In spite of the improvement of the cutaneous lesions, those of the oral mucous membrane, in the perineum and the bone, increased in size.

All authors agree that XD should have normal plasma lipid levels, and Altman and Winkelmann[12] stressed that XD is not primarily a systemic disorder of lipid metabolism. The histologic appearance of the lesions suggests that the disease is basically a reactive histiocytic proliferation in which lipid accumulates as a secondary phenomenon. The proliferation of histiocytes, whether benign or more atypical, would suggest to us that XD is possibly a variant of the histiocytosis X group of disorders. Altman and Winkelmann[12] consider only one case, that of Gottron, as being acceptable as a case of typical H-S-C syndrome associated with typical XD.

Supported in part by grant 15-10 from the Ontario Heart Foundation, and by a grant from the Canadian Life Insurance Association, Toronto.

The clofibrate used in this study was supplied by Leighton Smith, MD, Ayerst Laboratories, Montreal.

Congenital Cutaneous Candidiasis

Nathan Rudolph, MB, BCh; Arshad A. Tariq, MB, BS; Mario R. Reale, MD; Philip K. Goldberg; Philip J. Kozinn, MD

• **Three newborn infants are described in whom a generalized maculopapular rash was observed at birth or soon after. The eruption rapidly became vesicular, and in one infant it became bullous, and was followed in each case by extensive desquamation. *Candida albicans* was demonstrated on direct smear and on culture from the skin vesicles, and evidence of an intrauterine infection with this organism was detected on histologic examination of the placenta in at least two of the cases. Agglutinating antibodies to *Candida* were present in the sera of all three infants, though these may have reflected transplacental passage of maternal antibody.**

***(Arch Dermatol* 113:1101-1103, 1977)**

Candidal infection of the newborn infant is manifest most often in the form of oral thrush and is acquired by the infant during passage through the mother's birth canal. However, a generalized candidal dermatitis that appears at or shortly after birth implies an intrauterine infection, and there have been only nine such authentic reports.[1-7] Three additional cases are now added.

REPORT OF CASES

CASE 1.—A 3,260-gm male infant was delivered by low-forceps extraction to a 19-year-old primipara after 42 weeks of gestation. The infant's Apgar score was 9 at one minute. The mother had had recurrent urinary tract infections and required hospitalization during the eighth month of pregnancy, when she was found to have pyuria with *Escherichia coli*, enterococci, and yeasts that were identified on urine culture; she was discharged without specific therapy. At birth, the infant was active and in no distress. His abnormal physical findings were limited to the skin. A diffuse pinkish-red maculopapular eruption was present over the face, neck, front of chest, and arms with a few scattered lesions over the lower limbs. Twenty-four hours after delivery, the rash had become vesicular and had spread to the hands and feet (Fig 1). In some areas, especially the palms and soles, bullae subsequently developed, and some of the vesicles and bullae became pustular. By 4 days of age, eruption on the trunk and chest subsided but persisted on the palms and soles, where the lesions lasted for almost two weeks (Fig 2 and 3). The rash was followed by extensive desquamation.

The results of the infant's complete blood cell count (CBC), including his platelet count, were normal, as were the results of blood culture, CSF examination, and serum electrolyte determinations. At 2 days of age, a direct smear from the vesicles showed mycelia and yeasts that were identified as *Candida albicans* by culture. *Candida albicans* was also cultured from the umbilical stump, urine, and stool. At 3 days of age, immunoglobulin levels were as follows: IgG, 1,100 mg/100 ml; IgM, 10 mg/100 ml; and IgA, 15 mg/100 ml. At 14 days of age, immunoglobulin levels were as follows: IgG, 860 mg/100 ml and IgM, 24 mg/100 ml. At 28 days of age, immunoglobulin levels were as follows: IgG, 540 mg/100 ml and IgM, 24 mg/100 ml. Histologic examination of a PAS preparation of the umbilical cord and placenta showed an inflammatory process, karyorrhexis, and *Candida* on the umbilical cord and fetal surface of the placenta. Neither mother nor infant had constitutional manifestations of systemic disease. Results of specific immunologic tests for *Candida* in case 1 are shown in the Table. The infant's therapy consisted of nystatin cream applied locally three times daily for ten days and 200 mg of nystatin oral suspension four times daily for ten days because of *Candida* in the stool. The infant thrived and was discharged at the weight of 4,550 gm at 4 weeks of age.

CASE 2.—A 4,110-gm, full-term male infant was delivered by Cesarean section to a 21-year-old woman, para 0010 because of cephalopelvic disproportion. The mother had had a candidal vaginitis at 28 weeks of gestation that was not treated. Her membranes had ruptured 12 hours prior to delivery. The infant's Apgar score was 7 and 10 at one and five minutes, respectively. Twelve hours after delivery, a diffuse maculopapular rash was noted on the infant's face, chest, and extremities.

Fig 1.—Papulovesicular stage of eruption of congenital cutaneous candidiasis (patient 1).

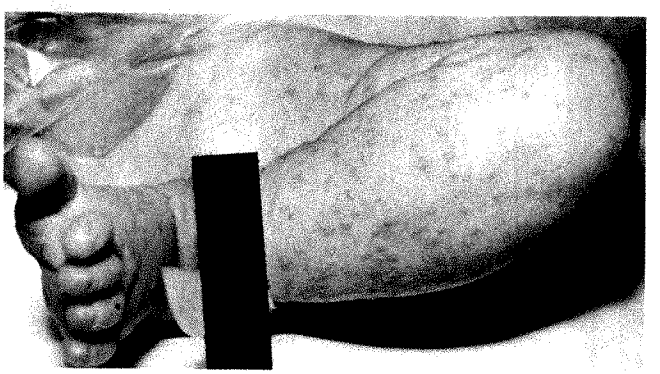

Fig 2.—Vesiculobullous candidal lesions on heel (patient 1).

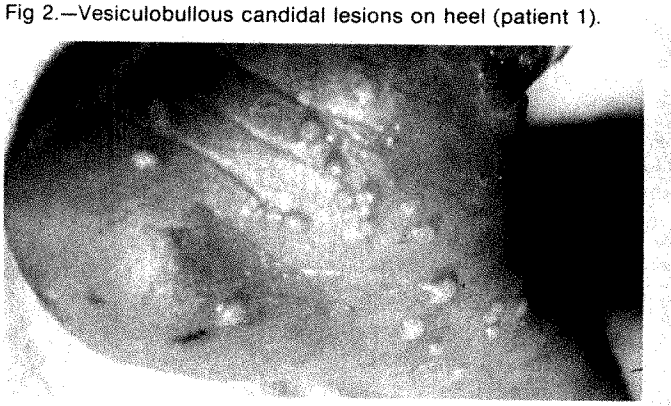

By 3 days of age, this rash had become vesiculopustular, and oral thrush was detected at 4 days of age. Desquamation commenced at 5 days of age and reached a peak by 9 days of age, after which gradual resolution occurred. The infant was afebrile throughout and manifested no constitutional signs of systemic disease. Positive smears and cultures for *Candida* were obtained from the skin lesions, mouth, and conjunctival sacs. Urine collected by bag yielded a growth of *Staphylococcus aureus* and *Candida*. The results of the infant's CBC, including his platelet count, were normal, as were the results of his serum electrolyte determinations; the result of the rapid plasma reagent test for syphilis was negative. At 6 days of age, immunoglobulin levels were as follows: IgG, 1,150 mg/100 ml; IgM, 30 mg/100 ml; and IgD, 1 mg/100 ml. The candidal dermatitis was treated with nystatin cream three times daily for ten days, and the oral thrush with 100,000 units of nystatin oral suspension every four hours after feeding for two weeks. He was discharged on the 18th day at the weight of 4,870 gm with normal physical findings.

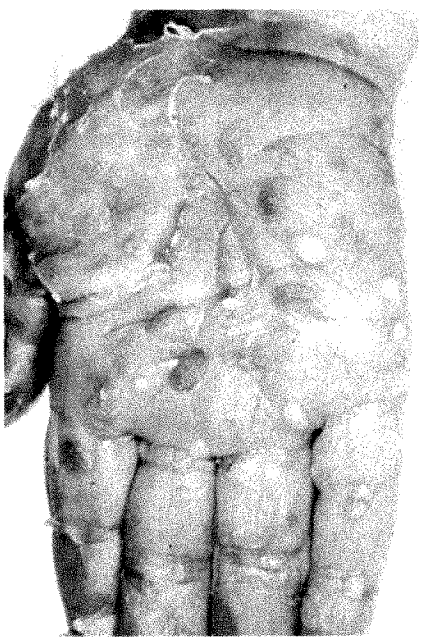

Fig 3.—Late clearing of bullous lesions on palm with commencing desquamation (patient 1).

The mother became febrile on the first postoperative day and fever persisted for six days. On the third postoperative day, small yellow vesicles appeared along her abdominal incision, and direct smear and cultures of material from these vesicles showed *C albicans*. She was treated with flucytosine (100/mg/kg/day) in four divided doses and with local applications of gentian violet. The fever subsided and the abdominal lesions cleared rapidly. She was discharged on the 13th postoperative day in good condition.

Histologic examination of the placenta showed the presence of an inflammatory process with karyorrhexis, and PAS staining showed *Candida* on the umbilical cord and fetal surface of the placenta. Results of specific immunologic tests for *Candida* in case 2 are shown in the Table.

Case 3.—A 2,270-gm female infant was born to a 22-year-old primipara by normal spontaneous delivery after 36 weeks of gestation. The mother's antepartum visits were irregular and no antepartum vaginal cultures were taken. Membranes ruptured two hours prior to delivery. The Apgar score was 9 at one minute. Three hours after delivery, a diffuse maculopapular rash was noted over the infant's face, chest, back, and extremities (Fig 4). This rash rapidly became vesicular. The lesions gradually dried and generalized desquamation occurred (Fig 5). On discharge at 2 weeks of age, the infant was thriving, and her skin was normal. At no time during her hospital stay was there fever or any other constitutional sign. A direct smear from the yellow vesicular fluid showed mycelia and yeasts that were confirmed as *C albicans* by culture. Urine obtained by suprapubic puncture yielded 5,000 colonies of *Candida* per milliliter. Results of the infant's CBC were normal. At 6 days of age, the infant's serum had an agglutinin titer for *Candida* of 1:320 and a negative precipitin test. Treatment consisted of local applications of nystatin cream. The mother's postpartum course was uneventful. Histologic examination of the umbilical cord and placenta showed inflammatory changes, but they were not stained specifically with PAS to demonstrate *Candida*.

COMMENT

A review of the known cases of congenital cutaneous candidiasis[1-7] indicates that this condition does not appear to be related to maternal age, parity, prematurity, type of delivery, duration of labor, or premature rupture of membranes. This fact is in contrast to the known correlation between the duration of rupture of membranes and neonatal bacterial infection.[8] In most of the previous cases, the rash was noted at birth or within 12 hours after delivery. However, in two cases with evidence of intrauterine infection of the fetal adnexae, the eruption appeared at 4 and 6 days of age, respectively.[6] The rash is diffuse and may involve the trunk, neck, face, and extremities. The lesions pass through macular, papular, vesicular, and pustular

phases, and even bulla formation has been noted. Desquamation had been a prominent feature of the recuperative period. It is of interest that in only one of the reported cases (case 2) was oral thrush noted. The oral lesions observed in a case by Cabaniss et al[9] at 4 weeks of age were presumably due to a postnatal infection.

The course of the cutaneous infection is characterized by an absence of constitutional signs and normal WBC and platelet counts. However, since *Candida* was cultured from urine obtained by suprapubic puncture in case 3, it appears that asymptomatic systemic dissemination of the organism might occur. Cultures from the mouth and skin in our three cases were positive only in association with clinically obvious lesions, while positive cultures from the conjunctiva in case 2 were not associated with recognizable clinical disease of the conjunctiva. This fact might be explained by local tissue immunity of the conjunctival mucosa.[10] Immunoglobulin levels, where determined, were not altered, in contrast to the hypergammaglobulinemia and hypogammaglobulinemia reported in systemic candidiasis.[11]

The mechanism whereby infection of the fetus and fetal adnexae occurs has been the subject of much discussion.[8,12,13,14] The appearance of candidal dermatitis at, or shortly after birth, clearly points to intrauterine infection. Flamm[15] demonstrated that *Candida* cannot pass the placental barrier and indicated that ascending infection via the birth canal, with or without colonization of the fetal adnexae, is the probable route of invasion. This infection may be facilitated by clinical or subclinical rupture of membranes prior to the onset of labor.[13]

Gotz and associates[16] demonstrated that *Candida* has the ability to invade and penetrate intact chick chorioallantoic membranes, which suggests the possibility that the organism may also infect the amniotic sac through intact membranes. Negative blood cultures in cases 1 and 2 and the absence of precipitating antibodies tend to indicate that there was no hematogenous spread of the candidal infection in the fetus.[17]

Since cutaneous candidiasis may occur from two to seven days after exposure to the organism, the intrauterine infection in each of our patients must have occurred within the week prior to labor. Intrapartum infection of the skin acquired during passage through the birth canal is possible,[14] but this would then have resulted in the appearance of the rash at a later age, as would infection transmitted by infected nursery personnel.

The clinical picture of the candidal dermatitis may initially resemble erythema toxicum or a bacterial folliculitis. At a later stage, other vesiculobullous eruptions such as herpes, syphilis, varicella, bullous impetigo, and histiocytosis may need to be differentiated. The diagnosis is suggested by the clinical features of the condition as manifested by a progressive but generally benign course, by the characteristic desquamation, and by the absence of constitutional signs; it is confirmed by direct smear and culture from the vesicles. Although all three infants had high serum agglutinin titers for *Candida*, the diagnostic importance of this finding is not clear since it could reflect transplacental passage of maternal antibodies, rather than antibodies produced by the fetus. In addition, testing for the presence of precipitating antibodies, which are generally associated with systemic disease,[17] appears to be of little diagnostic value in this cutaneous infection, in spite of the widespread dermal involvement.

Sporotrichoid Leishmaniasis

Stanley Spier, MD, FRCP(C); Maria Medenica, MD; Shirley McMillan, MA; Christopher Virtue, MD

• American leishmaniasis that is acquired in Panama may appear clinically as a sporotrichoid eruption. When lesions reminiscent of sporotrichosis are encountered, a careful history of the patient's travels should be made, as well as a search for the organism of leischmaniasis in tissue smears, histopathological sections, and cultured media. We report the case of an American soldier stationed in Panama who had developed an ulcer on the dorsum of his right wrist, and nodules on his right forearm that were arranged in a linear pattern. The initial clinical impression was that of sporotrichosis, but on careful study of the patient's history, and after other appropriate investigations were made, it was discovered that the patient had leishmaniasis.

(*Arch Dermatol* 113:1104-1105, 1977)

American leishmaniasis acquired in Panama may appear clinically as ulcers together with nodules that are arranged in a linear configuration that follow the course of the lymphatic channels[1-3] and thus mimic the classical features of sporotrichosis. We treated a patient who had sporotrichoid leishmaniasis, and we document the case and underline the necessity of considering leishmaniasis in the face of a sporotrichoid eruption.

REPORT OF A CASE

A 21-year-old man had enjoyed good health and had an unremarkable medical history. While stationed in Panama for 18 months with the US Army, he developed "raised red dots" on the back of his right wrist, on both forearms, and on his earlobes at the sites of recent sandfly bites. All the lesions except one healed after a few days. One lesion on the back of his right wrist steadily increased in size and eventually ulcerated. Approximately three weeks later, he developed nodules in a linear pattern on his right forearm.

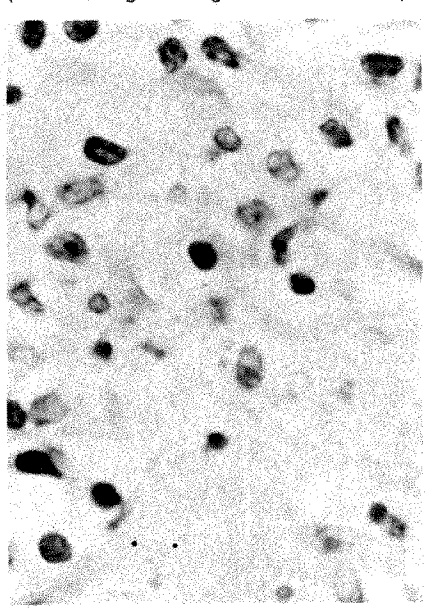
We saw the patient approximately seven weeks following the initial appearance of the lesions, and at that time he had a superficial ulcer (3×2 cm) on the dorsum of his right wrist. The ulcer had an indurated, rolled border with surrounding erythema, and a purulent base (Fig 1). On the right forearm there were nontender nodules in a linear arrangement (Fig 2). The epitrochlear and axillary lymph nodes were not palpable. The results of the remainder of the physical examination were normal.

The following laboratory tests were performed, and the results were found to be negative or within normal limits: complete blood cell count (CBC); urinalysis; chest film; serum protein electrophoresis; ECG; blood chemistry studies (including liver function tests and BUN) using an automated multiple analysis system (SMA-12); VDRL; culture of biopsy specimen from the edge of the ulcer for deep fungus, including sporotrichosis; fungal immunodiffusion for *Sporotrichum* antigen (four different antigens), *Aspergillus* antigen (five different antigens), *Histoplasma* antigen, *Blastomyces* antigen, and *Candida* antigen; fixation tests for histoplasmosis, blastomycosis, and coccidioidomycosis; smears and culture of biopsy specimens for

Fig 1.—Ulcer on dorsum of right wrist with indurated, rolled border and surrounding erythema.

Fig 2.—Right forearm showing nodules in linear arrangement.

Fig 3.—Leishman-Donovan bodies seen mainly within the cytoplasm of histiocytes (Giemsa, original magnification ×1,000).



typical and atypical mycobacteria.

Two punch biopsy specimens (4 mm) were taken from the edge of the ulcer. Sections were stained with hematoxylin-eosin (HE), PAS, Giemsa, and Ziehl-Neelsen. The purulent exudate at the base of the ulcer was cultured for bacteria, and sensitivity studies were made. With HE and Giemsa stains, Leishman-Donovan bodies were clear and abundant, mainly within the cytoplasm of the histiocytes (Fig 3).

Culture of the biopsy specimen for leishmania organisms on Novy-MacNeal-Nicolle medium was not successful.

Coagulase-negative staphylococci were found, as were Herbicola-Lathyri. The patient was treated with erythromycin stearate taken orally, by cool tap water compresses, and topical bacitracin ointment.

The patient was then admitted to the hospital and treated with sodium antimony gluconate (Pentostam), 600 mg (intramuscular) daily, for ten days. Prior to the antimony therapy two of the nodules on the dorsum of the right forearm enlarged, became fluctuant, and produced a serous exudate. Within four weeks of completion of the antimony injections, all the lesions were completely healed. The patient experienced no side effects other than temporary T wave inversion of his ECG.

The following laboratory tests were performed during antimony treatment, and the results were found to be negative or within normal limits: CBC, urinalysis, chest film, blood chemistry studies (including liver function tests and BUN), and serum protein electrophoresis. Compared with ECG tracings done prior to therapy, the ECG taken during antimony treatment showed inverted T waves in leads V_2 and V_3.

A CBC was done following treatment and was found to be within normal limits. An ECG performed following treatment showed reversal of T wave inversion in leads V_2 and V_3.

COMMENT

The first case of cutaneous leishmaniasis in the Republic of Panama was reported by Darling in 1910. Since then, many cases of the disease have been reported among military personnel stationed in the Canal Zone.

As in the other types of leishmaniasis, the disease acquired in Panama is transmitted via an insect vector (the *Phlebotomus*, or sandfly).[3] Most Panamanian cases are acquired in the dry-season months of January and February.[1,2] Our patient acquired his disease at the beginning of the dry season.

American mucocutaneous leishmaniasis differs clinically from oriental sore in that in the former, the mucous membranes of the nose and throat are frequently affected—sometimes even causing severe mutilation or death.[4]

Leishmaniasis acquired in Panama differs from that acquired in South America in at least two respects. In the former there is infrequent involvement of mucous membranes[3,5,6] and the presence of palpable nodules in a linear arrangement along the lymphatics that drain the ulcer.[1-3] The resultant clinical picture is reminiscent of that seen in sporotrichosis.

It is therefore important to take a complete history, particularly in regard to the patient's travels and to the possibility of exposure to the vectors of leishmaniasis. One should, when it is appropriate, aggressively look for the organism in tissue smears, histopathological sections, and cultured media. The search for *S schenkii* should be done concurrently.

The diagnosis in the case of our patient was made by finding the nuclei and parabasal bodies, which were located chiefly inside histiocytes. The organisms were visable equally well with HE and with Giemsa stains.

Our patient responded to antimony therapy within a few days, with quick healing of the ulcer and the disappearance of all nodules—in contrast to the slow rate of spontaneous healing that usually requires several months or years.

Epithelioid Sarcoma

A Distinctive Clinical Presentation

Norma Saxe, MB, Jan B. C. Botha, MB

• A case of epithelioid sarcoma occurred in an adult black man. The neoplasm recurred after 15 years in the form of multiple nodules and distinctive annular plaques. To our knowledge, this latter clinical manifestation has not been reported previously.

(*Arch Dermatol* 113:1106-1108, 1977)

Epithelioid sarcoma, a rare soft tissue neoplasm, was first described by Enzinger in 1970.[1] The histogenesis is uncertain, but ultrastructural studies suggest a synovial rather than a fibroblastic origin.[2-5] Although no age group is exempt, it usually occurs in young adults, predominantly males. Epithelioid sarcoma affects the soft tissues, manifesting as skin nodules and ulcers.[6-9] While it can occur at any site, it is most frequently found on the extremities.[1-5] The neoplasm grows slowly and may be present for months or years prior to treatment. The clinical course is characterized by frequent recurrences and late metastases, especially to the lungs and scalp.

We treated a patient with epithelioid sarcoma whose tumor recurred with multiple nodules and plaques consisting of an annular raised border with normal-appearing skin in the center. This distinctive clinical appearance has not been described previously, nor has any reference to epithelioid sarcoma appeared in the dermatologic literature, to the best of our knowledge, other than a brief reference.[10] and a case report.[11]

REPORT OF A CASE

Clinical History

A 38-year-old African (black) man was referred to Groote Schuur Hospital in 1960 from an outlying area, following incomplete excision of a tumor on the dorsum of the right wrist. A histologic diagnosis of anaplastic squamous carcinoma had been made. A soft pectoral lymph node was present, but no bony or other evidence of metastatic spread was found. An axillary block dissection at the time failed to reveal any evidence of tumor, and radiotherapy was administered to the wrist lesion. In 1975, the patient was seen elsewhere with a recurrence of the lesion at the original site. A biopsy specimen was interpreted as an amelanotic melanoma, and the patient was again referred to Groote Schuur Hospital. On examination, he had a fungating tumor measuring 6.0 × 4.0 cm on the dorsum of the right wrist, as well as multiple nodules, some ulcerated, and annular plaques on both the flexor and extensor surfaces of the forearm (Fig 1). The individual plaques resembled such benign annular lesions as annular sarcoid, although there was no doubt as to the malignant nature of all the lesions. Apart from squamous carcinoma and malignant melanoma, other conditions considered in the clinical differential diagnosis included Kaposi's sarcoma and atypical fibroxanthoma arising in a previously irradiated area. Another biopsy was performed, followed by amputation of the forearm.

Pathologic Findings

The biopsy specimen showed the presence of a well circumscribed nest of cells

Fig 1.—Annular plaques and nodules on flexor surface of forearm.

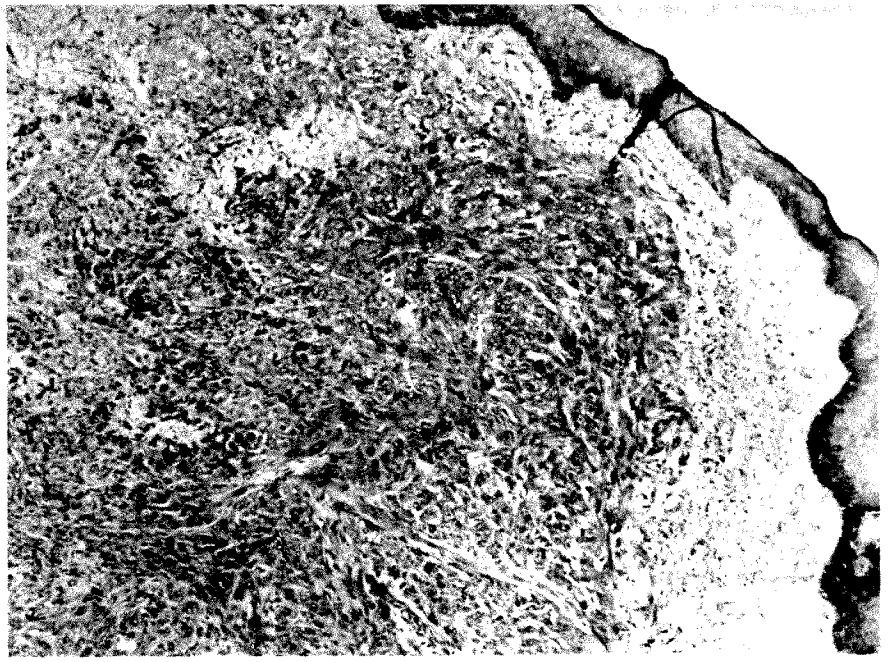

Fig 2.—Subepidermal location of tumor nodule (hematoxylin-eosin, original magnification ×40).

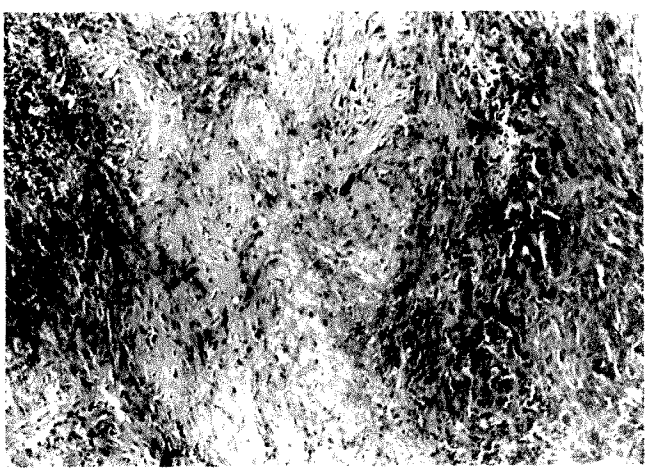

Fig 3.—Tumor nodule showing area of central degeneration (hematoxylin-eosin, original magnification ×40).

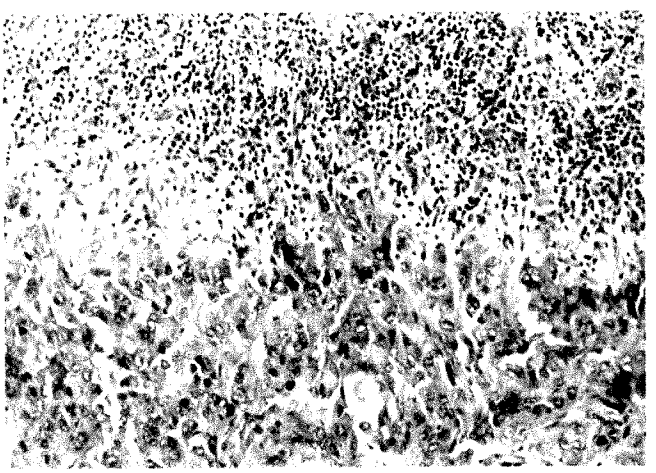

Fig 4.—Abundant lymphocytes along margin of tumor nodule (hematoxylin-eosin, original magnification ×100).

Fig 5.—Sheets of epithelioid cells with abundant cytoplasm and a single atypical mitotic figure (hematoxylin-eosin, original magnification ×800).

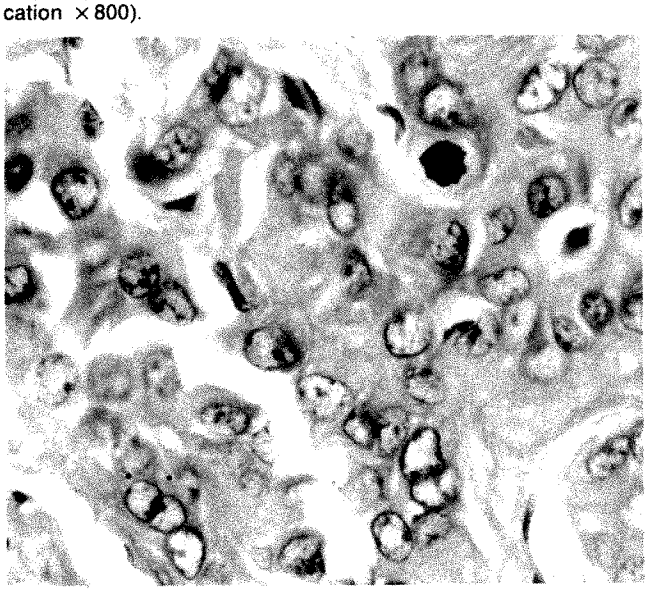

Fig 6.—Spindled neoplastic cells (hematoxylin-eosin, original magnification ×800).

Fig 7.—Annular plaques with central ulceration on left wrist of second patient.

situated in the dermis. The cells varied from spindle to epithelioid in appearance, had a moderately acidophilic cytoplasm, and contained numerous mitotic figures, some of which were atypical. The surrounding tissue showed a marked desmoplastic response, and, in areas, a prominent lymphocytic infiltrate. On the basis of the nodular configuration of the aggregates of malignant cells, and the appearances of the individual cells, a diagnosis of epithelioid sarcoma was made, despite the absence of areas of degeneration within the nests of cells.

Examination of tissue from the amputation specimen confirmed the diagnosis of epithelioid sarcoma. The characteristic microscopic features of this lesion—the nodular pattern, the acidophilia of the cytoplasm of the malignant cells, and the presence of central degeneration of many of the nodules—were all confirmed (Fig 2 and 3). The character of this latter degenerative process varied from frank necrosis to fibrosis and calcification. Many of the smaller tumor nodules appeared solid and showed little or no evidence of any degenerative change. Most of the tumor cells were arranged in discrete nodules, and a significant number of these showed the presence of a prominent lymphocytic infiltrate at the periphery. Where a marked desmoplastic response had been evoked, the margins of the neoplastic deposits were often ill-defined and the nodular pattern accordingly effaced.

Review of the slides originally identified as anaplastic squamous carcinoma and amelanotic malignant melanoma showed the microscopic appearances of epithelioid sarcoma (Fig 4 through 6).

COMMENT

Our patient's clinical course was that of tumor recurrence in the form of multiple nodules following a long asymptomatic period. Enzinger[1] found that recurrence usually occurred within six months after the initial surgery. Other authors state that the growth of this tumor is slow, although recurrences are frequent.[2] The presence of multiple nodules might suggest benign conditions such as sporotrichosis, clinically. Although no report has described annular plaques, such as occurred in our patient, Enzinger's only clinical illustration resembles this feature of our patient,[1] as does the description (not illustrated) of epithelioid sarcoma of the penis masquerading as Peyronie's disease.[12] This clinical appearance would therefore appear to be one of the characteristic lesions of epithelioid sarcoma.

Histologically, the occurrence of epithelioid cells in a nodular arrangement with central degeneration may mimic a benign granulomatous condition, particularly one of the palisading granulomas such as a granuloma annulare, necrobiosis lipoidica, or a rheumatoid nodule. Even when the malignant nature is recognized, it may be confused with other neoplasms such as malignant melanoma, synovial sarcoma, or poorly differentiated squamous carcinoma. The central degeneration is a typical feature, the diagnostic importance of which is emphasized in the literature, yet it may be absent in small nodules, as in the initial biopsy specimens of our patient. The diagnosis of epithelioid sarcoma may therefore have to be considered solely on the basis of the cellular morphological findings and configuration of the neoplastic mass.

The clinician's dilemma is not unlike that of the pathologist's in that the epithelioid sarcoma may both clinically and pathologically resemble a benign granulomatous condition. Enzinger, in fact, entitled this report "Epithelioid Sarcoma: A Sarcoma Simulating a Granuloma or a Carcinoma".[1] All 13 cases reported by Bryan et al[13] were misdiagnosed clinically.

A clinical awareness of the multifocal nodular or distinctive annular appearance of epithelioid sarcoma might enable the clinician to alert the pathologist to this possible diagnosis, thereby leading to adequate and prompt treatment.

Since this article was accepted for publication, we have seen a black woman, aged 43 years, referred from a distant area, with recurrent nodules and ulcers on the left wrist at the site of a tumor removed in October 1972. In view of the appearance of annular nodules with central ulceration (Fig 7), a clinical diagnosis of epithelioid sarcoma was made, which was confirmed histologically.

Choosing Dermatologic Instruction for Students in Family Practice

Richard M. Caplan, MD, Roger I. Ceilley, MD

• Sixty-three family practitioners responded to a special questionnaire designed to determine their judgment of what is most important to teach medical students and those residents headed toward careers in family practice. The ranking of emphases and specific diseases should be helpful to dermatologists responsible for the instruction.

(*Arch Dermatol* 113:1113-1115, 1977)

Deciding "what to teach" is a challenging problem for any conscientious teacher. For the dermatologist responsible for teaching cutaneous medicine to medical students and residents in nondermatologic disciplines, this problem may be compounded by the lack of personal experience with whatever is most important to the nondermatologist. Because of the current need for most academic institutions to foster careers and training efforts in primary care, dermatologic teachers should strive to prepare primary physicians for the cutaneous medicine they will ultimately practice.

Primary care is a concept with disputed definition, but *family practice* appears on all lists of "disciplines that provide primary care" and includes the largest number of practitioners. To help determine what objectives and content might be most suitable in the training of future family practitioners, a survey was conducted among family physicians attending a general refresher course for family physicians. This paper reports the findings and offers suggestions for planning the appropriate educational preparation for family physicians.

There is no generally accepted curriculum for all students of any given type, since circumstances and opinions are so varied among training centers. Even so, a general similarity exists within broad outlines, tempered by availability of time, space, personnel, case material, geography, and other local factors. Caplan and Solomon[1] have discussed educational objectives for dermatology and provided examples of many kinds that might be chosen. Yet it lies with the responsible teacher to identify his students' needs, which in turn are related to the learning sophistication, knowledge level, curricular obligations, and personal aspirations of the students. Further, any attempt at a universal educational prescription is muddled by what the instructor likes to teach, what the student likes and wants to learn, and what the public needs.

To approach the problem of what basic information should be taught medical students about ocular disorders, Spivey[2] conducted an extensive survey among practitioners and concluded that the collective opinion of nonophthalmologists was more appropriate in some particulars than the opinions of ophthalmologists. Academicians might offer justifications for modifying their approach and content away from the expressed desires of the learners, but the needs in actual practice or practice-to-be of their students should have high priority in guiding such decisions. Since no such information about student needs was known to us, we sought the opinion of one group that is a major educational target in most medical schools and teaching hospitals.

METHOD

A questionnaire was distributed to family physicians attending a refresher course for the family physician given at the University of Iowa in February 1975. The same instrument was distributed at a similar course given at the University of Oregon at about the same time.

The survey instrument asked the respondents to judge what they believed "most important to include in an educational program aimed at medical students

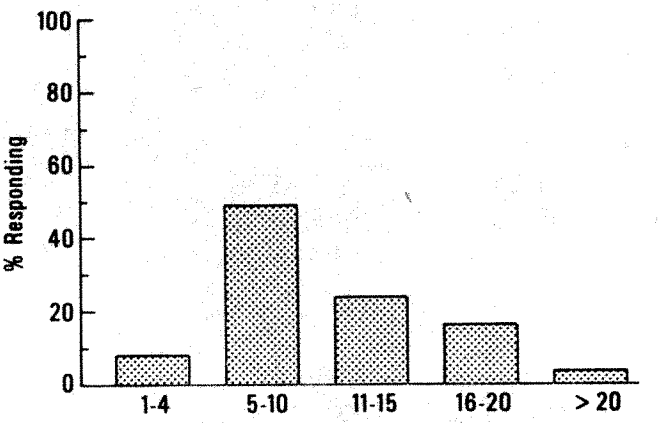

Fig 2.—Estimated percentage of family practice office visits that derive from cutaneous problems.

and residents headed toward careers in family practice." Not only were the respondents available to us, but they were practitioners whose presence at the refresher course was testimony to their concern for their own education and their patients' well being. Furthermore, those physicians had the experience to tell us what may be needed in day-to-day family practice.

The 63 respondents ranged from 5 to 45 years postgraduation from medical school. The great majority practiced in either Iowa or Oregon and most practiced in rural areas or small- to medium-sized cities.

The specific diseases mentioned in the questionnaire were derived largely from the list published by Caplan and Solomon.[1] That list had been derived from the collective wisdom of 99 dermatologists active in the Division of Education and Communication of the National Program for Dermatology. Our respondents were invited to list other conditions that they believed were important but that did not appear among the choices.

Additional questions sought an estimate of the relative importance of cutaneous problems in their practice, and their sense of priority about the general approach to instructional content.

The respondents were asked to assign a whole-number score of one to four to each item presented, with four representing the most important. The tally of scores for each item was determined in essentially the same manner that an academic grade-point is obtained: each value score was multiplied by the number of persons selecting it, all such products were summed, and the total was divided by the number responding. The final score (S) for each item is given by:

$$S = \frac{\Sigma N_1 + \Sigma 2N_2 + \Sigma 3N_3 + \Sigma 4N_4}{N}$$

where N is the total number responding on each item, and N_x is the number responding with each respective score of one to four.

RESULTS

The data from the 50 Iowa respondents and the 13 Oregon respondents were found to be so similar that the data were pooled. The numerical results from the combined respondents are shown beside the questionnaire items, arranged by decreasing score rather than the alphabetical sequence presented in the original questionnaire.

Each question invited additional suggestions from the respondent. A few verbal responses seemed to merit special consideration, and are listed beneath the numerical responses.

QUESTIONNAIRE RESPONSES

1. To what extent are skin problems an important part of family practice? (check one)
   a. Of extreme importance
   b. Of much importance
   c. Of some importance
   d. Of little importance
   e. Of no importance
   (See Fig 1)

2. Would you please estimate the percentage of office visits in your own practice that derive from cutaneous problems? (See Fig 2)

3. The following subject topics represent some *possibilities* for learning packages, which might consist of brief readings, audiotapes, and associated photographs or transparencies for projection. Please indicate your idea of the relative importance of including such a topic by ranking the items with a:
   1. Of too little importance–omit it
   2. Of some importance–include it if you have time and space
   3. Important–include
   4. Very important–a must

Score	Topic
3.71	Topically administered therapy
3.44	Discussion of virtues and hazards of over-the-counter products (soaps, shampoos, cosmetics, sunscreens, acne remedies, dermatitis remedies, etc)
3.34	Internally administered therapy
3.00	Principles of allergy and immunology as related to the skin
2.95	Percutaneous absorption
2.89	Basic dermatologic nomenclature
2.71	Eccrine glands and their activity
2.70	Sebaceous glands and their activity
2.53	The process of pigmentation
2.49	The process of keratinization
2.48	Brief presentation of cutaneous anatomy and physiology
2.00	Cutaneous microbiology

Additional suggestions deemed worthy of consideration by us include: Care of skin in summer and winter; external manifestations of sensitivity to foods, pollens, and drugs; and cutaneous surgical techniques.

4. Using the same rating system as in question 3, indicate your idea of how important it would be to include a discussion of the following diseases or disease groups.

Score	Disease or Disease Group
3.79	Contact dermatitis (allergic and irritant)
3.73	Premalignant lesions (actinic keratoses, leukoplakia, Paget disease, etc)
3.59	Eczema, atopic
3.57	Dermatophyte fungal infection
3.52	Basal cell carcinoma
3.51	Squamous cell carcinoma
3.49	Acne vulgaris
3.48	Stasis dermatitis and ulcer
3.41	Psoriasis
3.41	Verrucae
3.40	Urticaria
3.40	Erythema multiforme
3.40	Melanoma
3.38	Seborrheic dermatitis
3.38	Candidiasis
3.36	Nails, common disorders of
3.35	Pyoderma (includes impetigo, boils, cellulitis, erysipelas)
3.32	Herpes simplex
3.27	Herpes zoster
3.26	Erythema nodosum
3.25	Benign melanocytic nevi
3.24	Eczema, nummular
3.21	Viral exanthems
3.17	Tinea versicolor
3.15	Purpura
3.05	Seborrheic keratosis
3.03	Pityriasis rosea
3.00	Corns
2.98	Vitiligo
2.97	Photodermatitis
2.95	Acne rosacea
2.92	Hemangiomas
2.90	Alopecia (areata and male-pattern)
2.90	Syphilis
2.62	Mollusum contagiosum
2.60	Keloid
2.59	Ichthyosis
2.53	Drug eruptions
2.50	Milia

Additional suggestions deemed worthy of consideration by us include: miliaria; infestations; dry skin.

5. Using the same key, please indicate the importance, when discussing diseases in the list above, of initial factors:

Score	Factors
3.89	Diagnosis
3.87	Treatment
3.63	Differential diagnosis
3.46	Prognosis
3.32	Prevention
3.29	Cause
2.63	Pathogenesis

6. Other suggestions: (1) Provide clear statements of what should not be done; when to refer. (2) Use a problem-oriented approach. (3) Indicate how long it should take to resolve or improve specific diseases.

COMMENT

Medical educators should address the nation's health needs effectively and respond to public, professional, and governmental pressures for improvement in the quality and quantity of primary care service. Any dermatologist who teaches any level of medical student, primary care resident, primary care practitioner, or several types of practitioner-extenders, would be well-served to know the views of the intended learners. The instruction would become more welcome and valuable through the instructor's better knowledge of the practitioner's needs. Those needs, in turn, grow from the experience of actual clinical practice.

The questionnaire responses reported here were estimates and opinions, and were not data derived from audit of medical records or patients. Nonetheless, such estimates can provide useful guidelines for educational planning. The needs of trainees in other primary care disciplines (internal medicine, pediatrics, obstetrics and gynecology) cannot be safely inferred from this data derived from family physicians.

The traditional academician is likely to attempt to teach too much, because he is unwilling to label "relatively unimportant" certain topics of interest in his own research or practice. He is likely to give greater emphasis to basic science information or pathophysiology. Such emphasis is probably more appropriate at the level of medical students and dermatology residents. For nondermatologic residents and especially for practitioners, the emphasis on common problems and problem solving is what matters most. Diagnosis and treatment become paramount. A teacher may choose goals and content not of his student's liking, justifying to himself that "I know best what is important and what he should learn." Indeed, the right of a teacher to make such a judgement is a vital component of academic freedom. To be obliged to teach only prepackaged courses and explicit content mandated for all by some central educational authority, and thus exclude the variety and innovation of individual teachers who thoughtfully make carefully reasoned choices of content and method, would be disastrous to our educational system.

This study sought principally to help identify in what areas the teaching and learning of cutaneous medicine for family practice might be most effectively focused. How to teach most effectively and how to evaluate such effort are still other challenges for the conscientious teacher.

Frances Storrs, MD, administered the questionnaire at the University of Oregon.

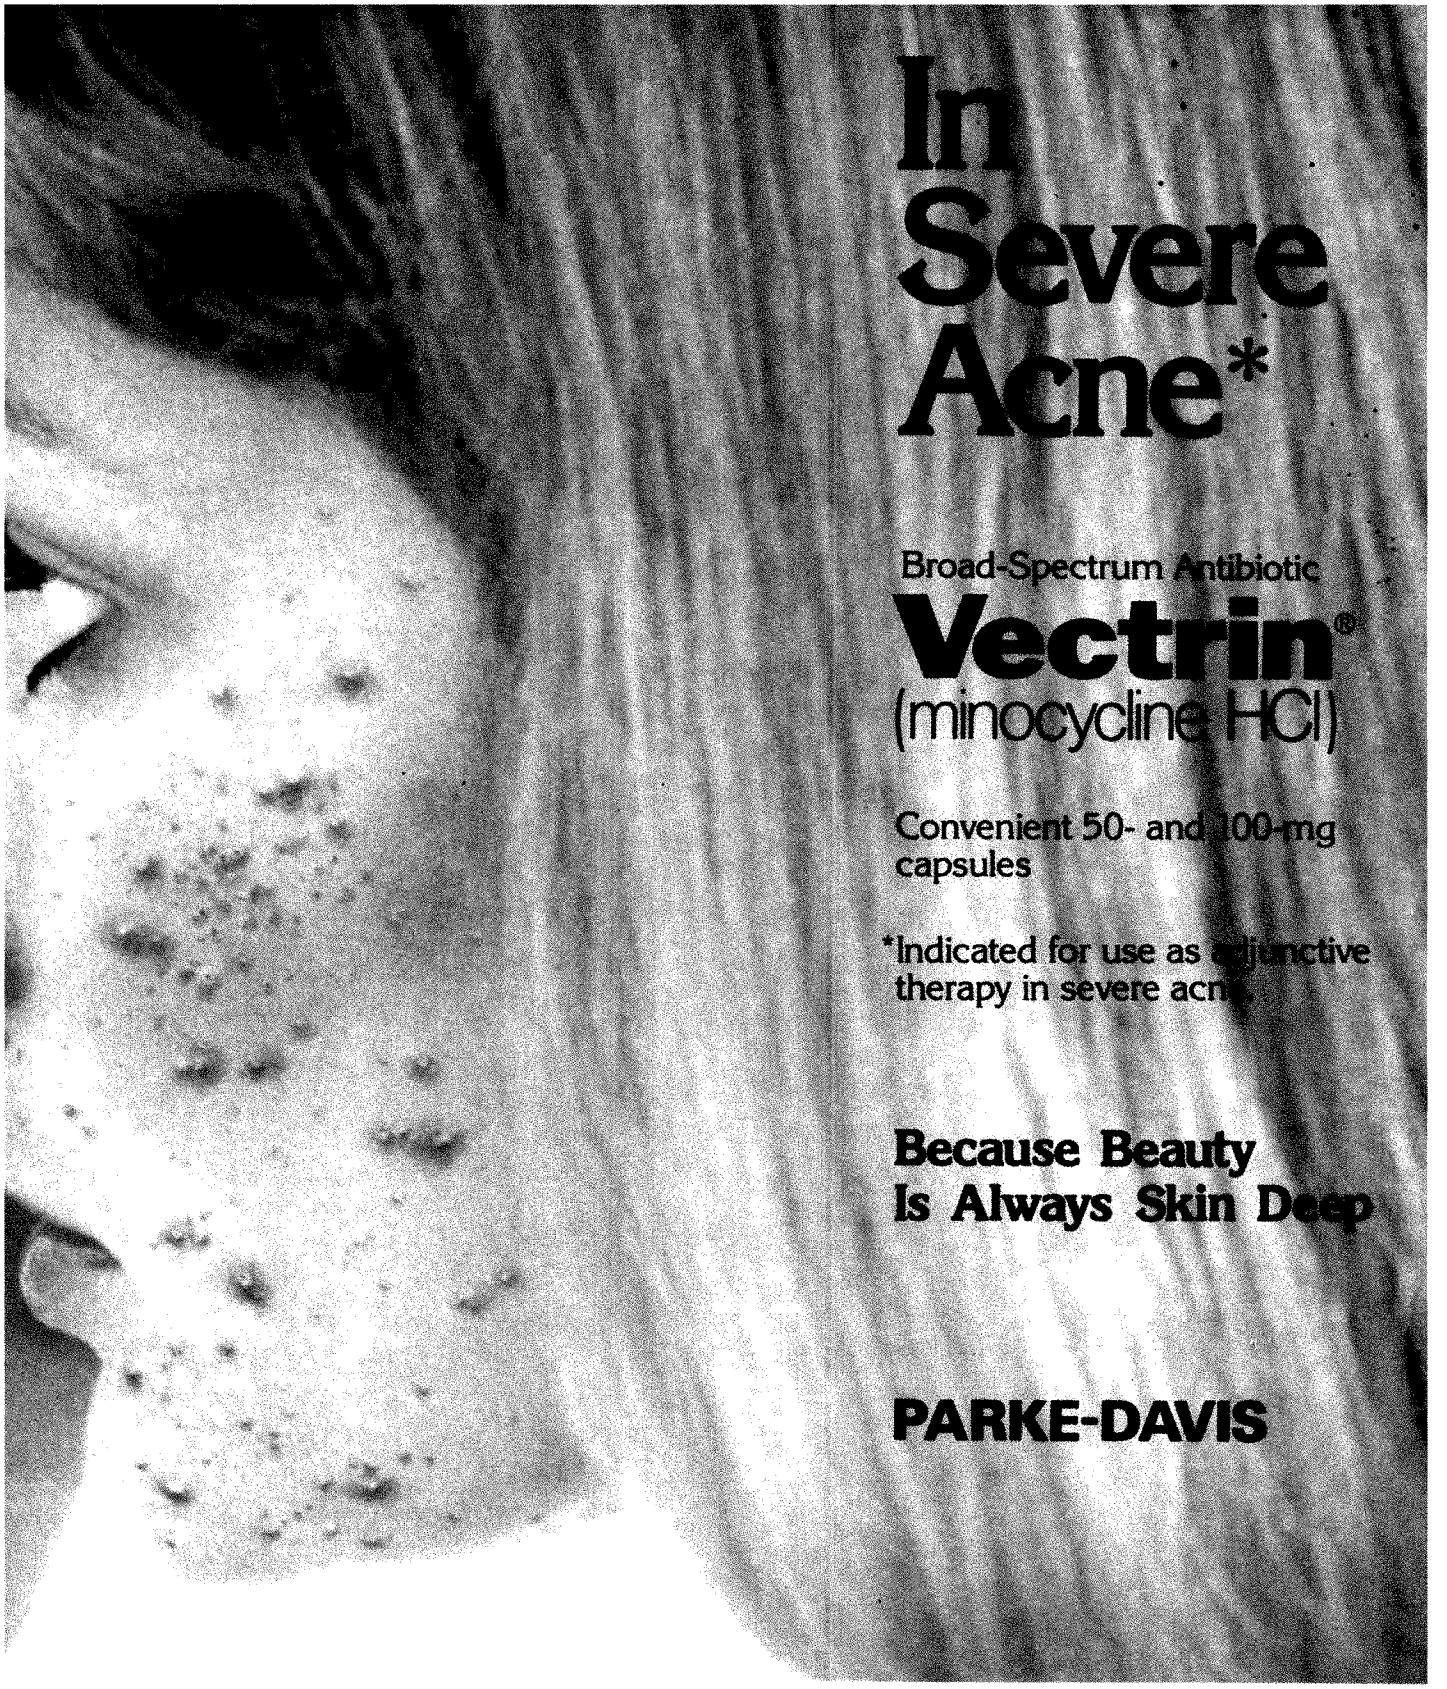
VECTRIN Capsules, 100 mg
(minocycline HCl capsules, USP)
Brief Summary of Prescribing Information

Indicated in severe acne as adjunctive therapy. Consult package insert for complete prescribing information.

Contraindication: Hypersensitivity to any tetracycline.

Warnings: When need for intensive treatment outweighs potential dangers, perform renal and liver function tests before and during therapy; also follow serum concentrations. In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, use lower total doses, and in prolonged therapy, determine serum levels. The use of tetracyclines during tooth development (last half of pregnancy, infancy and childhood to the age of 8 years) may cause permanent discoloration of the teeth (yellow-gray-brown). This is more common during long-term use but has been observed following repeated short-term courses. Enamel hypoplasia has also been reported. Tetracyclines, therefore, should not be used in this age group unless other drugs are not likely to be effective or are contraindicated. Photosensitivity manifested by an exaggerated sunburn reaction has been observed in some individuals taking tetracyclines. Advise patients apt to be exposed to direct sunlight or ultraviolet light that such reaction can occur, and discontinue treatment at first evidence of skin erythema. Studies with minocycline HCl indicated that photosensitivity did not occur. However, reports have been received. In patients with significantly impaired renal function, the antianabolic action of tetracycline may cause an increase in BUN leading to azotemia, hyperphosphatemia, and acidosis. **CNS side effects:** (light-headedness, dizziness, vertigo) have been reported, may disappear during therapy, and always disappear rapidly when drug is discontinued. Caution patients who experience these symptoms about driving vehicles or using hazardous machinery while taking this drug. **Pregnancy:** In animal studies, tetracyclines cross the placenta, are found in fetal tissues, and can have toxic effects on the developing fetus (often related to retardation of skeletal development). Embryotoxicity has been noted in animals treated early in pregnancy. The safety of minocycline HCl for use during pregnancy has not been established. **Newborns, infants, and children:** All tetracyclines form a stable calcium complex in any bone-forming tissue. Prematures, given oral doses of 25 mg/kg every six hours, demonstrated a decrease in fibula growth rate; reversible when drug was discontinued. Tetracyclines



In Severe Acne*

Broad-Spectrum Antibiotic

Vectrin®

(minocycline HCl)

Convenient 50- and 100-mg capsules

*Indicated for use as adjunctive therapy in severe acne.

Because Beauty Is Always Skin Deep

PARKE-DAVIS

are present in the milk of lactating women who are taking a drug in this class.

Precautions: Use may result in overgrowth of non-susceptible organisms, including fungi. If superinfection occurs, antibiotics should be discontinued and appropriate therapy instituted. In venereal diseases when coexistent syphilis is suspected, darkfield examination should be done before treatment is started and blood serology repeated monthly for at least four months. Patients on anticoagulant therapy may require downward adjustment of such dosage. Test for organ system dysfunction (eg, renal, hepatic, and hemopoietic) in long-term use. Treat all group A beta-hemolytic streptococcal infections for at least 10 days. Avoid giving tetracycline in conjunction with penicillin.

Adverse Reactions: GI: Anorexia, nausea, vomiting, diarrhea, glossitis, dysphagia, enterocolitis, inflammatory lesions (with mucosal overgrowth) in anogenital region. **Skin:** Maculopapular and erythematous rashes. Exfoliative dermatitis (uncommon). Photosensitivity is discussed above. (See Warnings.) **Renal toxicity:** Rise in BUN, dose-related. (See Warnings.) **Hypersensitivity reactions:** Urticaria, angioneurotic edema, anaphylaxis, anaphylactoid purpura, pericarditis, exacerbation of systemic lupus erythematosus. In young infants, bulging fontanels have been reported following full therapeutic dosage, disappearing rapidly when drug was discontinued. **Blood:** Hemolytic anemia, thrombocytopenia, neutropenia, eosinophilia. **CNS:** (See Warnings.) When given over prolonged periods, tetracyclines may produce brown-black microscopic deposits in scleral tissue, thyroid glands; no abnormalities of thyroid function studies are known to occur.

NOTE: Concomitant therapy: Antacids containing aluminum, calcium, or magnesium impair absorption; do not give to patients taking oral tetracycline. Studies to date indicate that absorption of VECTRIN (minocycline hydrochloride) is not notably influenced by foods and dairy products.

Full prescribing information available upon request.

PARKE, DAVIS & COMPANY
Detroit, Michigan 48232

Obviously, efficacy is foremost in your mind when you recommend a therapeutic shampoo. And efficacy, coupled with cosmetic acceptability, usually guarantees a successful therapeutic course.

That's why Head & Shoulders is so highly regarded in the treatment of dandruff.

Clinically effective

For years, Head & Shoulders has proved effective in the treatment of dandruff—whether for initial therapy or long-term control. And now, research shows that Head & Shoulders is effective in the treatment of seborrheic dermatitis.*

Cosmetically pleasing

Head & Shoulders lathers well, has a pleasant odor and appearance, and need not be left on the scalp for an extended period of time. Also, it leaves hair clean, manageable, and attractive.

Head & Shoulders®

You'll like it for its therapeutic benefits. Your patients will like it for its cosmetic appeal.

William B. Reed, MD
1924-1976

Bill Reed died unexpectedly on June 15, 1976, shortly before his 52nd birthday. He was a kind, generous physical and intellectual giant who spent much of his enormous energy and talent to further our specialty. He traveled widely, met unusual people, and made lasting friends. He had an uncanny knack for discerning the real from the fake, the innovative from the imitation, the fresh, forward thinker from the devious obstructionist. He delighted in discovering new young talent and helping those with interesting findings to bring it all together. He was harsh, opinionated, and vocal and a busybody. But more importantly he tied together the world of many thinking dermatologists and scientists through his personal communications system. He telephoned everywhere and at all hours. Once you learned his mumbled, half-sentence jargon, huge amounts of new information and ideas, as well as some opinions, were transmitted with each call or personal visit. He was constantly busy with a new research project or a new syndrome, or he was writing a paper or chapter on cutaneous genetic disorders. His broad experience, enormous intellect, and elephantine memory made his discussions of genetic problems at scientific meetings an awe-inspiring, educational experience. He prepared several "Bill Reed Horror Movies" that still prove to be diamond-in-the-rough teaching aids.

Bill was proud to be a dermatologist, proud to be a Norwegian of Pennsylvania Dutch extraction, and proud to have been trained at Columbia, Johns Hopkins and the Mayo Clinic. He also was proud of his friends, but he expected each of them to return his pride with excellence. When they did not match up he told them so in no uncertain terms. His father figure in dermatology was Louis Brunsting, and he was a disciple of the Paul O'Leary Mayo Clinic System. He spent much of his time at St Joseph's Hospital in Burbank, Calif, and enhanced the delivery of medical care there. At various times he was on the teaching staffs of most of the dermatology departments in southern California, most recently as a clinical professor of dermatology at the University of California at Irvine. He was an honorary or corresponding member of nine foreign societies. He published about 150 scientific papers in his short life, some of the best known of which concerned psoriasis and arthritis, ataxia, telangiectasia, melanomas and congenital nevi, xeroderma pigmentosum, and, of course, the Reed syndrome.

His private practice office, a small, converted house in downtown Burbank was a sight to behold it was always crowded, with people often waiting outside. Here he provided superb dermatological care. He was a father confessor to kids with acne; he knew he was considered an offbeat freak by many, and his compassion and understanding for the less fortunate was beautiful. They loved him as one who really could understand their problems, and they filled his office. He made house calls and transported patients to get proper appliances and to see experts. He even paid the expenses of some patients to consult experts in a different locality. His own medical fees were always minimal. He was the local dermatologist's expert in many areas.

He loved good music, especially operas. He often brought hard-to-get records to his foreign friends. He loved his niece and nephew, and he mostly loved humanity. None of his friends ever felt sorry for Bill, they truly admired and loved him for the so many wonderful things he stood for; Bill was himself, with no apologies. We will miss you Bill Reed, and only hope you are still the same, wherever you are.

HLA in Bullous Pemphigoid

A. Razzaque Ahmed, MD; Elias Cohen, PhD; Leslie E. Blumenson, PhD; Thomas T. Provost, MD

A possible genetic link has been suggested in several dermatologic diseases. An increased incidence of HLA-A10 and HLA-B13 has been reported in pemphigus vulgaris, HLA-B17 and HLA-B13 in psoriasis, and HLA-B5 in Behçet syndrome.[1] HLA-B8 has been reported in 70% to 88% of dermatitis herpetiformis cases and in 90% of adult celiac disease cases,[2] which is suggestive of a close association between these two diseases.

The purpose of this study was to determine the HLA phenotype frequencies in a group of white patients with bullous pemphigoid (BP).

Subjects and Methods

Nineteen white patients with BP were studied. All had typical clinical disease and subepidermal bullae and all demonstrated the presence of immunoglobulins and/or C3 along the basement membrane zone (BMZ) of peribullous skin, as previously described.[3]

HLA typing was performed by Amos microcytotoxicity tests[4] with the use of 70 anti-HLA antisera. Similar tests were performed on 60 controls matched for age, sex, race, and geographic area. Statistical analysis of the data was performed using χ^2 test and, when necessary, the Fisher exact test.[5]

From the Department of Dermatology, State University of New York at Buffalo, School of Medicine, Buffalo, NY (Drs Ahmed and Provost), and the Blood Bank Laboratory (Dr Cohen) and the Biostatistics Department (Dr Blumenson), Roswell Park Memorial Institute, Buffalo, NY. Dr Ahmed is now with the University of California at Los Angeles School of Medicine.

Reprint requests to Department of Dermatology, State University of New York at Buffalo, School of Medicine, 50 High St, Buffalo, NY 14203 (Dr Provost).

Results

No statistically significant increased incidence of HLA antigen was noted in patients with BP compared to the control group. The incidence of HLA-A3 was decreased among the patients, although the difference (5% vs 32%) was not statistically significant (Table). There was no correlation between HLA phenotypes and serum skin BMZ antibody titer. Three patients with IgD and IgE deposition on the BMZ had HLA-B12.

HLA Typing in Bullous Pemphigoid (BP)*

	No. (%) in 60 Controls	No. (%) in 19 BP Patients
HLA-A1	20	3
HLA-A2	50	5
HLA-A28	10	1
HLA-A3	32	5
HLA-A9	23	1
HLA-A23	2	0
HLA-A24	0	0
HLA-A10	12	2
HLA-Aw25	0	0
HLA-A26	0	0
HLA-A11	8	5
HLA-Aw33	5	5
HLA-A29	7	1
HLA-B5	15	1
HLA-Bw35	3	0
HLA-B7	25	1
HLA-Bw22	3	1
HLA-B27	10	2
HLA-B8	15	1
HLA-B12	35	3
HLA-B13	2	0
HLA-Bw40	22	2
HLA-B14	3	0
HLA-Bw15	7	2
HLA-Bw16	2	0
HLA-Bw17	17	5
HLA-B18	5	2
HLA-Bw21	0	0

*Since 28 antigens were surveyed, the probability level of the χ^2 test must be corrected to obtain the correct probability of obtaining a difference as large or larger (under the null hypothesis) as actually observed. This correction is obtained by multiplying the probability level by 28.

Comment

Histocompatible antigens present on the cell membrane of all nucleated cells are controlled by a single chromosomal region. In mice this region is termed the H2 locus and in man the HLA system. The HLA region is located on chromosome 6 and is composed of two loci termed A and B.[6]

In our study there was no statistically significant increase in the incidence of a specific HLA phenotype among 19 white patients with BP.

This study was supported in part by grant R01 AM 16593-03 from the National Institutes of Health, by grant CA-11987021 from the National Cancer Institute, and by the Juliet and Israel Cohen Memorial Research Fund.

Cutaneous Myiasis Due to *Dermatobia hominis*

Lt Col E. Dale Everett, MC, USA; Lt Col Richard L. DeVillez, MC USA; Lt Col Charles W. Lewis, MC, USA

With the ease and frequency of worldwide travel, unfamiliar diseases are often encountered by the American physician. We would like to share two such cases that are infrequently reported in the United States.[1-3]

Report of Cases

Two middle-aged women traveled to Costa Rica in June 1976 on a three-week bird-watching expedition. During this time, they remained in good health, except for sustaining some insect bites. In early July, a few days after their return to the United States, one woman noted intense pruritus associated with small papules on the upper part of her back, and the other noted it on the proximal portion of her upper extremities. The papules gradually enlarged and formed nodules with small apertures. Both women were seen after two weeks of symptoms. One of the patients had extracted a "worm" from one of the lesions on her arm, which she brought with her (Fig 1). The other had applied a heavy cream to the lesion on her back. This latter patient had noticed considerable reduction in pruritus for about three days before being examined. One had seen a physician a few days earlier and had been given an antimicrobial agent for "infection."

Results of examination of the lesions disclosed erythematous, indurated, raised lesions that appeared to be healing. However, in one of the women a brightly erythematous nodule with an aperture was present. A small amount of seropurulent material was present, and a white structure could be seen to protrude and then disappear from the opening (Fig 2).

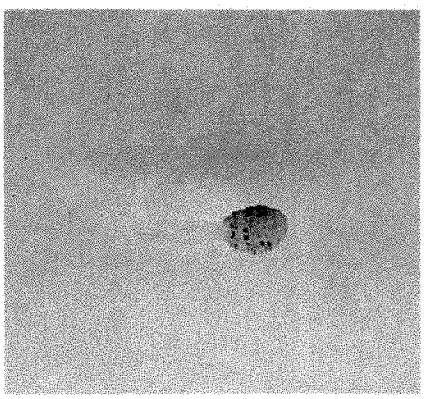

Fig 1.—Extracted larva of *Dermatobia hominis*. Concentric black rings around head are small barbs.

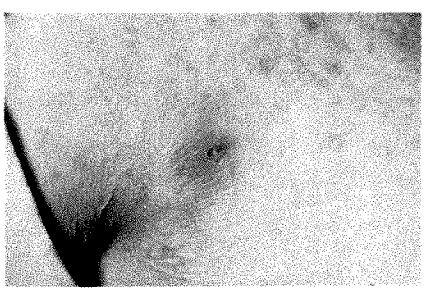

Fig 2.—Larval structure (white dot) protruding from lesion.

A biopsy specimen from the lesion on the back showed a superficial and deep polymorphous cellular infiltrate of histocytes, lymphocytes, and eosinophils, consistent with a benign reactive process due to parasitosis of the skin. The lesion with the active larva was incised, and the organism was removed.

Comment

Dermatobia hominis (human botfly, warble fly) is widely distributed throughout Central and South America. Man becomes an accidental host after being bitten by a mosquito that is carrying the eggs of the botfly on her abdomen.

Symptoms include pruritus, a gradually enlarging lesion, and pain. A seropurulent drainage from the punctum is common. If left alone, the larva gradually matures over a period of 50 to 100 days; it then exits from the host and drops to the ground where further maturation takes place. During the period of maturation in the host, the aperture in the skin remains open, allowing the organism to breathe.

Treatment has usually been incision and extraction of the larvae. Some may be squeezed out, but the barbed head makes this difficult. Occlusion of the punctum in the skin with pork fat has also been used, causing the larvae to migrate out of the skin to breathe.[1] The application of heavy cream to the lesion by one of our patients may have resulted in this phenomenon, since no organism was found.

Recognition of this unusual, but easily treated, disease is important. It allays the anxiety of the patient and, in one of our cases, would have saved the exposure to and expense of an antimicrobial agent.

Skin Eruption Caused by Ethambutol

Jagjit S. Pasricha, MD, PhD, Amrinder J. Kanwar, MD

Of all the drugs commonly used for the treatment of tuberculosis, streptomycin sulfate, isoniazid (isonicotinic acid hydrazide), aminosalicylic acid, and thiosemicarbazone are well known to produce skin eruptions,[1] but those due to ethambutol hydrochloride have been referred to only twice in the literature, to our knowledge. Jesiotr[2] reported one case of purpura due to ethambutol, while Kauppinen[3] listed another case without specifying the nature of the cutaneous eruption. In neither case, was the eruption confirmed to be caused by ethambutol. Enquiries from some of the pharmaceutical firms marketing this drug indicated that skin eruptions due to ethambutol have not been reported (Cyanamid India Ltd, June 30, 1976, and Fenochem Laboratories, July 8, 1976, written communications). We are reporting a patient who devel-

From the Department of Dermatology and Venereology, All India Institute of Medical Sciences, New Delhi.
Reprint requests to Department of Dermatology and Venereology, All India Institute of Medical Sciences, New Delhi-110016, India (Dr Pasricha).

oped a generalized erythematous macular and papular eruption that was later confirmed by the provocation test to be caused by ethambutol. This is important because ethambutol is a first-line antitubercular drug in some countries, and it has been reported to be remarkably free of side effects in humans.

Report of a Case

A 23-year-old woman with pulmonary tuberculosis was being treated with streptomycin injections, isoniazid, and aminosalicylate sodium. On Nov 9, 1975, she started having palpitation and tremors, for which treatment with streptomycin was stopped. On Nov 14, she received ethambutol and diphenhydramine hydrochloride, but two days later she developed a high fever, for which trimethoprim, sulphamethoxazole, and acetaminophen were given. On Nov 21, treatment with trimethoprim and sulphamethoxazole was stopped, and she was given promethazine hydrochloride. On Nov 22, she was given chloroquine in addition to ethambutol, isoniazid, aminosalicylate sodium, acetaminophen, and diphenhydramine. The next day she noticed the appearance of erythematous macular and papular lesions on her body, which soon became generalized. Treatment with all of the drugs was stopped. On Dec 1, she developed jaundice, for which she was given an injection of dexamethasone, cyproheptadine hydrochloride, and an antacid; she was referred to the hospital.

At the time of admission, she had diffuse erythema and scaling over the body with a few erythematous papules on the face and trunk. She was afebrile. She was treated with 40 mg of prednisolone daily. The skin lesions and jaundice cleared completely within two weeks.

Provocation Test

When treatment with corticosteroids had been withdrawn and the patient was free from all the lesions, provocation tests were undertaken with the drugs to find out the actual cause of the skin eruption. On Dec 23, she was given streptomycin sulfate (0.5 gm, intramuscularly), but there was no reaction. On the next day, she was given streptomycin sulfate (1.0 gm) without adverse effects. Since then she continued to receive streptomycin sulfate (1.0 gm) daily. On Dec 26, she was orally administered 500 mg of ethambutol hydrochloride. Within ten hours, the patient developed pruritic and erythematous papular lesions over the face and trunk. The eruption was treated with 20 mg of prednisolone daily. When the lesions subsided, the prednisolone was also tapered off. Subsequently, she was tested with isoniazid (50, 100, and 300 mg, respectively) on three consecutive days. She did not develop any reaction and therefore received streptomycin and isoniazid.

Comment

Allergic cutaneous eruptions can be caused by almost any drug, but some drugs produce allergic reactions more commonly than others. It is often presumed that the drug given last or the one that is known to produce such reactions most frequently, is the drug responsible for the reaction. Many times, as in our patient, this is not so. In an individual patient, any drug can be responsible for the reaction, and, therefore, it is always preferable to confirm the cause of the eruption.

At present, the most reliable method of discerning which drug is responsible for a skin eruption is the provocation method.[3] Of course, provocation must be avoided if the drug reaction is anaphylactoid in nature. Also, it may not be necessary if alternative drugs are available. However, the procedure is quite safe when the eruption is not of a severe or life-threatening nature.

Hair Follicle Involvement in Bullous Pemphigoid

Thomas F. Downham II, MD, Thomas A. Chapel, MD

Immunofluorescence of biopsy specimens from patients with bullous pemphigoid almost invariably demonstrates localized immunoglobulins at the dermoepidermal junction adjacent to bullous lesions and in skin. Indirect immunofluorescence of serum samples from patients with bullous pemphigoid has demonstrated circulating antibodies localized to the basement membrane zone. Direct immunofluorescence has revealed IgG localized to the basement membrane zone. Indirect and direct complement staining methods have shown complement fixed to the basement membrane zone.

We report a case of bullous pemphigoid to emphasize that deep dermal hair follicles also may have localized immunoglobulins around the outer root sheath. This finding can confirm a diagnosis of bullous pemphigoid and the more typical involvement at the dermal-epidermal junction.

From the Department of Dermatology and Syphilology, Wayne State University, Detroit.
Reprint requests to Department of Dermatology and Syphilology, Scott Hall, 540 E Canfield, Detroit, MI 48201 (Dr Downham).

Report of a Case

An 80-year-old woman with adult onset diabetes and arteriosclerotic heart disease developed vesicles on her neck. Mildly pruritic vesicles and bullae later appeared on the extremities, trunk, and oral cavity.

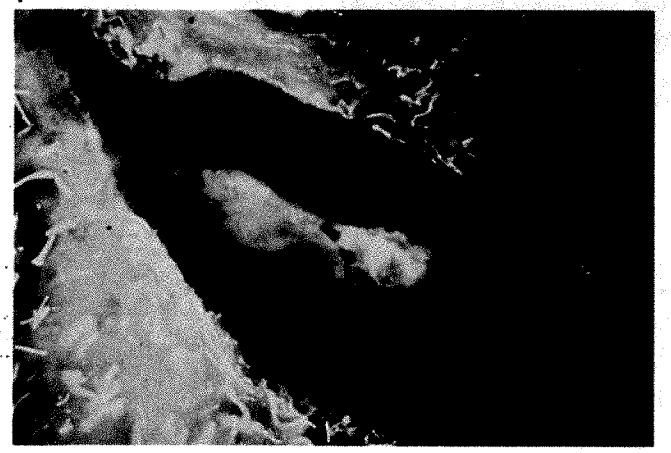

Fig 1.—Control slide of deep dermal hair follicle showing no immunofluorescence around hair follicle epithelium (×200).

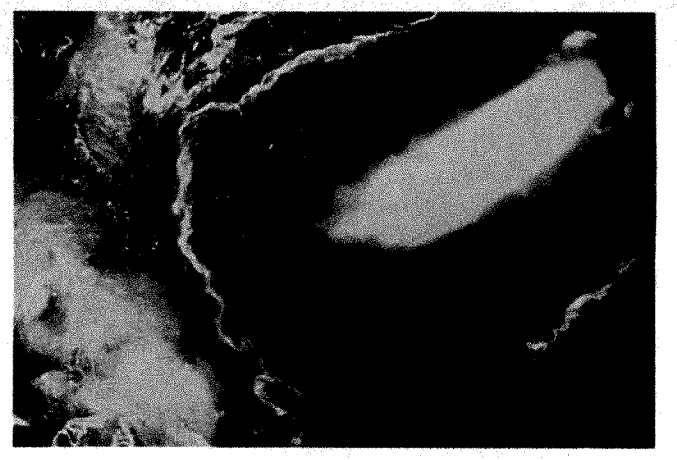

Fig 2.—Deposition of IgG is indicated by irregular fluorescent "band" around hair follicle epithelium (×200).

Biopsy findings were compatible with bullous pemphigoid.

Immunofluorescence studies showed deposition of IgG at the dermoepidermal junction adjacent to the bullous lesion and around the hair follicle epithelium of deep dermal hair follicles (Fig 1 and 2).

The patient was treated orally with prednisone, but aggravation of her diabetes forced discontinuation of the drug. Courses of methotrexate, cyclophosphamide (cytoxan), and prednisone were used subsequently, but exacerbations of her pemphigoid necessitated four hospitalizations during the next 17 months.

She was readmitted to the hospital for the fifth time, and was started on a regimen of 80 mg of prednisone every morning, insulin zinc suspension (Lente Insulin) on a sliding scale, hydroxyzine hydrochloride (25 mg three times daily), nystatin oral suspension (100,000 units four times daily), and 0.5% gentian violet to denuded blisters. Cyclophosphamide, 25 mg twice a day, was later added because of a poor therapeutic response.

Despite therapy new lesions appeared, and old lesions were slow to reepithelialize. The patient subsequently developed bilateral bronchopneumonia with septicemia, rectal bleeding, and congestive heart failure, and died.

Comment

According to Pinkus and Mehregan, the adult hair follicle is surrounded by two layers of optically different connective tissue: the dense fibrous root sheath and the hyaline membrane between ectodermal and mesodermal components. The hair follicle is surrounded also by an intricate net of elastic fibers that are more prominent in the area of the isthmus or middermal portion.[1]

Major studies using indirect immunofluorescence testing for specificity of bullous pemphigoid antigen where hair follicle epithelium was used as a substrate failed to mention the problems of autofluorescence of the hair follicle.[2,3] Burnham and Fine[4] and Rodrigue[5] emphasized the problem encountered when using human hairy skin for the detection of circulating bullous pemphigoid antibody, and stressed that the brightly fluorescent hair follicle connective tissue sheath had to be differentiated from the bullous pemphigoid "band." Therefore, use of hairy skin for indirect immunofluorescence of bullous pemphigoid sera should be approached with caution. Familiarization with the normal microanatomy of the pilary complex is essential.

Burnham and Weinberger[6] recently reported that patients with bullous pemphigoid and cicatricial pemphigoid almost invaribly demonstrate an immunofluoresent band of localized immunoglobulin at the dermoepidermal junction in skin and adjacent bullous lesions. A band around only deep dermal hair follicles in inflammatory lesions may also be present. Hair follicle involvement in bullous pemphigoid, may be as confirmatory as the band at the dermoepidermal junction, especially if the clinical manifestation is plaque-type bullous pemphigoid in contrast to the presence of bullous lesions.[6]

With direct immunofluorescence we have found that irregular fluorescent staining of the area around the follicle epithelium in deep dermal hair follicles was specific, while very regular linear bright-green fluorescence observed around the hair follicle was nonspecific. This irregular fluorescent staining is specific because it was not present in unstained controls.

This study was supported in part by the Detroit General Hospital Research Corporation and National Institutes of Health grant RR0534.

Help Prevent Both Psychic...And Physical Scarring!

BENZAGEL®

(5% or 10% benzoyl peroxide, 6% polyoxyethylene lauryl ether)

and your counselling are BASIC to Successful Topical Therapy

"Results...Subjective and objective clinical results with this form of therapy were impressive. A rapid improvement could be seen within two weeks...Cysts, pustules and papules decreased in numbers, with a simultaneous reduction of accompanying inflammation. The distinct decline of oily conditions was dramatic."[2]

5 BENZAGEL® ACNE GEL & 10 BENZAGEL® ACNE GEL

Description: 5% or 10% benzoyl peroxide, 6% polyoxyethylene lauryl ether and 40% alcohol in an astringent gel containing colloidal magnesium aluminum silicate, hydroxypropyl methylcellulose, citric acid, fragrance and purified water.

Action: Provides drying, desquamative and antiseptic activity.

Indication: An aid in the treatment of acne.

Dosage and Administration: Wash affected areas prior to application. Apply once or more daily or as directed by physician.

Contraindications: Should not be used by patients having known sensitivity to either benzoyl peroxide or polyoxyethylene lauryl ether.

Precautions: For External Use Only. Not for ophthalmic use. Keep away from eyes and mucosae. Very fair individuals should begin with a single application at bedtime allowing overnight medication. May bleach colored fabrics. Keep this and all other medications out of the reach of children.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Plastic tubes, 1½ oz. and 3 oz.

Dermik

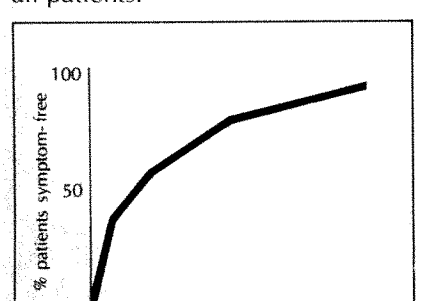
Dermik Laboratories, Inc.
Fort Washington, Pa. U.S.A. 19034

The seven most important reasons to prescribe a topical antifungal. Right at your fingertips.

1 It is effective against the most prevalent fungal pathogens. MicaTin brand miconazole nitrate 2% offers exceptional effectiveness against the most difficult-to-treat pathogen—*Trichophyton rubrum*, and is equally effective against *Trichophyton mentagrophytes, Epidermophyton floccosum, Candida albicans* and *Malassezia furfur.*

2 It clears the most common fungal infections. MicaTin provides outstanding clinical and mycological efficacy in tinea pedis,* tinea corporis* and tinea cruris* as well as candidiasis and tinea versicolor.

3 It relieves symptoms quickly. Within 72 hours for the majority of patients. Within 1 to 2 weeks for virtually all patients.



4 It demonstrates effectiveness in extensive studies. Clinical studies† demonstrate the outstanding success rate of MicaTin in the treatment of tinea pedis, tinea corporis and tinea cruris, when used with the recommended dosage of twice daily for one month. At the end of therapy, 88—94% of the patients were clinically clear.

The clinical studies of patients with candidiasis and tinea versicolor are equally impressive. Nine out of ten patients with candidiasis or tinea versicolor were clinically and mycologically clear within two weeks—the recommended duration of treatment.

Pathogen	Infection	Conversion KOH	Conversion Culture	Clinical Clearance or Improvement
Trichophyton rubrum	Tinea pedis	82%	86%	88%
Trichophyton mentagrophytes / *Epidermophyton floccosum*	Tinea corporis / Tinea cruris	93%	90%	94%
Candida albicans	Candidiasis†	92%	86%	88%
Malassezia furfur	Tinea versicolor	89%	—	92%

5 Its low relapse rate promises an outstanding chance of cure. To prove how effective MicaTin really is in keeping fungal infections clear, we evaluated these same patients one month later (median).† Of the 121 patients who were clear of tinea pedis, tinea corporis and tinea cruris at the end of treatment *and* were available for follow-up, 92% showed no clinical or mycological recurrence of the original infection.

And of the 34 patients cleared of cutaneous candidiasis *and* available for follow-up, 91% were still clear two weeks later (median).

6 It has a low incidence of side effects. Reports of "burning" sensation, irritation and maceration with MicaTin have been few and isolated. Naturally, it should not be used in patients with known hypersensitivity to any of its ingredients.

7 It is economically priced. The retail price of MicaTin is usually lower than that of other prescription antifungals.

Introducing new
MicaTin Lotion
brand miconazole nitrate 2%
12 ml. and 30 ml. bottles

MicaTin cream
brand miconazole nitrate 2%
new 85 g. (3 oz.) tube
and familiar 1 oz. and 15 g. sizes

Description: MicaTin brand miconazole nitrate cream 2% and lotion 2% each contain miconazole nitrate‡ 2%, formulated into a water miscible base consisting of pegoxol 7 stearate, peglicol 5 oleate, mineral oil, benzoic acid, and butylated hydroxyanisole.

Actions: Miconazole nitrate is a synthetic antifungal agent which inhibits the growth of the common dermatophytes, *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum,* the yeast-like fungus, *Candida albicans,* and the organism responsible for tinea versicolor *(Malassezia furfur).*

Indications: For topical application in the treatment of tinea pedis (athlete's foot), tinea cruris, and tinea corporis caused by *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum,* in the treatment of cutaneous candidiasis (moniliasis), and in the treatment of tinea versicolor.

Contraindications: MicaTin has no known contraindications.

Precautions: If a reaction suggesting sensitivity or chemical irritation should occur, use of the medication should be discontinued.

For external use only. Avoid introduction of MicaTin brand miconazole nitrate cream 2% and lotion 2% into the eyes.

Adverse Reactions: There have been isolated reports of irritation, burning, and maceration associated with application of MicaTin.

Dosage and Administration: Sufficient MicaTin cream should be applied to cover affected areas twice daily (morning and evening) in patients with tinea pedis, tinea cruris, tinea corporis, and cutaneous candidiasis and once daily in patients with tinea versicolor. It is preferable to use MicaTin lotion in intertriginous areas; if the cream is used, it should be applied sparingly and smoothed in well to avoid maceration effects.

Early relief of pruritus (first week) and early clinical improvement (one to two weeks) have been seen in treatment of infections caused by common dermatophytes. Even though clinical improvement may be seen fairly soon after treatment is begun, *Candida* infections should be treated for two weeks and dermatophyte infections for one month in order to reduce the possibility of recurrence. If a patient shows no clinical improvement after a month of treatment, the diagnosis should be redetermined. Patients with tinea versicolor usually exhibit clinical and mycological clearing after two weeks of treatment.

How Supplied: MicaTin brand cream 2% containing miconazole nitrate at 2% strength is supplied in 1 oz., 15 g., and 3 oz. tubes. MicaTin brand lotion 2% containing miconazole nitrate at 2% strength is supplied in polyethylene squeeze bottles in quantities of 12 and 30 ml.

*When infecting organisms are *Trichophyton rubrum, Trichophyton mentagrophytes* and *Epidermophyton floccosum.*

†Data for tinea pedis is based on 4 weeks' therapy in 138 patients; for tinea cruris and tinea corporis—4 weeks' therapy in 50 patients; for tinea versicolor—2 weeks' therapy in 38 patients; for candidiasis—2 weeks' therapy in 23 patients and 4 weeks' therapy in 20 patients. (There was no significant difference in effectiveness between the two candidiasis groups.) Data on file, Dermatological Division, Johnson & Johnson.

Treatment of Lentigo Maligna

To the Editor.—A potentially valuable lesson can be gleaned from the experience of Kopf and coworkers[1] in the radiotherapy of lentigo maligna. One patient (case 14) in their series developed regional lymph node metastases from a lesion in which an incisional (punch) biopsy specimen showed only noninvasive lentigo maligna. This fact adds weight to the argument advanced by many that, when possible, complete but conservative excision of the lesion should be performed, not only to achieve accurate microstaging, but also to reduce the likelihood of recurrence, so commonly observed after ablative therapy. While the authors rightfully suggest that the primary tumor might have shown dermal invasion had multiple biopsy specimens been taken, they subsequently imply that the absence of clinically obvious papular or nodular components argues against such a possibility.

In tracing the origin of this oft-repeated axiom that a melanotic freckle without palpable nodularity is likely benign (ie, noninvasive), we must return to 1894, when Jonathan Hutchinson first described a small series of patients with lentigo melanosis.[2] Understandably, little was known of the histopathologic evolution of the disease at that time. Aided by the eloquent work of McGovern et al[3] and Clark et al[4] within the past decade, our understanding of the biologic behavior of melanoma has blossomed. If one examines its vertical growth phase, one finds that the earliest level of dermal invasion, level 2, displays a range of thickness from less than 0.3 to greater than 1.0 mm.[5] Surely, not all of the more superficially invasive lesions in this group are papular or nodular. This point is underscored by Clark and Mihm, who emphasize that "although lentigo maligna melanoma has characteristically raised areas, we have observed lesions that clinically appeared to be lentigo maligna but histologically were found to have definite foci of invasion. This flat variant of lentigo maligna (sic) that is only diagnosable histologically must be included in the differential diagnosis of these flat pigmented lesions."[6] Indeed, as evidenced by clinical data from patients with superficial spreading and lentigo maligna melanoma, flatness is far from a reliable clinical marker of benignancy, particularly in the earlier stages of invasion. According to unpublished data from the Melanoma Clinical Cooperative Group, absence of clinical elevation was a feature of 32 of 320 superficial spreading melanoma (10%), 3 of 17 lentigo maligna melanoma (18%), 18 of 74 all level 2 melanoma (24%), 15 of 63 level 2 superficial spreading melanoma (24%), and 2 of 3 level 2 lentigo maligna melanoma (67%).

To invoke the shibboleths of 80 years ago as a guide for the treatment of a disease with such grave potential leaves much to be desired. Until larger numbers are available for review, I believe that whenever feasible, all Hutchinson's freckles (especially including those without a palpably or visibly elevated component) should be subjected to surgical excision, subserial sectioning, and microscopic examination to determine if invasion has indeed supervened. As the authors suggest, the Melanoma Clinical Cooperative Group could be instrumental in providing the answers to this and other questions regarding the clinical expression of this problematic disease, particularly as it relates to its natural history and response to therapy.

A final note: In abandoning the Miescher technique of x-ray therapy in this setting, the authors express interest in the reports of other therapeutic modalities. Litwin and coworkers[7] have previously reported their experience with topical 5% fluorouracil (5-fluorouracil) in three patients with lentigo maligna. Interestingly, two of the patients had melanomas excised from within the melanotic freckle, one having developed after cessation of therapy. Since that time, all have remained free of disease for periods of up to 66 months postherapy, while an additional two patients similarly treated are also without recurrence (MS Litwin, oral communication, July 1976). While this modality may hold promise for effecting durable remissions in lentigo maligna, it is difficult at present to underwrite its routine use, when it appears that the very diagnosis on which its success rests, cannot , short of total excision, be made with reasonable surety.

Treatment for Acne

To the Editor.—I must respond to the recent debate concerning the use of clindamycin in the treatment of moderately severe acne. For the past two years, I have been treating a number of patients with moderately severe acne resistant to tetracycline, minocycline, and various topical agents, with lincomycin hydrochloride monohydrate (Lincocin) (300 to 450 mg intramuscularly) at intervals of three to four weeks with improvement noted by both the patient and the doctor by the second or third injection. To date, there have been no side effects. I have also injected cystic acne lesions with triamcinolone hexacetonide (Aristospan) (5 mg/ml), diluted equal parts with lincomycin hydrochloride monohydrate with satisfactory resolution

of lesions and again no side effects. For many patients who have had months of painful acne nodules, lincomycin hydrochloride monohydrate has brought welcome relief. Before we throw out a useful treatment, perhaps a change in the method of administration may be all that is needed.

Simultaneous Occurrence of Goodpasture's Syndrome and Follicular Mucinosis

To the Editor.—Both Goodpasture's syndrome and follicular mucinosis are uncommon or even rare conditions, both of obscure cause. We recently had the opportunity to study a patient with both conditions.

Report of a Case.—In July 1974, a 12-year-old girl developed hemoptysis and subsequently hematuria. She was hospitalized and thoroughly examined, and the diagnosis of Goodpasture's syndrome was confirmed by characteristic routine and immunofluorescence findings on lung and renal biopsy specimens, as well as by positive circulating antiglomerular basement membrane antibodies. She was treated with high doses of prednisone (60 to 100 mg daily), azathioprine (Imuran) (100 mg daily), as well as methyldopa (Aldomet), hydralazine hydrochloride, furosemide (Lasix), and potassium chloride. She did well, except for seizures due to hypertensive encephalopathy, and her prednisone was gradually tapered. In December, she developed a follicular eruption on her forehead and cheeks, which was believed to be steroid acne. This was treated with tretinoin (Retin-A) cream from April 1975 to June 1976. The treatment provided no relief, and the patient sought further dermatologic treatment in June. At that time she had innumerable firm, follicular papules, and only few comedones, over her forehead and cheeks. A biopsy specimen of a papule showed changes typical of follicular mucinosis. Direct immunofluorescence staining performed on an adjacent papule was entirely negative. By September the prednisone had been discontinued, while the other medications remained the same. The rash had almost entirely cleared by this time without any specific treatment.

Comment.—Goodpasture's syndrome is uncommon, and is said to have no cutaneous manifestations,[1] although a faint macular rash has been described.[2] In general, however, the patients are quite ill, and it is likely that all but the most obvious cutaneous manifestations would be ignored by patient and physician alike. Furthermore, as in our case, a follicular eruption on the face of a patient receiving steroids would probably be called steroid acne, without further investigation.

While the simultaneous occurrence of Goodpasture's syndrome and follicular mucinosis is probably coincidental, clinicians should be made aware of this association so that it can be looked for in future patients with Goodpasture's syndrome, as well as in other immunosuppressed patients who might otherwise be thought to have steroid acne. While the cause of follicular mucinosis is unknown, its occasional association with reticuloses, especially mycosis fungoides,[3] raises the question of the role of abnormal antigens, immunologic responsiveness, or other factors in bringing about the inflammation and subsequent deposition of mucin in the hair follicle. Goodpasture's syndrome is an autoimmune disease in which antiglomerular basement membrane antibodies, produced in response to an unknown stimulus, cause damage to the glomeruli[4,5] and possibly to the lungs.[6] Again the question is raised as to the possible role of this abnormality of antibody production in the development of follicular mucinosis.

Follicular mucinosis has been reported in association with reticuloses[3] and familial reticuloendotheliosis.[7] To my knowledge, this is the first report of its occurrence with Goodpasture's syndrome, an autoimmune disease.

Immunotherapy of Leprosy

To the Editor.—In reading the minutes[1] of the SOCIETY TRANSACTIONS in the August 1976 issue of the ARCHIVES, the reader is left suspended in one of the discussions on the immunotherapy of leprosy. The minutes alluded to some leprosy research by a "Korean physician"[2] in an obscure manner that invites inquiry.

In 1972, Lim et al[2] reported that repeated whole WBC transfusions given over approximately a three-month period substantially cleared patients with either lepromatous or tuberculoid leprosy. The clinical, bacteriologic, and histologic data all became normal soon after the end of the immunotherapy and remained normal. These results were recently confirmed in a communication[3] that also reiterates the previous failure of the use of transfer factor.[4]

Bands in Cellular Blue Nevus

To the Editor.—Banded structure in cellular blue nevus presented by Bhawan and Edelstein in the ARCHIVES (112:1176-1177, 1976) warrants further comment.

Extensive investigation with the electron microscope on the relationship between blue nevus cells and nerves led me to believe that the blue nevus cells proliferate outside of the perineurium and do not invade the endoneurium. Even in the most tiny myelinated and unmyelinated fibers, devoid of perineurial sheath, the "fundamental architectural unit"[1] is respected, and degeneration of Schwann cells and axons takes place very late if ever. The picture published by Bhawan and Edelstein stresses this, and, as far as it is found repeatedly, represents an objective argument against the neural origin of blue nevus.

The "striated body," is quite common in normal tissues with immature collagen fibers (the so-called reticulin fibers) and especially in the central and peripheral nervous structures.[1] It is present too in tumors of the same, but lacks specificity. Experimental work by Carasso and collaborators[2] and by Luse and collaborators[3] proved it to be abnormal collagen fibril.

Collagen brought into solution may, in definite conditions, precipitate and organize into banded periodic structures (periodicity sway between 1,400 and 2,600 A). This makes at least speculative the hypothesis of actin and myosin-like material.

3. Luse S, Zopf D, Cox J: An electron microscopic study of in vitro and in vivo long-spacing collagen. *Anat Rec* 145:254-255, 1963.

In Reply.—Our experience on the relationship between cellular blue nevus and nerves is different from that of Dr Bourland. We have observed invasion of nerves by cellular blue nevus cells. In fact, a cell containing melanosomes, indistinguishable from the nevus cells present outside the nerve, can be seen in the Figure (close to the banded structure in black rectangle in the uppermost part of the electron micrograph).[1] This has also been reported by other workers, both in experimentally induced nevi in animals[2] and humans.[3]

In contrast to Dr Bourland's observations, ultrastructural evidence of degeneration of Schwann cells and axons was seen in almost every nerve within the cellular blue nevi of our three patients. Figure 1 in our report showed multiple layers of basement membrane surrounding a Schwann cell from a nerve within a cellular blue nevus. Such changes have been considered to result from repeated segmental demyelination and remyelination. They are described in a variety of human hypertrophic neuropathies and can be produced experimentally (unpublished data).

We did nothing more than speculate that banded structures may contain actin and myosin, and further stated that they are reported in a variety of tissues.[1] However, it has been shown quite clearly that these banded structures are different from native collagen or experimentally reconstituted long spacing collagen.[4]

Insect Sting Kit

To the Editor.—I am convinced that lives now needlessly lost due to severe systemic reactions to insect stings could be saved. How? By a greater awareness of the possibility of such fatal reactions plus knowledge of the existence of an insect sting kit. The kit is an emergency first aid measure to stave off anaphylaxis. Because of my convictions, I am presently collecting and correlating data on the incidence of such fatalities.

I am especially interested in time lapse between sting and death, although information concerning the following would be helpful: (1) time sequence of symptoms; (2) previous reactions to insect stings; (3) medication on hand at time of sting; (4) type of medication; (5) type of insect; (6) number of stings; and (7) estimation as to whether or not a physician or hospital emergency room could have been reached in time to avoid a fatal outcome.

CLAUDE A. FRAZIER, MD

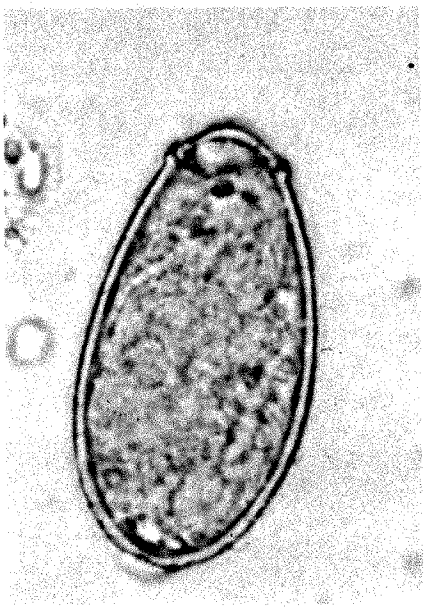
Urticaria Due to *Clonorchis sinensis*

To the Editor.—Intestinal parasites are a rare cause of urticaria.[1] I would like to report a case of urticaria probably due to infestation with *Clonorchis sinensis*.

Report of a Case.—A 54-year-old Oriental woman who lived in Michigan was seen on July 1, 1976, because of generalized urticaria. Her history was notable in that she had been in Hong Kong for one month and had only recently arrived home. She had a similar episode of urticaria when she was in Hong Kong four years previously.



Typical egg of *Clonorchis sinensis*.

Laboratory studies were obtained at the time she was seen. The WBC count was 9,000/cu mm with a normal differential, except for 6% eosinophils. The hemoglobin, urinalysis, blood glucose, BUN, serum creatinine, serum bilirubin, SGOT, alkaline phosphatase, serum uric acid, serum cholesterol, serum calcium and phosphorus, serum protein, as well as albumin and globulin levels were all normal. Stools for ova and parasites were negative at first, but when repeated showed many eggs of *C sinensis* (Figure).

The patient was treated with 10 mg of hydroxyzine hydrochloride three times a day, and the eruption resolved in about ten days. Because of the tendency for *C sinensis* to spread to the liver, this woman was referred to a gastroenterologist. However, she neglected to see him because of a lack of symptoms.

Comment.—*Clonorchis sinensis* is also referred to as the Chinese liver fluke. Infestation with it is obtained by eating raw or undercooked fish that contain the encysted larvae. This parasite is endemic in Japan, Korea, China, and Viet Nam. After ingestion, affected persons may be asymptomatic or if they have a heavy infestation, they may have epigastric distress, malaise, anorexia, hepatomegaly, and jaundice. During this stage, eosinophilia may be present. Eggs are not found in the stool until after one month.

The fluke ascends the biliary tree from the duodenum or may go to the liver by the portal circulation. They mature in the bile ducts and may live there many years. Light infections may be symptomless, but heavier ones may result in "chronic cholangitis with inflammation of the biliary tree, proliferation of biliary epithelium and progressive portal cirrhosis."[2] As a late complication, cholangiocarcinoma may occur. There is a high incidence of this in Hong Kong in men after the fourth decade.

The diagnosis is made by finding the typical egg in the stool. Treatment is with chloroquine, but it may not be effective. In some instances of biliary obstruction, surgery may be needed to remove the flukes.[2,3]

Although *C sinensis* infection is not mentioned as a cause of urticaria in the text books I reviewed,[1-3] it probably was the cause in my patient's case. Clinicians should consider intestinal parasites as a possible cause of hives in patients who have recently returned from the Orient or Africa.

Accidental Intraocular Injection With Dermojet Syringe

To the Editor.—Accidental intraocular injection of corticosteroids by a Dermojet syringe is a rare occurrence that has, to the best of our knowledge, not been reported previously. This letter reports the accidental intraocular injection of steroids by a dermatologist while treating psoriasis of the lids.

Report of a Case.—A 35-year-old man had an acute onset of pain and blurred vision of the right eye of four hours' duration. Earlier that day the patient had received a 0.1-ml injection of triamcinolone acetonide (40 mg/ml) administered to the right upper lid via a Dermojet syringe. Instantly the patient became aware of severe pain, decreased vision, and an abrupt onset of floaters. Vision was completely absent at first, but within minutes it returned, although still diminished. On examination later that day, visual acuity was 20/60 in the right eye and 20/20 in the left. Ocular tension was normal. On eversion of the right upper lid, a small area of hemorrhage was seen in the palpebral conjunctiva. The anterior segment was unremarkable in both eyes, and the left fundus was normal. The vitreous of the right eye contained many white particles of various sizes and shapes. The fundus could be seen around these particles, a small hole was present at the equatorial region of the fundus superotemporally, and there were scattered small retinal hemorrhages (Figure). The patient was treated with analgesics and mydriatics, and after one week the visual acuity in the right eye was 20/20. Many steroid particles remained in the vitreous overlying the retina, and the patient still complained of floaters. During the ensuing three-year period, the patient's visual acuity remained normal, and he was asymptomatic except for occasional floaters. Results of ocular examination were unremarkable, except for several residual steroid particles floating in the vitreous and a chorioretinal scar around the previous retinal hole in the right eye.

Comment.—The Dermojet syringe uses a high-velocity microspray in single doses of 0.1-ml to a depth of 2 to 5 mm without actual contact with the site of injection. At first impression it would seem that this depth of penetration could not be sufficient to penetrate the lid and ocular tissues. Yet there is no doubt that ocular penetration occurred through the closed upper lid.

Previous reports of accidental intraocular injection of steroids, using conventional syringes with various gauge needles, have led to severe decreases in visual acuity and even blindness.[1] If the patient retains good vision after the injection, the presence of a given amount of intraocular steroids may lead to other problems. Severe secondary glaucoma or steroid-induced cataract in susceptible patients may develop.[2] Although intraocular penetration is unlikely with the Dermojet syringe, in this day of medicolegal jurisprudence, discretion dictates avoidance of this type of injection around or into the eyelids and necessitates great care in administering any type of injection that might inadvertently enter the eye.

Fundus photograph of right eye three days after accidental intraocular injection showing intraocular steroid particles, with retinal and vitreous hemorrhage.

Nevi in Leprosy

To the Editor.—Indeterminant leprosy may be a difficult diagnosis to make due to the paucity of organisms in skin biopsy material. Observations on a recent case suggest that biopsy specimens of cellular nevi may facilitate diagnosis, since the organism has an affinity for nevus cells. We were unable to find any previous references to this effect; however, this observation is apparently well known to many leprologists (oral communication with Dr Samuel Moschella, Aug 27, 1976).

Report of a Case.—A 38-year-old man was seen in the dermatology clinic at University of California Irvine Medical Center with a two-year history of progressive numbness of the hands and feet. Results of physical examination showed multiple hypopigmented macules on the back, chest, and in the axilla. Multiple biopsy specimens were taken, fixed in a formaldehyde solution, and processed routinely, and sections were stained with hematoxylin-eosin and Fite-Faraco stains. The sections exhibited a mild perivascular inflammatory infiltrate composed of lymphocytes and histiocytes. There was some suggestion of perineural fibrosis. The Fite-Faraco stain exhibited rare acid-fast organisms that were found only on reexamination of the tissue. The sections were interpreted as indeterminant leprosy. The patient was administered dapsone. Five months later, the patient returned to the clinic and had an intradermal cellular nevus removed from the left side of his nose. The hematoxylin-eosin stained sections exhibited the microscopical features of an intradermal cellular nevus. To our surprise, the Fite-Faraco stain exhibited several acid-fast organisms that were not abundant, but were found without difficulty within the nevus. Unfortunately, a biopsy of normal skin was not performed.

Comment.—The discovery of *Mycobacterium leprae* within an otherwise

normal cellular nevus was not expected, but its occurrence seems reasonable due to the well-known affinity that the organism has for neural crest cells, particularly Schwann's cells. As previously stated, a biopsy should have been taken from normal skin at the time of the removal of the nevus, but the patient was unavailable. It is still unlikely that this finding was just a coincidence since, with the exception of lepromatous leprosy, organisms are not usually found in uninvolved skin. Although this represents only a single case, it is hoped that physicians who see many patients with leprosy will consider examining nevi when organisms may be difficult to find in skin lesions, which is frequently the case in indeterminant or tuberculoid varieties. Such a procedure is considerably less traumatic than nerve biopsies and possibly may prove to be just as useful.

Familial Localized Scleroderma (Morphoea)

To the Editor.—Familial scleroderma is a rare condition; to our knowledge, only nine documented instances of the disease have been reported. This report adds one more family to the literature. Four children, three brothers and one sister, had clinically and histologically established localized scleroderma.

In 1953, Rees and Bennett[1] reported the first documented instance of localized scleroderma occurring in two members of the same family. In 1968, Burge and Perry[2] after reviewing the literature on familial scleroderma presented four more documented instances. In 1972, Szczepanski and Jakubowicz[3] reported another instance of localized scleroderma in two sisters. In 1975, Wuthrich et al[4] reported another two instances of localized scleroderma.

Report of Cases.—CASE 1.—In November 1975 a 15-year-old boy with morphoea involving all four limbs was examined. The lesions had started to develop 11 years previously and gradually increased in size. During the winter, he had symptoms of Raynaud's phenomenon.

Clinical examination of the affected areas revealed claw-like hands, with considerable tightening of the skin over the fingers that resulted in flexion deformities.

The skin over the fingers was shiny and smooth and could not be lifted. The skin over the dorsum of the hands was rough and hyperpigmented (Fig 1). The radial pulse was normal.

The feet were also severely affected; the right one was grossly deformed. The skin was rough and dry with hyperpigmentation. There was gross wasting of the small muscles of the feet, with contracture of the toes.

The tibial pulsation was normal on both sides and so were the sensations. There was no other obvious skin involvement. The rest of the physical examination showed him to be a well-built, intelligent adolescent.

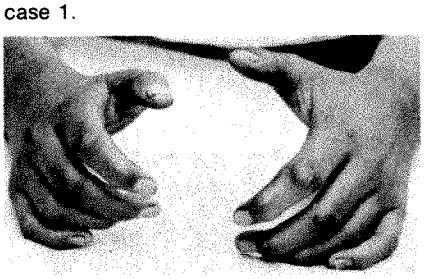
Laboratory investigations gave the following values: hemoglobin, 10 gm/100 ml; WBCs, 8,150/cu mm: polymorphonuclear leukocytes, 75%, lymphocytes, 30%, monocytes, 2%; ESR, 32 mm Hg. The results of a lupus erythematosus (LE) cell test were negative, but the rheumatoid arthritis (RA) factor was positive. Results of urinalysis, chest roentgenogram, barium swallow, spine roentgenogram, and ECG were normal. A skin biopsy specimen showed a considerably thickened dermis with hypertrophic, closely packed collagen bundles; sebaceous glands and hair structure were completely absent.

CASE 2.—The 13-year-old sister of the boy in case 1 was seen at the same time with clinically typical lesions of morphoea that were almost-identical to those of her brother in case 1 (Fig 2).

Her symptoms started nine years previously and progressed gradually with the passage of time. However, Raynaud's phenomenon in this case was more severe than in case 1.

Laboratory investigations gave the following values: hemoglobin, 8 gm/100 ml; WBCs, 8,000/cu mm, polymorphonuclear leukocytes, 25%, lymphocytes, 75%, and eosinophils, 1%. Results from an LE cell test were negative; however, the RA factor was negative. Results from urinalysis, barium swallow, chest and spine roentgenograms and ECG were normal. A skin biopsy specimen showed hypertrophic section and closely packed collagen bundles. Most of the vessels in the dermis had considerable thickening of the wall with narrowing of their lumens and they were surrounded by few inflammatory cells.

Fig 1.—Skin over dorsum of hands was rough and hyperpigmented for patient in case 1.



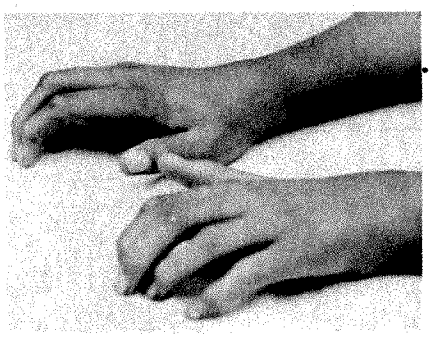


Fig 2.—Thirteen-year-old sister of patient in case 1 has clinically typical lesions of morphoea almost-identical to those seen in her brother in case 1.

CASE 3.—The 7-year-old brother of the patients in cases 1 and 2 was also examined at the same time. His symptoms started three years earlier with thickening of the skin over the fingers of both hands and knees. This progressed gradually and the lesions increased in size.

Clinical examination revealed tightness of the skin over the fingers of both hands that led to mild flexion deformity of the fingers. The skin over the knees was thick and hyperpigmented. Raynaud's phenomenon in this case was less noticeable.

Laboratory investigations gave the following values: hemoglobin, 8 gm/100 ml; WBCs, 10,300/cu mm, polymorphonuclear leukocytes, 75%, lymphocytes, 20%, monocytes, 1%, eosinophils, 1%. The ESR was 20 mm Hg. Results of an LE cell test were negative; the RA factor was negative. Results from urinalysis, chest and spine roentgenograms, barium swallow, and ECG were normal. A skin biopsy specimen showed sclerotic collagen in the dermis, with sweat glands bound down in the middermis.

CASE 4.—The 5-year-old brother of the aforementioned patients was seen at the same time. His symptoms started six months previously with thickening of the skin of proximal interphalangeal joints of both hands.

On examination, the skin was tight over the proximal interphalangeal joints with moderate induration but no discoloration. No lesions were present on any other parts of the body. Systemic examination did not reveal any other abnormality.

Laboratory investigations gave the following values: hemoglobin, 7.5 gm/100 ml; WBCs, 9,650/cu mm; neutrophils, 30%, lymphocytes, 69%, monocytes, 1%. The ESR was 15 mm Hg. Results of an LE cell test were negative; the RA factor was negative. Results from urinalysis, chest and spine roentgenograms, barium swallow, and ECG were normal. A skin biopsy specimen showed a considerably thickened dermis. Collagen bundles were hypertrophic, sclerotic, and closely packed.

Comment.—Nine other documented instances of localized scleroderma that have been published and the one reported here suggest hereditary predisposition in this disease, but obviously more work is needed to prove this factor.

Previous workers have shown that females have a greater predisposition for scleroderma developing than males, but in our four cases, there was a greater incidence in boys than in girls. The ratio was 3 boys:1 girl. Raynaud's phenomenon in scleroderma has been reported and the incidence is greater in females. In the brothers and sister of our four cases, this phenomenon was present in all, but the symptoms were more severe in the sister who was affected.

Christianson et al[5] found anomalies in the vertebral column in 32 of 68 patients with localized scleroderma. None of the patients in our cases had any abnormality in the vertebral column.

Several authors have found an increased incidence of positive antinuclear antibody factor in patients with scleroderma.

Recently, Hanson et al[6] reported an increased incidence of positive RA factor in children with focal scleroderma. In our cases, only the boy in case 1 has a positive RA factor.

Hereditary Syringomas

To the Editor.—There are a large number of epidermal appendage tumors of the skin, and they have been carefully classified according to clinical appearance, light and electron microscopical structure, and enzyme histochemistry.[1,2] Most of these tumors appear to be acquired and are representative of developmental defects, although disorders such as the basal cell nevus, trichoepithelioma, cylindroma, and steatocystoma multiplex have a genetic basis, and they are inherited in an autosomal dominant manner.[3] Of these disorders, however, in only the basal cell nevus syndrome is a second type of skin lesion—palmar keratoses and pits—observed. This report describes a patient with both syringomas of the face and palmar keratoses, whose mother had similar lesions.

Report of a Case.—The patient was a 65-year-old woman who requested removal of several lesions of the face that had developed when she was in her teens. She had also noted keratotic lesions of the palms at about the same time. Her mother had similar lesions. The patient was unaware of this condition in other family members, but she had no siblings or children. She denied having been given arsenic as medication or having been exposed to arsenical sprays.

The pertinent findings on physical examination were restricted to the skin. Multiple, yellowish papules, some of which had telangiectasia, were noted around the eyes, and numerous 1- to 2-mm keratotic papules were present on the palms. There was no raindrop-like pigmentation. Studies of biopsy specimens of three lesions from the face showed typical features of syringoma.

Comment.—The appearance of multiple syringomas is rather distinctive, and the correct diagnosis is usually made prior to histopathological study. In this case, some confusion arose because of the apparent hereditary nature of the disorder and its association with palmar lesions. This uncommon genetic basis has been described previously,[4] and subsequent to seeing this patient, I had observed two additional patients who had an affected parent, but no palmar lesions were noted in these cases.

The differential diagnosis in this case included a number of hereditary diseases in which keratotic lesions of the palms and soles occur (Table). In most of these diseases, cutaneous lesions may be observed in other areas; in basal cell nevus syndrome and lipoid proteinosis facial lesions are very common. The typical palmar lesions of the former disorder are circular pits with perpendicular sides and a reddened base that is formed by normal keratin; keratotic lesions are also observed. In the other disorders, a depression may be seen in the palmar lesions—a "pseudopit"—but the base is lined with greatly thickened stratum corneum.

Keratotic Lesions in Genetic Diseases

Disease	Mode of Inheritance	Distinguishing Features
Keratosis punctata	AD*	Palmar and plantar lesions develop during first decade
Basal cell nevus syndrome	AD	Palmar lesions are pits without keratotic plugs; papules found on face; multiple anomalies of bone
Darier's disease	AD	Keratotic papules on trunk and head that show acantholysis on biopsy
Acrokeratosis verruciformis	AD	Keratotic lesions on dorsum of hands and feet
Epidermodysplasia verruciformis	AR†	Warts may be widespread on body
Pachyonychia congenita	AD	Subungual hyperkeratosis and mucous membrane involvement
Acrokeratoelastoidosis	AD	Yellowish papules on dorsum of feet and hands
Lipoid proteinosis	. . .	Ivory papules and plaques on face; mucous membranes are involved
Cutaneous papillomatosis	. . .	Pigmented keratotic lesions on trunk in various configurations

*AD, autosomal dominant.
†AR, autosomal recessive.

Cantharidin Treatment of Warts at Home

To the Editor.—Cantharidin treatment of warts has become increasingly popular since first suggested by Epstein and Kligman in 1958.[1] The presently available commercial preparation of cantharidin carries a package insert suggesting application by the physician and the use of occlusive tape dressing to enhance the drug's blistering effect. Because the proper application of small pieces of occluding tape can be time-consuming, and because office treatment usually requires one or more return office visits, we decided to investigate the use of cantharidin as a self-applied, home treatment for warts.

The cantharidin was supplied as a 0.7% solution in acetone-flexible collodion in specially sized, 2.5-ml applicator bottles for ease of self-application. A standard (green) food color was added to simplify the process of self-application. The patients (or their parents) were told to apply a small amount of the colored solution directly to the wart, allow it to dry, and then to cover the area with an ordinary cotton adhesive bandage. Patients were instructed to apply the agent daily until a blister appeared or the wart disappeared.

These directions deliberately omitted mention of the application of an occlusive tape over the wart. We recognized that omitting the occlusive tape might result in a less therapeutic effect. We felt, however, that this might be preferable because it was expected to simplify the process of application and produce fewer painful reactions.

We treated a total of 336 hand warts in 100 patients with this method. Of the warts, 158 were common and 178 were subungual or paronychial warts. Thirty of the 100 patients were children under the age of 12. None of the patients experienced pain, untoward blistering, or any other side effect. The treatment resulted in removal of 112 of 178 subungual or paronychial warts and 103 of 158 common warts (on hands and fingers). One patient with a wart on her palm developed a so-called fairy ring of tiny satellite warts after the original wart disappeared. These were treated by freezing with liquid nitrogen.

This treatment compares favorably with the results that were obtained by Bunney et al,[2] who used a preparation that contained one part salicylic acid, one part lactic acid, and four parts flexible collodion. That treatment was as good as any, such as cryosurgery or curettage, that might be given in the office.

We conclude that home treatment with 0.7% cantharidin solution, applied without the use of occlusive tape, is a safe, easy, and reasonably effective method for the treatment of warts and may be safely prescribed by the physician.

The cantharidin was supplied as Cantharone by the Ingram Pharmaceutical Co, San Francisco.

Skin Closures

To the Editor.—We have been using the new Clearon Skin Closures by Ethicon in our office for several months. They are effective for holding wound edges together after suture removal and seem superior to Steri-Strips by 3M Company in their transparency. We feel it is important to see the wound edge when applying the strips, especially when strips are used in lieu of sutures.

At first, we used Hollister Medical Adhesive on the skin around the wound edge to increase the holding power of the tapes and the length of time the tapes would stay in place. This was the same technique we had used for the Steri-Strips. We quickly found that Clearon Skin Closures fell off in a day or two. On investigating the problem, it became apparent that there is a basic chemical incompatibility between the polyacrylic adhesive used in Clearon Skin Closures and the polysiloxane adhesive used in the Hollister Medical Adhesive.

Now we wipe the skin well with alcohol and allow it to dry before applying the Clearon Skin Closures. They adhere tightly and remain in place for seven to ten days without difficulty.

This letter is to advise our colleagues that these very practicable skin closures by Ethicon should not, in our opinion, be used with Hollister Medical Adhesive.

SYNALAR®
(fluocinolone acetonide)
CREAM 0.025%
CREAM 0.01%
OINTMENT 0.025%
SOLUTION 0.01%

Description Synalar (fluocinolone acetonide) has the chemical name 6α, 9α-difluoro-16α-hydroxyprednisolone-16, 17-acetonide.

The cream contains fluocinolone acetonide 0.25 mg./g. or 0.1 mg./g. in a water-washable aqueous base of stearic acid, propylene glycol, sorbitan monostearate and monooleate, polysorbate 60, purified water and citric acid with methylparaben and propylparaben as preservatives.

The ointment contains fluocinolone acetonide 0.25 mg./g. in a white petrolatum U.S.P. vehicle.

The solution contains fluocinolone acetonide 0.1 mg./g. in a water-washable base of propylene glycol with citric acid.

Indications For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications Topical steroids are contraindicated in vaccinia and varicella.

Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions If irritation develops, the product should be discontinued and appropriate therapy instituted.

In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled.

If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Synalar products are not for ophthalmic use.

Adverse reactions The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, dryness, folliculitis, hypertrichosis, acneform eruptions, hypopigmentation.

The following may occur more frequently with occlusive dressings than without such therapy: maceration of the skin, secondary infection, skin atrophy, striae, miliaria.

How Supplied
Synalar (fluocinolone acetonide)
Cream 0.025% — 15 and 60g. tubes and 120 and 425g. jars.
Cream 0.01% — 15, 45 and 60g. tubes and 120 and 425g. jars.
Ointment 0.025% — 15 and 60g. tubes and 425g. jars.
Solution 0.01% — 20cc. and 60cc. plastic squeeze bottles.

Also Available
Synalar-HP® (fluocinolone acetonide)
Cream 0.2% 5g. and 12g. tubes.

If there's
tinea versicolor
here
there's probably
malassezia furfur
here
here
here
and here.
Tinver®
sodium thiosulfate USP 25%, salicylic acid USP 4%
where tinea versicolor is seen and
where malassezia furfur is suspected
Please see following page for prescribing information.

DESCRIPTION:
Sodium thiosulfate 25%, salicylic acid 1%, isopropyl alcohol NF 10%, propylene glycol USP, menthol USP, disodium edetate, colloidal alumina, and purified water.

INDICATIONS:
For topical use in the treatment of tinea versicolor (Malassezia furfur infection).

PRECAUTIONS:
If signs of irritation or sensitivity develop, discontinue use. Do not use on or about the eyes.

ADMINISTRATION:
Thoroughly wash, rinse and dry the affected areas before application of medication. Apply a thin film of lotion to all affected areas and other susceptible areas twice a day. Although diagnostic evidence of the disease may disappear in a few days, it is advisable to continue treatment for a much longer period. Clothing should be boiled to prevent reinfection.

HOW SUPPLIED:
6 fl. oz. plastic dispenser bottles.

CAUTION:
U.S. Federal law prohibits dispensing without prescription.

Amir H. Mehregan, MD, Recorder

Focal Dermal Hypoplasia. Presented by ROBERT LEE, MD.

The patient is a 1-month-old baby boy, the first child born of full-term pregnancy and an uncomplicated vaginal delivery. The examination at 3 days of age revealed a jaundiced baby with cutaneous lesions that have persisted. There are multiple oval and annular depressed areas over the face and trunk. The surface of the skin lesions appears atrophic and gives a button-hold type of feeling when palpated. The baby has recession of maxilla and cryptorchidism. There is some asymmetry of face and ears. The jaundice has gradually subsided.

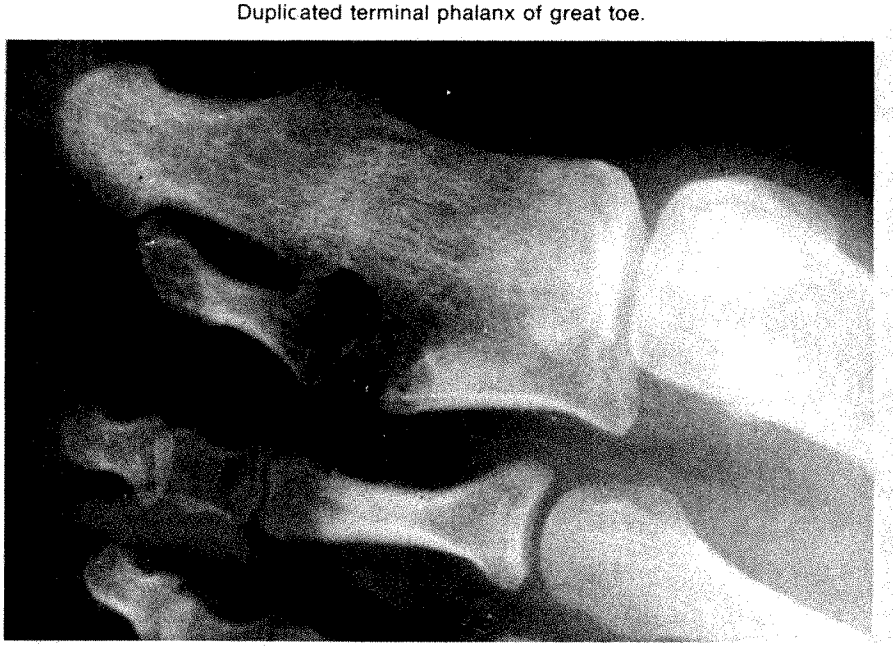
Discussion

AMIR H. MEHREGAN, MD: Biopsy specimen shows definite dermal hypoplasia with the subcutaneous fat tissue situated close to the epidermis. The hypoplastic dermis shows a few telangiectatic capillaries. The network of elastic fibers is well organized. The findings support the clinical impression of focal dermal hypoplasia.[1]

L. LEE, MD: Focal dermal hypoplasia or Goltz-Gorlin syndrome is an autosomal or X-linked dominant congenital malformation characterized by cutaneous, soft tissue, ocular, and neuroskeletal manifestations.[2] Cutaneous changes consist of linear or patchy red streaking of the skin and areas of dermal hypoplasia with herniation of subcutaneous fat tissue and linear or reticular areas of dyschromia and telangiectasia. Fibroepithelial papillomas occur over the lips, in axilla or periumbilical regions, and may also involve buccal or genital mucosa. The scalp hair may be sparse or brittle. Fingernails and toenails may be absent or may show dystrophic changes. Soft tissue defects include asymmetry of the face and ears and auricular appendages. There is a defect in abdominal musculature, umbilical or inguinal hernia, and rectal prolapse. Ocular abnormalities are anophthalmia, aniridia, wide spacing of the eyes, strabismus, nystagmus, heterochromia, blue sclera, and irregularity of the pupils.

Skeletal defects are variable and may include short stature, microcrania, pointed

Duplicated terminal phalanx of great toe.



chin, and deviation of nasal septum in addition to the deformities of vertebral bones, bones of the hands and feet, and generalized osteoporosis. Oral and dental anomalies exist such as prognathism, underdevelopment of the mandible, microdontia or dysplasia of the teeth, developmental abnormalities of the tongue, and hypertrophy of the gums. This syndrome may also be complicated by mental deficiency and epileptiform seizures. There are 47 famale cases and three males with this syndrome that have been reported. The case presented is the fourth male infant with focal dermal hypoplasia showing cutaneous manifestations and characteristic histologic findings of this condition. The infant shows asymmetry of the face and ears, but other components of this syndrome have not yet been detected.

Rubinstein—Taybi's Syndrome. Presented by JAMES STROUD, MD.

The patient is a 19-year-old woman with severe mental retardation. On physical examination considerably enlarged thumbs and toes were seen. The patient also has epileptic seizures and self-destructive tendencies marked by picking at herself and by the pulling of her nails. X-ray films of the toes show duplicated terminal phalanx of both great toes (Figure). The thumbs are similarly affected.

Discussion

JAMES STROUD, MD: This syndrome is characterized by broad terminal phalanges of the thumb and hallux, broad terminal phalanges of other fingers, and overlapping toes in association with varieties of facial abnormalities and mental deficiency.[1] In addition, there are often other skin changes such as nevus flammeus, hirsutism of the trunk and limbs, and changes in the dermatoglyphic pattern.

Waine C. Johnson, MD, Recorder

Blue Rubber Bleb Syndrome. Presented by HERBERT A. LUSCOMBE, MD; YOUNG C. KAUH, MD; MARGERY A. SCOTT, MD.

A 17-year-old boy from Puerto Rico had skin lesions involving the arms, legs, feet, and genitalia since birth. Although they have occasionally become painful during the summer, they have generally remained asymptomatic and have increased in size only in proportion to his growth. The lesions do not show an increase in sweating. He denies melena but has had recurrent episodes of spontaneous epistaxis. His paternal grandfather had similar lesions, but nine siblings are unaffected. Dermatological examination revealed numerous elevated hemangiomas varying in color from dark blue to purple that involved the arms, trunk, feet, and penis. The lesions will empty completely on steady pressure. A complete blood count and platelet studies have been normal. No occult blood was found in the stool, and upper and lower gastrointestinal (GI) studies were normal. A biopsy specimen was reported as hemangioma.

Discussion

THOMAS BUTTERWORTH, MD: The term "blue rubber bleb nevus" was used by Bean to describe hemangiomas of skin that were compressible and that refilled fairly promptly on release of pressure and were associated with nocturnal pains, supralesional sweating, and melena from GI hemangiomas. The patient presented does not show all of the features described by Bean in that some of the angiomas were firm whereas others were soft and compressible; increased sweating was not seen; the growths are only occasionally painful and blood has not been found in the stools.

Multiple glomangiomas must be considered a diagnostic possibility in this case. They favor the extremities but may be widely scattered elsewhere. The solitary glomangioma is extremely painful, especially when found beneath the nail, whereas the multiple scattered lesions are usually not painful. Sweating and melena do not occur as a rule. We need the help of the dermatopathologist to make an exact diagnosis in this case.

HERBERT GOLDSCHMIDT, MD: Hereditary glomangiomas of the multiple type usually show a different clinical picture in that they are less conspicuous and are a very light blue in color. The histologic findings are usually diagnostic.

DONALD BAXTER, MD: Clinically, this patient's lesions looked very much like the familial glomangiomas that I have seen. They do not show herniations like the blue rubber bleb nevi usually do. However, the biopsy specimen shows changes of a hemangioma and does not show the features of a glomangioma. Perhaps another lesion should be excised.

WAINE C. JOHNSON, MD: The histology of a blue rubber bleb nevus is not entirely specific but shows features of a cavernous hemangioma with large vascular spaces and often will have a good bit of smooth muscle about the vascular spaces. The features seen in this patient's biopsy specimen are those of a cavernous hemangioma with a considerable amount of smooth muscle and would be consistent with a blue rubber bleb nevus. The histological features are not those of a glomangioma. I think the diagnosis depends on how you define the blue rubber bleb nevus syndrome as to whether or not intestinal vascular tumors and the other features mentioned have to be present. The possibility of intestinal lesions probably cannot be entirely ruled out, although there is no evidence of such lesions at this time. The possibility of bleeding from any internal lesions, if they are present, is of course the most significant concern for this patient.

Mycosis Fungoides and Sarcoidosis. Presented by YOUNG KAUH, MD; HERBERT A. LUSCOMBE, MD; J. MCFARLAND, MD.

A 47-year-old woman states that she was refused employment in 1966 because of an abnormal chest roentgenogram that was interpreted as sarcoidosis. A scalene node and a skin biopsy were performed and were interpreted as sarcoidosis. She was started on treatment of prednisone, 10 mg per day. In 1969, she had a liver biopsy specimen taken that was interpreted as being consistent with sarcoidosis. By 1971, she had disseminated skin lesions, and a biopsy specimen from one lesion was interpreted as sarcoidosis and that from another as chronic dermatitis. Between 1971 and 1974, her treatment included prednisone, chlorpropamide, and topical steroid creams. The skin lesions progressed, an exfoliative dermatitis developed, and as this cleared somewhat, eczematoid lesions were noted. She was treated with oral steroids for systemic effect and chlorambucil. The skin lesions were treated in 1975 with 2,000 rads of electron beam therapy and later with topical mechlorethamine hydrochloride (Mustargen).

Dermatological examination shows multiple plaques and tumors, some of which are ulcerated, involving most of the body surface. Skin tests to intermediate strength of purified protein derivative, mumps, *Candida*, and trichophytin antigens were negative. No Sézary cells were identified in the peripheral blood. The present treatment includes mechlorethamine, chlorpropamide, and antibiotic ointment.

Discussion

HAROLD ISRAEL, MD: This patient has had generalized sarcoidosis with characteristic pulmonary changes and granulomas demonstrated in skin, lymph node, and liver biopsy specimens. In 1974 when the large ulcerating nodules developed, I was concerned that there was a superimposed deep fungal infection. Skin biopsy specimens at that time showed mycosis fungoides and she was treated with radiation and mechlorethamine with considerable improvement. Two Kveim tests were performed and were negative although the reaction could have been suppressed because of steroids. In my experience, a positive Kveim test is seen in 60% to 80% of the patients with sarcoidosis.

A question that deserves consideration is whether patients with sarcoidosis are prone to having neoplasms develop because of their impaired delayed hypersensitivity

or altered immunity. In general, we have not been persuaded that patients with sarcoidosis show an increased incidence of neoplasms. Brincker and Wilbek[1] reported a possible increase in the association of sarcoidosis and Hodgkin's disease. An epidemiologic survey in Denmark of patients with sarcoidosis was cross-checked with the tumor registry, and a greater frequency of neoplasms (mostly lymphomas) was found in patients with sarcoidosis.[1] I am not completely convinced that their data are correct.

HERMAN BEERMAN, MD: I would like for Dr Israel to comment on the validity and significance of the Kveim test.

DR ISRAEL: There has been a recent outbreak of correspondence about the Kveim test.[2] Hurley et al[3] reported that their antigen is usually positive in sarcoidosis but is nonspecific in that patients with other diseases also show a positive reaction. I believe that many or most of the antigens available will give false-positive reactions. We had hopes of developing an in vitro equivalent measuring migration inhibition of lymphocytes from the affected patients, but this has not yet proved practical.

CHICAGO DERMATOLOGICAL SOCIETY
January 1975

David F. Fretzin, MD, Recorder

Dermatomyositis Sine Myositis. Presented by SIDNEY BARSKY, MD, RAYMOND W. VAHL, MD.

This 62-year-old woman was well until 18 months ago, when she noted progressive, erythematous, macular hyperpigmentation of her forehead and forearms. Two months previously, she had had a "flu-like" illness, with weakness of her arms and legs that persisted for three weeks. She relates "soreness of the flesh" and tenderness of her arms during that time that improved without treatment. She has since developed hyperpigmentation of the chest and back, and violaceous, papular lesions on the dorsums of the hands. She noted occasional warm sensations and a 15-pound weight loss in the past two months. Her medical history includes adult-onset diabetes and intermittent diastolic hypertension. Her current medications include: phenformin hydrochloride, tolbutamide, chlorthalidone, and methyldopa.

Results of physical examination show slight erythema of the palatal and pharyngeal mucosa. Her strength is normal in all muscle groups. A hyperpigmented, erythematous, macular eruption is present on her forehead, malar area, upper arms, and hands. There is violaceous, papular thickening over her knuckles and proximal interphalangeal joints, and periungual telangiectasia and tenderness with cuticular hyperkeratosis of the hands.

A skin biopsy specimen of the arm was consistent with the poikilodermatous changes of dermatomyositis. Immunofluorescence was negative for IgG, IgM, and complement in involved and uninvolved skin. Laboratory studies disclosed the following values: WBC, 4,200/cu mm; hemoglobin, 11.6 gm/100 ml, with a normal differential cell count; sedimentation rate, 29 mm/hr; fasting blood glucose, 220 mg/100 ml. The following tests were negative: urinalysis, antinuclear antibody, rheumatoid factor, cryoglobulins, and VDRL (test for syphilis). The EMG of her girdle muscles was normal. The SGOT, creatinine phosphokinase, aldolase, and urine creatinine levels were all within normal limits. The urine porphyrins were normal (24-hour determination). Evaluation for occult malignant neoplasms (upper and lower gastrointestinal [GI] tracts, gallbladder, intravenous pyelogram, and chest roentgenograms was unremarkable. Sputum and cervical cytologic findings were also normal.

The patient has had no further weakness or myalgias in the past two months. She has occasional pain of her shoulder joints. Her sedimentation rate remains elevated. Tenderness at the tips of the digits persists. Treatment consists of fluocinonide ointment (0.05%) to the erythematous and periungual areas and cool-water soaks for her hands.

Discussion

DR ROY S. ROGERS: This is a fascinating case of what looks like dermatomyositis without the myositis component. We have seen in the past week an interesting husband and wife from Montana with a similar picture, the classical eruption of dermatomyositis with no myopathic findings. They are ranchers and are exposed to a variety of chemicals, and I wonder if this patient has been exposed to some insecticide or potent chemical that could be playing a role in her curious disease. The biopsy specimen was consistent with the poikilodermatous changes seen in dermatomyositis: there is epithelial atrophy and liquefaction degeneration of the basal cell layer, incontinence of pigment, and dilated vessels. I did not notice the hyperkeratotic cuticular manifestations that Dr Samitz has emphasized, but she did have periungual and cuticular telangiectasias that would be consistent with any of the connective-tissue diseases. There was no evidence of malignant neoplasms in this patient. Patients with polymyositis and dermatomyositis seem to have a disorder of cell-mediated immunity in which the lymphocytes, probably T-lymphocytes, are responsible for attacking the muscles. Lymphotoxin (which is a product of T-lymphocytes) is generated by the lymphocytes attacking the muscles. In addition, muscle antigens, though crude in nature, have been shown to cause lymphocytes harvested from patients with these disorders to release lymphokines, such as the migration inhibition factor for macrophages. This would then lead one to wonder if we could study delayed hypersensitivity reactions to see if those are intact. If not, one would wonder about malignancy, since it has been reported that patients with dermatomyositis who have malignant neoplasms also have a profound diminution in circulating T cells, whereas they have the normal number of B cells.

DR FREDERICK MALKINSON: Although cases of dermatitis without myositis are well recognized, they are rare. I would make a plea for observation and continued study only, rather than submit her to any kind of systemic therapy. This treatment approach might have to be modified in the relatively rare cases where dermatitis is finally followed, months or years later, by the advent of muscle involvement.

Are these patients any more susceptible to malignant neoplasms than normal persons? Patients with polymyositis without the dermatitis seem to be much less susceptible to the development of cancer. Perhaps the inflammatory changes in the skin per se are the critical factors, reflecting an increased tendency to develop malignant neoplasms. There are so few patients with dermatomyositis without myositis that have been followed up long-term that this question is currently unsettled. I would not altogether rule out the possibility that malignant neoplasms might complicate this picture sooner or later, however.

DR MARIA MEDENICA: Patients with dermatomyositis and underlying malignant neoplasms usually have less-pronounced manifestations of myositis. Serum enzyme levels are slightly elevated, but the dermatitis is usually acute and much more widespread.

DR RICHARD WINKELMANN: I have never seen malignant neoplasms develop in a case of this kind, and we have followed up a number of similar cases. I believe that this falls into that same category as discoid lupus erythematosus. Most cases of discoid lupus erythematosus do not progress to more severe disease. We recognize them as strictly cutaneous, and we can, with our more-sophisticated techniques, narrow down a small number of indeterminate cases that need to be followed up with the question of systemic involvement. The same is true for periarteritis nodosa. I believe that if we do not find a serious disease at the time we see the patients in the full flower of the eruption, the chances are they will not develop it. We should recognize that it does indicate a better prognosis. I would corroborate what Dr Malkinson said about conservatism for these patients. Indomethacin has been our form of therapy for patients of this kind. I am not sure it is entirely necessary, but it has provided some antiinflammatory action for them.

DR MARVIN S. KAGEN: Chlorothiazide (Diuril) or hydrochlorothiazide (Hydrodiuril) can produce a lupus erythematosus-like

picture. I had a patient who was being treated for hypertension with a chlorothiazide who developed subacute systemic lupus erythematosus, which disappeared after stopping the drug. In this case, the woman is receiving chlorthalidone (Hygroton), and it may be a good idea to stop that medication to see if it would affect the picture. We know that a drug reaction can simulate any eruption, and maybe this is the first case of a dermatomyositis-like syndrome due to chlorthalidone. In early cases of dermatomyositis, the patient may have no symptoms except erythema on the neck, forehead, and eyelids, with erythematous papules appearing later on the fingers and hands. The serum enzyme levels may be elevated several weeks before weakness appears.

Multiple Subcutaneous *Pseudomonas* Abscesses. Presented by WILLIAM STORINO, MD, ASANEE LERTSBURAPA, BRUCE BENNIN, MD.

This 45-year-old woman's current problem began in June 1974, when she developed a low-grade fever and subcutaneous nodules in her axillae and perineal area. The lesions increased in number and size, and she was admitted to Cook County Hospital on July 7, 1974. She had a history of tuberculous osteomyelitis of the spine at the age of 1 year and three years ago had active pulmonary tuberculosis. She has intermittently received antituberculosis medications for most of her life. Two years ago, she was found to be diabetic and was treated with insulin. She has no evidence of diabetes now. There is also a past history of ethanolism. The patient has had various "allergic" reactions to penicillin, tetracycline, chlorpromazine (Thorazine), aspirin, and gentamicin sulfate.

Results of physical examination showed multiple, firm, movable subcutaneous nodules 3 to 5 cm in diameter (Figure). Most lesions were tender but not erythematous. The areas of predilection were the breasts, axillae, and perineum. The thighs and abdomen were also involved to a lesser extent, but the face was spared. She also had a palpable smooth liver, measuring 16 cm.

The following laboratory tests were normal: complete blood cell count; urinalysis; serum electrolytes; VDRL (test for syphilis); SGOT; SGPT; creatine phosphokinase; serum bilirubin; serum albumin; globulin; antinuclear, antimitochondrial, and anti-smooth-muscle antibodies; immunoglobulin electrophoresis; 17-OH corticosteroids and 17-ketosteroids; serum cortisol; cold agglutinins; EKG; upper GI tract series, intravenous pyelogram, fungal serologies; and a gallium scan. The following laboratory tests were abnormal: chest roentgenogram showed a right lower lobe calcified nodule. Barium enema showed diverticulosis. Cultures of purulent material and tissue from abscesses yielded *Pseudomonas aeruginosa* and were negative for fungi and mycobacteria. All blood cultures were negative. A battery of immunologic studies was within normal limits.

A biopsy specimen from a nodule showed a chronic inflammatory cell infiltrate in the dermis and subcutis. Intermixed were also foamy histiocytes and foreign-body giant cells. A few giant cells contained nondoubly refractile amorphous filaments in the cytoplasm.

Large subcutaneous cold abscess on anterior part of thigh.

The patient received a three-week course of gentamicin, achieving blood levels ten times above the minimal inhibitory concentration for *Pseudomonas*. The lesions improved, but never completely resolved. New lesions have continued to form, some healing spontaneously and others requiring incision and drainage. No evidence of visceral involvement or of any constitutional symptoms or signs has been found.

Discussion

DR WINKELMANN: This patient has had tuberculosis in the past, for which she has received multiple forms of therapy, including isoniazid, aminosalicylic acid, and streptomycin sulfate. It occurred to me that isoniazid is one of the drugs that can induce lupus erythematosus. I carefully examined this woman with abscesses and inflammatory disease of the subcutaneous tissue to see if there was evidence of a lupus panniculitis. I did not find any satisfactory evidence for that. She appeared chronically ill. The subcutaneous lesions were chronic with hemosiderosis pigmentation and a chronic fibrotic inflammatory reaction.

I wondered whether this might be one of those unusual factitial cases of panniculitis that Dr Forstrom and I reported in the ARCHIVES. *Pseudomonas* disease that I have seen has been associated with an acute, febrile, severely wasting illness, and I found this woman outside my experience. This was why I was looking for an alternative explanation for her problem. I would not be at all surprised if we found on biopsy some refractile material or some evidence that she has been injecting some of these areas, or some other explanation for her panniculitis. The histologic findings do not permit me to speculate on what other cause the panniculitis might be. If it were an acute panniculitis, many differential diagnostic possibilities would have to be considered. I was not happy with explaining this as a pyogenic infection of the subcutaneous tissue.

DR ALBERT SLEPYAN: I recall a recent patient in whom, after many months of observation, a diagnosis of nocardiosis was made by culturing old tissue containing a pocket of activity deep within the tissue. I suggest repeating the culture studies.

DR BRUCE BENNIN: The problem is how the abscesses are taking seed. Originally it was believed that there was some internal nidus. This possibility was evaluated, but no nidus was found—not surprising in light of the lack of constitutional symptoms of the patient. A second possibility was some immunodeficiency, but both cell-mediated and humoral immunity appear intact. A third possibility was self inoculation. We believed it would be difficult to inject pure *Pseudomonas* into multiple sites at various times, unless she had access to pure *Pseudomonas* cultures or withdrew material for injection from existing abscesses. She has been in the hospital for three months and has carefully been observed by the house staff and nurses. The possibility of placing a cast over the sites of predilection has been entertained; however, the lesions develop so slowly that it was believed that this was not practical.

The way they start out is not characteristic of most abscesses. However, cold abscesses, as in the Job's syndrome,[1] sometimes begin like this. The patient's IgE level was normal.[2] A fourth possibility was superinfection, as has been mentioned previously. There is no evidence to support this. A fifth possibility was that of primary cutaneous infection. Maibach and Kligman[3] described multiple cutaneous cold abscesses in children. These were of staphylococcal type, and were believed to be due to direct access through the eccrine sweat glands. Since many of our patient's lesions are in the area of apocrine gland concentration, some variant of this entity might be a possibility. We still do not know how the organisms gain access to the patient, nor do we know of any particular effective therapy. She is hypersensitive to most antibiotics. Even the most effective in vitro antibiotic apparently was not able to reach sufficient tissue levels to eradicate the organism. About 20 cultures of the *Pseudomonas* have shown the same antibiotic sensitivities. Typing is being done now to confirm whether organisms from all sites are identical. Cultures have also been made from various sites on the skin surface, nails, and stools to try and locate a similar organism, but these have been to no avail.

Nonproprietary Names and Trademarks of Drugs

Chlorpromazine—*Chlor-PZ, Cromedazine, Promachel, Thorazine.*

IN SKIN INFECTIONS, WHERE CLEANLINESS REQUIRES MORE THAN SOAP

BETADINE® Skin Cleanser

Degerms as it cleanses

Patients can use BETADINE Skin Cleanser to degerm and cleanse face, hands and body, gently and thoroughly—particularly when it is essential to prevent autoinoculation of new sites, as may be the case in infected acne pimples.

BETADINE Skin Cleanser, with its rich, golden lather, provides these advantages:

- Prompt, broad-spectrum microbicidal action—kills both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts.
- Maintains microbicidal activity in the presence of blood, pus and serum.
- Virtually nonirritating to skin and mucosa.*
- Nonstaining to skin and natural fabrics.

Supplied: 4 fl. oz. plastic bottles.

* In the rare instance of local irritation or sensitivity, discontinue use by the individual.

spots for

Uticort™

(betamethasone benzoate)

a highly effective topical steroid in a special base

UTICORT contains the fluorinated corticosteroid ester — betamethasone benzoate 0.025% — in a specially formulated, clear, self-liquefying gel base to increase steroid activity.
Patients with seborrheic dermatitis treated with UTICORT improved 86% in an average of 11.6 days.

liquefies on application for better surface contact

UTICORT is especially valuable in the treatment of seborrheic dermatitis on hairy areas of the body.

cosmetically acceptable

UTICORT dries to a clear film and can be used confidently on either smooth or hairy skin areas. Moreover, it is greaseless, nonstaining, and nonsticky.

preservative free

Contains no parabens or other potentially sensitizing preservatives.

Brief summary of prescribing information

INDICATIONS. Uticort Gel (betamethasone benzoate) is intended for relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS. Topical steroids are contraindicated in viral diseases of the skin, such as varicella and vaccinia. Topical steroids are contraindicated in patients with a history of sensitivity to any of the components of the preparation.

This preparation is not for ophthalmic use.

PRECAUTIONS. If irritation develops, the gel should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid, and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, or in large amounts, or for prolonged periods of time.

Due to the alcohol content of the vehicle, Uticort Gel (betamethasone benzoate) may cause mild, transient stinging without irritation if used on excoriated skin.

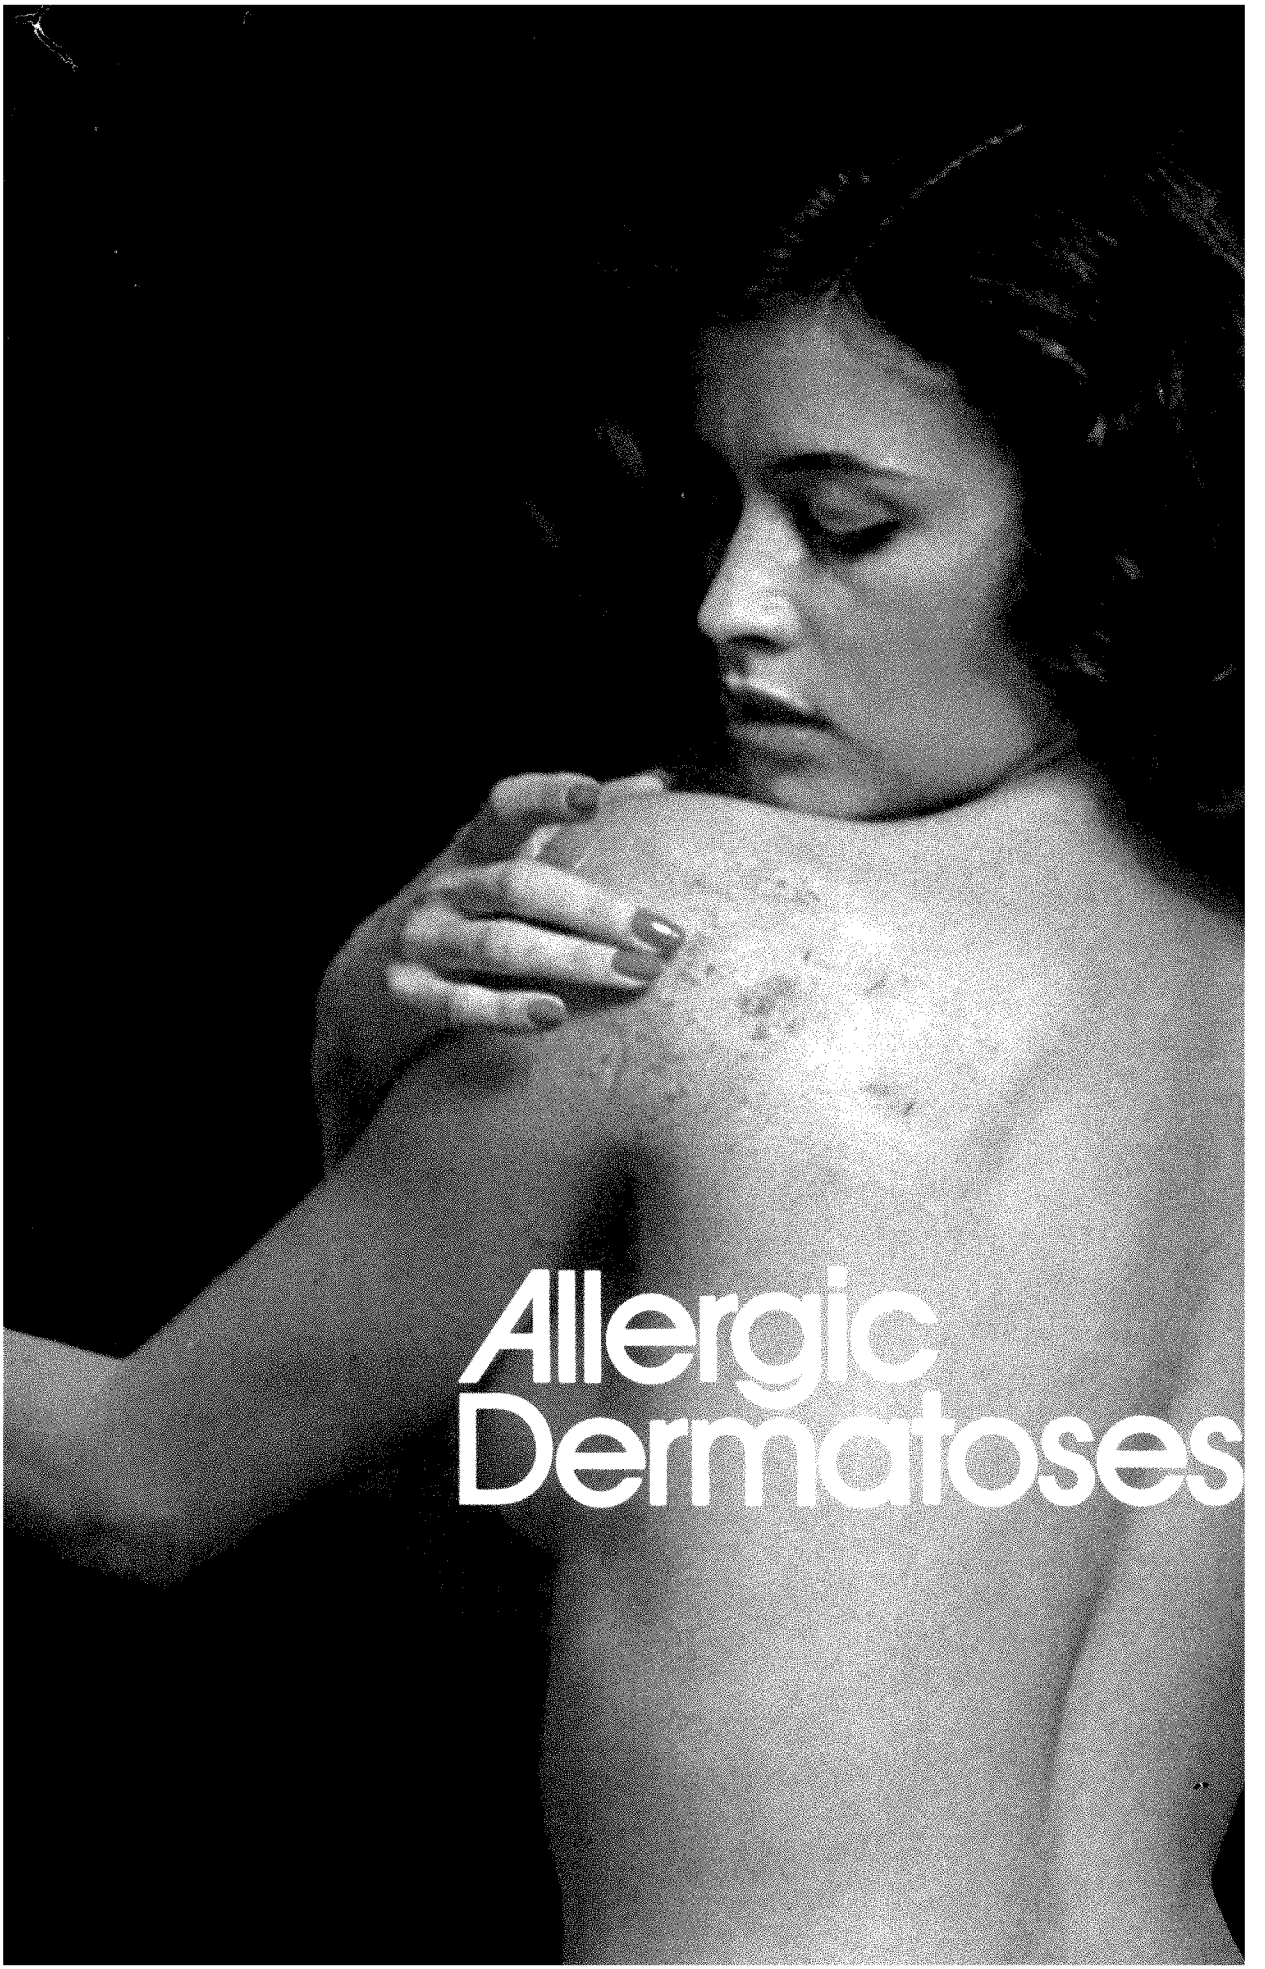
ADVERSE REACTIONS. The following local adverse reactions have been reported with topical corticosteroids: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruptions, and hypopigmentation.

DOSAGE AND ADMINISTRATION. Apply to affected areas two to four times daily as needed.

HOW SUPPLIED. N 0071-3025 Uticort Gel is supplied in 15-g and 60-g tubes.

Caution: Federal law prohibits dispensing without prescription.

PARKE-DAVIS



Allergic
Dermatoses

Contraindications: Hypersensitivity to hydroxyzine. Hydroxyzine, when administered to the pregnant [illegible] rat, and rabbit, induced fetal abnormalities in the rat at doses substantially above the human therapeutic range. Clinical data in human beings are inadequate to establish safety in early pregnancy. Until such data are available, hydroxyzine is contraindicated in early pregnancy.

Precautions: Hydroxyzine may potentiate the action of central nervous system depressants such as meperidine and barbiturates. In conjunctive use, dosage for these drugs should be reduced. Because drowsiness may occur, patients should be cautioned against driving a car or operating dangerous machinery.

Adverse Reactions: Drowsiness may occur; if so, it is usually transitory and may disappear in a few days of continued therapy or upon dosage reduction. Dryness of the mouth may occur with higher doses. Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with higher than recommended dosage.

Supply: Tablets, containing 10 mg, 25 mg, or 50 mg hydroxyzine hydrochloride, 100's and 500's; Tablets, containing 100 mg, 100's; Syrup, containing 10 mg per teaspoonful (5 ml) and ethyl alcohol 0.5% v/v, pint bottles.

Before prescribing or administering, see package circular.

Books

Skin Surgery, ed 4, edited by Ervin Epstein, MD, and Ervin Epstein, Jr, MD, 839 pp, with illus, $98.75, Springfield, Ill, Charles C Thomas Publisher, 1976.

The fourth edition of *Skin Surgery*, like the third edition, is the premiere textbook on dermatologic surgery. Nearly every surgical aspect of our specialty is well covered in the clearly printed, easily read, 839 glossy pages of this quality book.

The subject matter has been reorganized to accentuate the increased importance of cryosurgery and chemosurgery. In this textbook, chemosurgery includes chemotherapy, chemical peels, and chemosurgery for microscopic controlled excision of cutaneous cancers. Important chapters have been added dealing with medico legal problems, maxilofacial prostheses, laser skin surgery, cryotherapy for acne, and local anesthetics. Two excellent new contributions are the "Diagnosis and Treatment of Surgical Emergencies" by Krull and Ande and "Skin Surgery of the Eyelids" by Beard. Nearly all of the chapters have been updated, including many good-quality photographs. However, a few surgically treated conditions were less well covered or deleted—conditions I think are not uncommonly encountered by the dermatologist: rhinophyma, hidradinitis suppurativa, and chondrodermatitis nodularis helicis.

One addition (prominently located in the prefice) that I consider inappropriate is the reprinting of "Max the Knife" by Ralph Leukart. This poem is clever and portrays every practicing physician's daily frustrations, but it does not belong in the introduction to this major and serious medical textbook. In the same vein, the last two chapters, "Gimmicks and Gadgets in Skin Surgery" and "Do It Yourself Instruments," detract from the major effort of this book and of our specialty in general.

One hundred dollars is a great deal of money for a textbook. To me, however, the value of the book justifies the price. A week-long seminar on skin surgery (at a far greater cost) could not cover the volume and scope of the material presented here. As I read the book, I graded each chapter. By my arbitrary scale, 75% of the chapters are good to excellent, with only a few chapters irrelevant or outdated.

The editors recognize the advantages and disadvantages of a multiauthored book and purposely did not delete opinions contrary to their own. Without excessive repetition, various opinions are presented on most subjects. Samuel Ayer's conservative views on chemical face peels for wrinkling is balanced by Thomas Bakers aggressive presentation. Many contributors present a historical viewpoint in their particular subjects, which adds to our understanding of the natural growth of dermatologic surgery and highlights our progress.

However, in several instances I would have been happier if the editors had editorialized more. For example, in the chapter "Deep Cryosurgery" by Andrew Gage, a surgeon, cryosurgery is recommended for treatment of recurrent cutaneous tumors. Most dermatologists know of the high second recurrence rate from the reapplication of a "blind" modality for recurrent tumors. Other contributors, careless with cure-rate statistics, were left unchallenged by the editors.

For the fifth edition of *Skin Surgery*, I hope the editors include more on skin closures and skin flaps, more on suture materials, and add the treatment of keloids. Until then, this excellent book is rightfully the keystone of skin surgery.

SAMUEL J. STEGMAN, MD
Burlingame, Calif

Cancer, Epidemiology and Prevention: Current Concepts, edited by David Schottenfeld, 574 pp, $46.41, Springfield, Ill, Charles C Thomas Publisher, 1975.

This volume brings into focus a number of aspects of the cancer problem, ranging from economic costs to immunologic parameters. As with all multiauthored books (there are 37 contributors), there is some unevenness to the presentations. However, over all it is well done. Perhaps the three chapters of most interest to the dermatologic community concern ionizing radiation, sunlight, and immunovirology. The review by Farrington Daniels Jr on sunlight and cancer is thorough and clearly presented. It is one of the highlights of the book. The chapter on immunovirology, by W.D. Winters and D.L. Morton, is also informative. In contrast, the section on ionizing radiation is somewhat less complete.

This book would not be of interest to dermatologists in general. However, it would be of value to those involved in the various aspects of cancer research. It certainly belongs in medical center libraries as an important reference volume.

JOHN H. EPSTEIN, MD
San Francisco

KENALOG® SPRAY
Triamcinolone Acetonide Aerosol N.F.

DESCRIPTION: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) provides 3.3 mg. triamcinolone acetonide per 50 grams in an isopropyl palmitate vehicle with alcohol (4.7%) and propellants.

INDICATIONS: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) is indicated for relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS: Topical steroids are contraindicated in viral diseases of the skin, such as vaccinia and varicella, and in patients with a history of hypersensitivity to any product component. This preparation is not for ophthalmic use. Topical steroids should not be used when circulation is markedly impaired.

WARNINGS: Usage in Pregnancy— Although topical steroids have not been reported to have an adverse effect on the fetus, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

PRECAUTIONS: Administer suitable antifungal or antimicrobial therapy if infection exists; if there is not a prompt, favorable response, discontinue the corticosteroid until the infection has been adequately controlled. Discontinue the drug and institute appropriate therapy if irritation develops. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. When used about the face, the eyes should be covered and inhalation of the spray avoided.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids either with or without occlusive dressings: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, miliaria, hypertrichosis, acneform eruptions, maceration of the skin and hypopigmentation; contact sensitivity to a particular dressing material or adhesive may occur occasionally. Some patients (particularly those with very dry skin or dry lesions) may find the cooling effect of the spray objectionable or complain of a transient burning or stinging sensation.

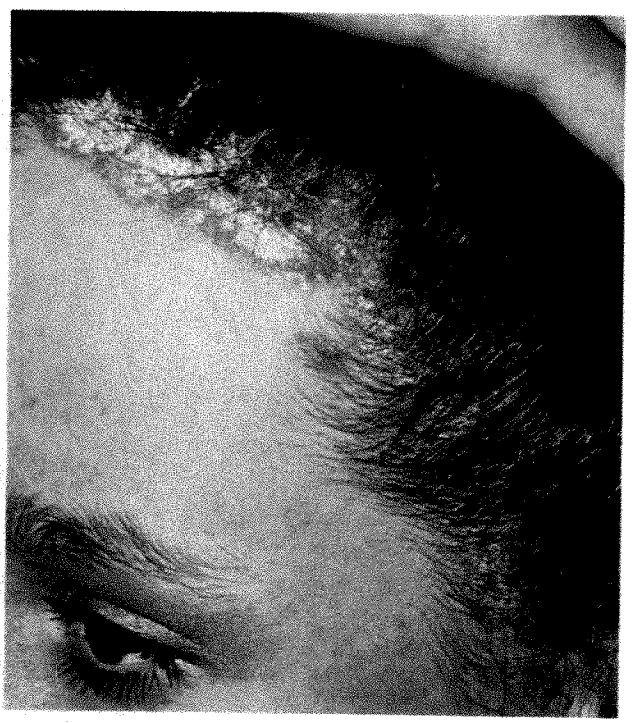
For full prescribing information, consult package insert.

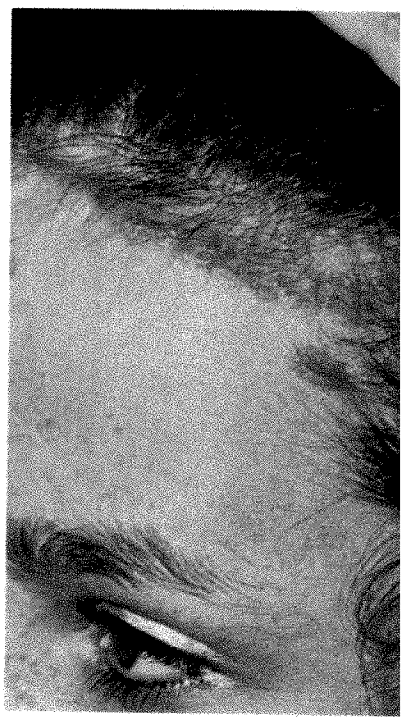
HOW SUPPLIED: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) is available in spray dispenser cans of 50 and 150 g. with adapter.

SQUIBB®

©1977 E.R.Squibb & Sons, Inc. 327-503

"INTRACTABLE" SCALP PSORIASIS





MARCH 4, 1977

A 15-year-old patient complaining of severe, intractable psoriasis of the scalp. Previous therapy with tar shampoo, keratolytic agents and fluorinated topical steroids had been unsuccessful. Because prior topical agents had been difficult to apply, Kenalog® Spray b.i.d. was prescribed.

Patient reported that pruritus had been relieved promptly. Marked improvement observed at this time: absence of scales, decrease in erythema and central clearing of plaques. Patient continuing on Kenalog® Spray b.i.d.
Case history on file at Squibb Institute for Medical Research.

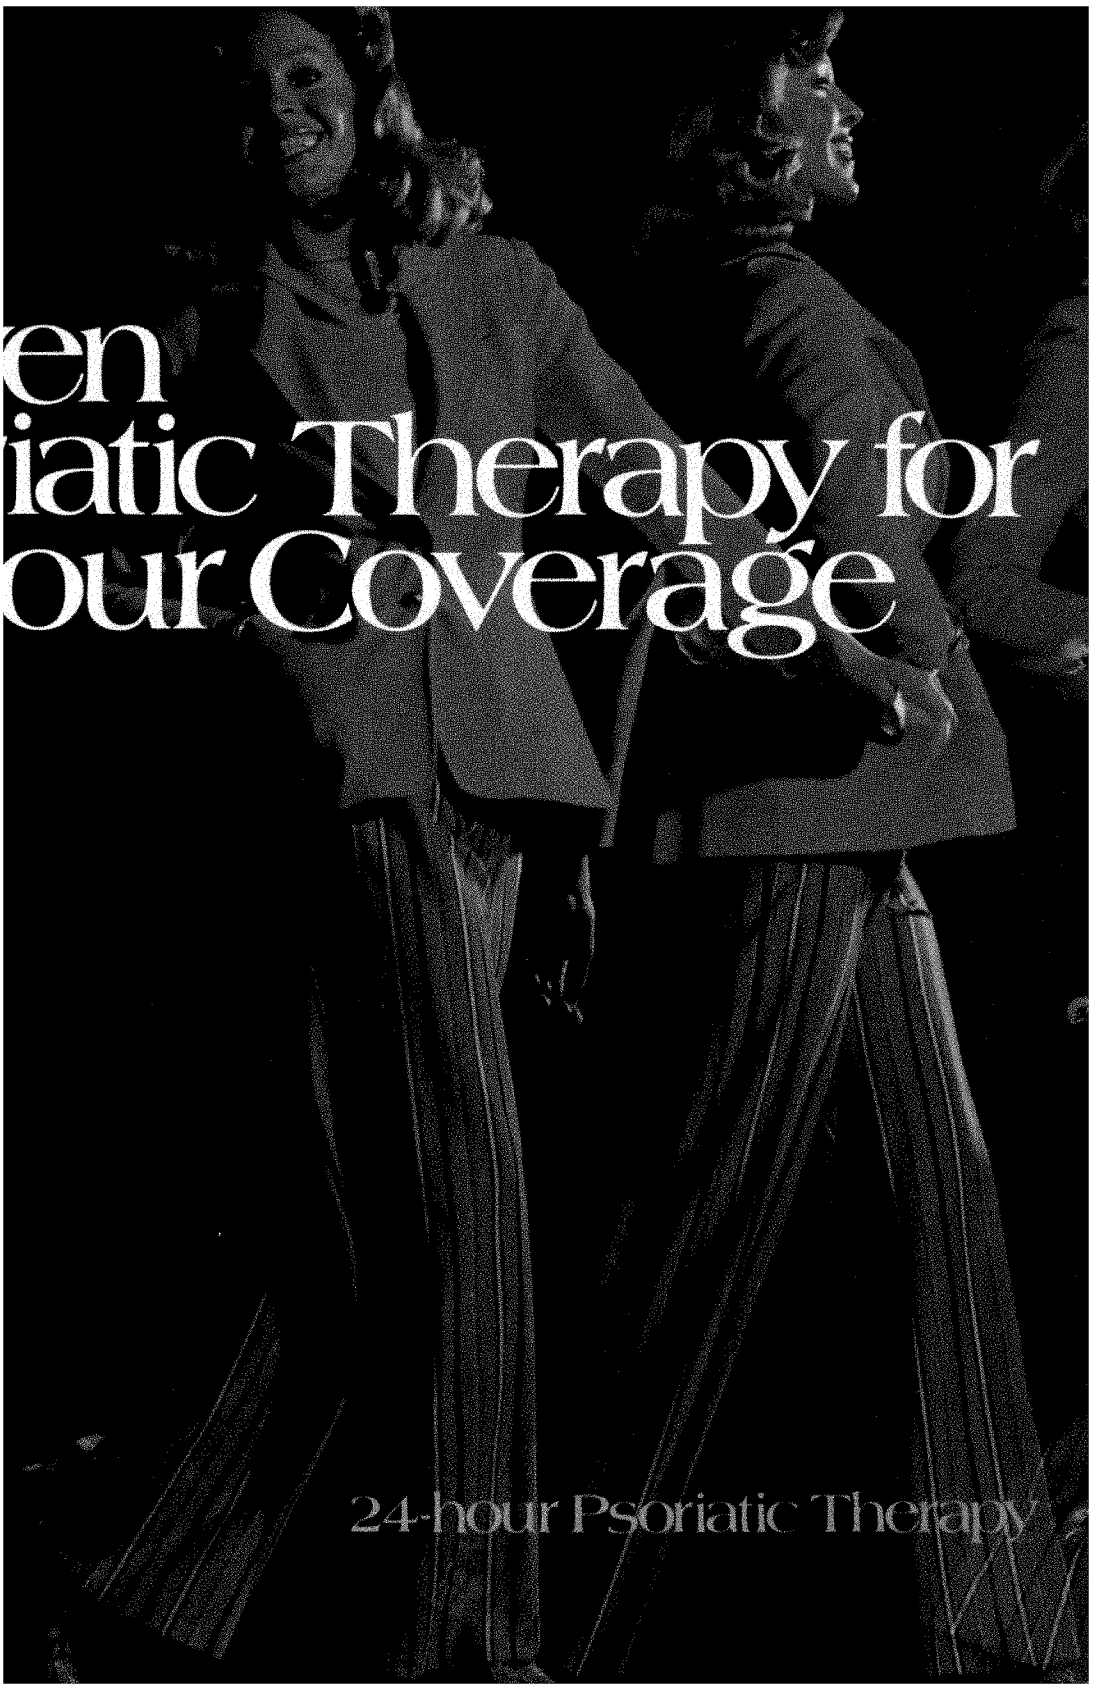
A CASE FOR KENALOG® SPRA

TRIAMCINOLONE ACETONIDE AEROSOL N.F.

See adjacent column for brief summary.



en
iatic Therapy for
our Coverage
24-hour Psoriatic Therapy

estar™

Therapeutic Tar Gel

Tar odor won't betray **estar** therapy. Proven **estar** Therapeutic Tar Gel is equivalent to 5% crude coal tar in everything but odor. No sticky, greasy residue to remain on the skin . . . proven therapy to control the formation of psoriatic scales and reduce itching with antipruritic action so that scratching is less likely.

The gel base enables the patient to apply **estar** evenly and smoothly. Tar therapy that doesn't smell like it . . . **estar** Therapeutic Tar Gel.

Balnetar®

Water-dispersible Emollient Tar

Change ordinary water into a psoriatic treatment for patients who bathe before bedtime. **Balnetar** can work through the night to provide keratoplastic, antieczematous, and antipruritic action. It lubricates and moisturizes the skin to relieve and help prevent excessive dryness while it softens and aids in the removal of scales and crusts. One to three capfuls of **Balnetar** added to a tub of warm water can extend the effect of **estar** Therapeutic Tar Gel to twenty-four hour tar therapy. The active ingredient in **Balnetar** treats the skin without staining it or the porcelain of the tub.

Sebutone®

Therapeutic Tar Shampoo

When psoriasis finds its way to the scalp, **Sebutone** can penetrate, soften, and remove scales, crusts, and excess oil with its chemically and biologically standarized tar. Microfine particles of tar remain on the scalp for up to three days (as shown with Wood's light) providing prolonged residual action. The fresh, clean fragrance and excellent cleansing properties of **Sebutone** make no other shampoo necessary when treating scalp psoriasis or any stubborn case of seborrhea or dandruff.

ith estar/Balnetar/Sebutone

WESTWOO
PHARMACEUTICALS
Buffalo, New York 14
In Canada, Belleville, Ontario K8

estar™
Therapeutic Tar Gel

Composition: Westwood® Tar (biologically equivalent to 5% Coal Tar USP) in hydro-alcoholic gel (29% alcohol).

Actions and Uses: A therapeutic aid in the treatment of psoriasis and other tar responsive dermatoses such as eczema (atopic dermatitis, lichen simplex chronicus, nummular eczema) and seborrheic dermatitis. **estar** is suitable for use in a modified Goeckerman regimen, either in the hospital or on an outpatient basis; it also can be used in follow-up treatment to help maintain remissions.

Contraindications: estar should not be applied to acutely inflamed skin or used by individuals who are known to be sensitive to coal tar.

Dosage and Administration:

Psoriasis:
The patient should massage **estar** into affected areas, once or twice per day or as directed by physician. Rub in well, allow the gel to remain for five minutes, and then remove excess by patting with tissues.

Chronic atopic dermatitis, Lichen simplex chronicus, Nummular eczema, and Seborrheic dermatitis:

One or two applications per day, as described above, are suggested. If dryness occurs, an emollient may be applied one hour after **estar.**

Caution: AFTER USING, PROTECT TREATED AREAS FROM SUNLIGHT UNLESS DIRECTED BY PHYSICIAN. DO NOT USE ON HIGHLY INFLAMED OR BROKEN SKIN. If used on the scalp, temporary discoloration of blond, bleached, or tinted hair may occur. If undue irritation develops or increases, discontinue use and consult physician. AVOID CONTACT WITH EYES. In case of contact, flush eyes with water.

Slight staining of clothing may occur. Standard laundry procedures will usually remove stains.

For complete prescribing information, see PDR.

SUPPLIED: 3 oz. plastic tube.

Balnetar®
Water-dispersible Emollient Tar

CONTAINS: WESTWOOD® TAR (Equivalent to 2.5% crude coal tar U.S.P.) mineral oil, and lanolin oil.

Balnetar is an important adjunct in the management of a wide range of dermatoses, including:

Atopic dermatitis
Psoriasis
Chronic eczematoid dermatitis
Eczematoid dermatitis
Seborrheic dermatitis

Suggested for use in modified Goeckerman regimen.

Directions:
Balnetar should always be used with water—either added to water or rubbed into wet skin.

Bath: Add 1 to 3 captuls to a tub of warm water. Do not use soap. Soak for 10 to 20 minutes. Pat dry. Frequency depends on nature and severity of condition.

Direct Application: Pat off excess with tissue or old towel to help minimize staining of clothing or linens.

Scalp Application: Mix 2 to 3 captuls with ¼ cup of water. Rub into scalp with fingertips. Apply once a day, preferably before bedtime. A therapeutic shampoo may be used the following morning.

Contraindication: Not indicated when acute inflammation is present.

CAUTION: If irritation persists, discontinue use and consult physician. In rare instances, temporary discoloration of blond, bleached, or tinted hair may occur. In rare cases, Balnetar may cause allergic irritations attributable to coal tar. Keep out of the reach of children. AVOID CONTACT WITH EYES.

PRECAUTION: After use of Balnetar, avoid exposure to sunlight unless otherwise directed by physician. GUARD AGAINST SLIPPING IN BATHTUB. TO AVOID STAINING, DO NOT USE IN FIBER GLASS BATHTUBS.

SUPPLIED: 8 fl. oz. plastic bottles.

Sebutone®
Therapeutic Tar Shampoo

CONTAINS: WESTWOOD® TAR (equivalent to 0.5% Coal Tar U.S.P.) sulfur 2% and salicylic acid 2% in SEBULYTIC® brand of unique penetrating surface-active combination of soapless cleaners and wetting agents.

CAUTION: If undue skin irritation develops or increases, discontinue use and consult physician. In rare instances, temporary discoloration of blond, bleached, or tinted hair may occur. For external use only. Keep out of the reach of children. AVOID CONTACT WITH EYES. IN CASE OF CONTACT, FLUSH EYES WITH WATER.

SUPPLIED: 4 and 8 oz. bottles and Sebutone Cream in 4 oz. tubes.

News and Notes

Dermatopathology Fellowship.—The Dermatopathology Fellowship that will be offered at the New York University School of Medicine from 1979 to 1980, is designed to prepare dermatologists and pathologists for a career in dermatopathology within a medical center environment. This will be accomplished by full participation in an active dermatopathology laboratory that will function within a department of clinical dermatology.

The fellow will learn the optimal handling of specimens in the laboratory and will study microscopically the more than 200 skin specimens that are processed daily in the laboratory. The program will include attendance at clinical conferences in the Department of Dermatology and twice-weekly dermatopathology luncheon conferences where subjects of interest will be discussed in depth. In addition, the fellow will be actively involved in planning and presenting the weekly Dermatopathology Conference.

Stipend is $18,000. Dr A. Bernard Ackerman, Director of Dermatopathology, is in charge of this program and will serve as tutor and supervisor. For further information, contact A. Bernard Ackerman, MD, 562 First Ave, New York, NY 10016, or call (212) 679-3200, ext 2766.

Dermatologic Surgery Fellowship.—The Dermatology Department of the Cleveland Clinic Foundation announces a fellowship in dermatologic surgery. This is a 12-month program intended for persons who have completed three years of an approved dermatology residency program. A minimum of 50% of the fellow's time will be devoted to intensive training and experience in Mohs' chemosurgery, which will lead to eligibility for membership in the American College of Chemosurgery. The remainder of the fellow's time will be devoted to excisional surgery, dermabrasion, hair transplantation, and other surgical modalities. Didactic material includes surgical anatomy, the biology of wound healing, and dermatopathology. Considerable emphasis will be placed on the interdisciplinary approach to cutaneous surgical problems, with ample exposure to plastic surgery, ophthalmology, otorhinolaryngology, and radiation therapy. Furthermore, research in dermatologic surgery or a related basic science area will be encouraged.

A stipend commensurate with graduate level V training will be provided by the Cleveland Clinic Educational Foundation. The first available vacancy for this fellowship is Jan 1, 1978. Inquiries should be sent to Philip L. Bailin, MD, head, Section of Chemosurgery, Department of Dermatology, Cleveland Clinic Foundation, 9500 Euclid Ave, Cleveland, OH, 44106.

Seminar.—The American Society for Dermatologic Surgery announces a seminar on dermabrasion and chemical peel Sept 30 through Oct 2, 1977 in New Orleans. The course moderator will be George Farber, MD. For further information write to Dr Farber at 144 Elk Pl, Suite 1604, New Orleans, LA 70112.

Scleroderma Research Award for 1977.—The Monterey Bay Scleroderma Foundation announces its first $1,000 annual award for scleroderma research for 1977. The establishment of an award carries with it the hope that it will act as an incentive to study this chronic disabling disease.

The award is designed for the individual or group whose investigative work in this field has been outstanding. Names of applicants for the award, together with supporting data should be submitted for consideration by Dec 1, 1977. Results of the research must have been presented at a scientific medical meeting or published in a recognized medical journal.

The award recipient will be determined by a committee of five men. If in the committees' opinion, none of the applications reflect outstanding research, no award will be given for that year. Address all communications to Denny L. Tuffanelli, MD, Department of Dermatology, University of California School of Medicine, San Francisco, CA 94143.

Skin Tumor Seminar.—There will be a seminar titled "Tumors Involving the Skin" on April 12, 1978, organized by the Department of Dermatology of Roswell Park Memorial Institute (RPMI). The chairperson is Dr Ole Holtermann. For further information contact Ms Claudia Lee, Cancer Control, RPMI, 666 Elm St, Buffalo, NY 14263.

Reference Sera and Voluntary Proficiency Testing Programs for ANA and Other Tissue Antibodies.—A reference service established in 1975 through a nonprofit foundation, the International Service for Immunology Laboratories (ISIL), offers reference sera for (1) antinuclear antibodies; (2) smooth muscle and mitochondrial antibodies; (3) thyroid cell and thyroglobulin antibodies; and (4) pemphigus and pemphigoid antibodies. This service, which affords coded and uncoded reference sera, is being extended now to comply with another need of participating laboratories. That is, in addition to reference sera with known types and titers of antibodies that are available for a handling charge of $25, self-evaluation with coded sera can now be done by one of two methods. Either laboratories receive four to six coded sera on request (as before) or an annual "blind" evaluation is done. Since specimens of the first type tend to receive more than average attention, the results are open to question. For blind evaluations laboratories provide the ISIL ten to 20 copies of their "request slips" used for their routine test requests. Participating laboratories then receive serum samples with request slips on a prearranged basis. On reporting results of routine tests, they in turn receive an evaluation of their findings and, if indicated, some suggestions for adjustments and modifications of their methods.

For further information write to ISIL, Inc, 219 Sherman Hall, SUNY/Buffalo, Buffalo, NY 14214.

Mexican Board of Dermatology.—The Mexican Board of Dermatology was founded on Feb 26, 1974 in Mexico City and officially registered on Aug 26, 1974 at the Mexican National Academy of Medicine; its foundation was announced before the secretary of health and welfare on March 7, 1975. As with all other Mexican specialty boards, the aim of the Mexican Board of Dermatology is the improvement of its specialty in the country. On July 23, 1976, the Mexican Board of Dermatology awarded, without examination and on the basis of curricula vitae only, 139 diplomas to well-known and generally recognized dermatologists who had been practicing and teaching dermatology in Mexico for many years. On July 31, 1976, fifteen young dermatologists took the first written examination, and on Oct 22, 1976, they took the corresponding oral examination. Fourteen of them passed. This year, in July and October, respectively, the board will give the second written and oral examinations.

The creation of the Mexican Board of Dermatology represents a landmark in the organization and progress of dermatology in Mexico. The 15 members of the board are, as follows: Raul Aceves, MD; Miguel Ahumada, MD; Rafael Andrade, MD (president); José Barba-Rubio, MD; Luciano Domínguez, MD; Juventino Gonzáles, MD; Amado González, MD; Antonio González-Ochoa, MD; Pedro Lavalle, MD; Ernesto Macotela, MD (secretary-treasurer); Mario Magaña, MD; Jorge Peniche, MD; Ramón Ruiz-Maldonado, MD; Amado Saúl, MD; and Jorge Vega-Núñez, MD.

Practical Dermatopathology Symposium.—This two-day symposium sponsored by the Department of Dermatology, Stanford University Medical Center, will be held at the Holiday Inn in Palo Alto, Calif, on Oct 7 and 8, 1977. The course represents an approach to dermatopathology based on types of disease processes and recognition of which affords practical methods of reaching definitive diagnoses. Time will be devoted to oral mucosal lesions, mycology, and cutaneous ultrastructure, subjects not usually included in dermatopathology courses. Exercises using projected photomicrographs will provide opportunities for self-assessment and for discussion of subjects of interest to participants. American Medical Association-accredited postgraduate seminar. For information, contact: Paul H. Jacobs, MD, Department of Dermatology, Stanford University Medical Center, Stanford, CA 94305, or phone (415) 497-6101.

Research Training Fellowship Award.—The Society for Investigative Dermatology is pleased to announce that it will again offer Research Fellowship Awards. These are designed for individuals embarking on academic careers who wish to spend one or more years working primarily in basic research. This training must be obtained under the guidance of a sponsoring investigator. The Fellowships are not intended to support individuals who have substantial teaching and/or patient care commitments. The award will provide a stipend of $16,000 per year.

Applications may be obtained from: W. Mitchell Sams, Jr, MD, Secretary-Treasurer, The Society for Investigative Dermatology, Department of Dermatology, North Carolina Memorial Hospital, Chapel Hill, NC 27514. Deadline for submitting applications is Oct 15, 1977. Awards will be announced by Dec 15, 1977, and may commence any time between Jan 1 and July 1, 1978.

Workshop in Soft Tissue Surgery.—This workshop will be held Oct 7-9, 1977, in Dallas. The University of Texas Otolaryngology programs in conjunction with The American Academy of Facial Plastic and Reconstructive Surgery offer this intensive 2½-day workshop that will emphasize the basic principles and concepts in soft tissue surgery and their use in clinical situations. Didactic lectures, faculty panels, videotapes, and problem case solving sessions will be presented by a multidisciplined faculty. Laboratory periods will be conducted for practicing suture techniques, design of local skin flaps, and methods of scar camouflage. Tuition (includes $30.00 worth of instruments) is $110 for residents and $185 for practicing physicians. For information contact: Jack P. Gunter, MD, Course Coordinator, Office of Continuing Education, University of Texas Health Science Center at Dallas, 5323 Harry Hines Blvd, Dallas, TX 75235.

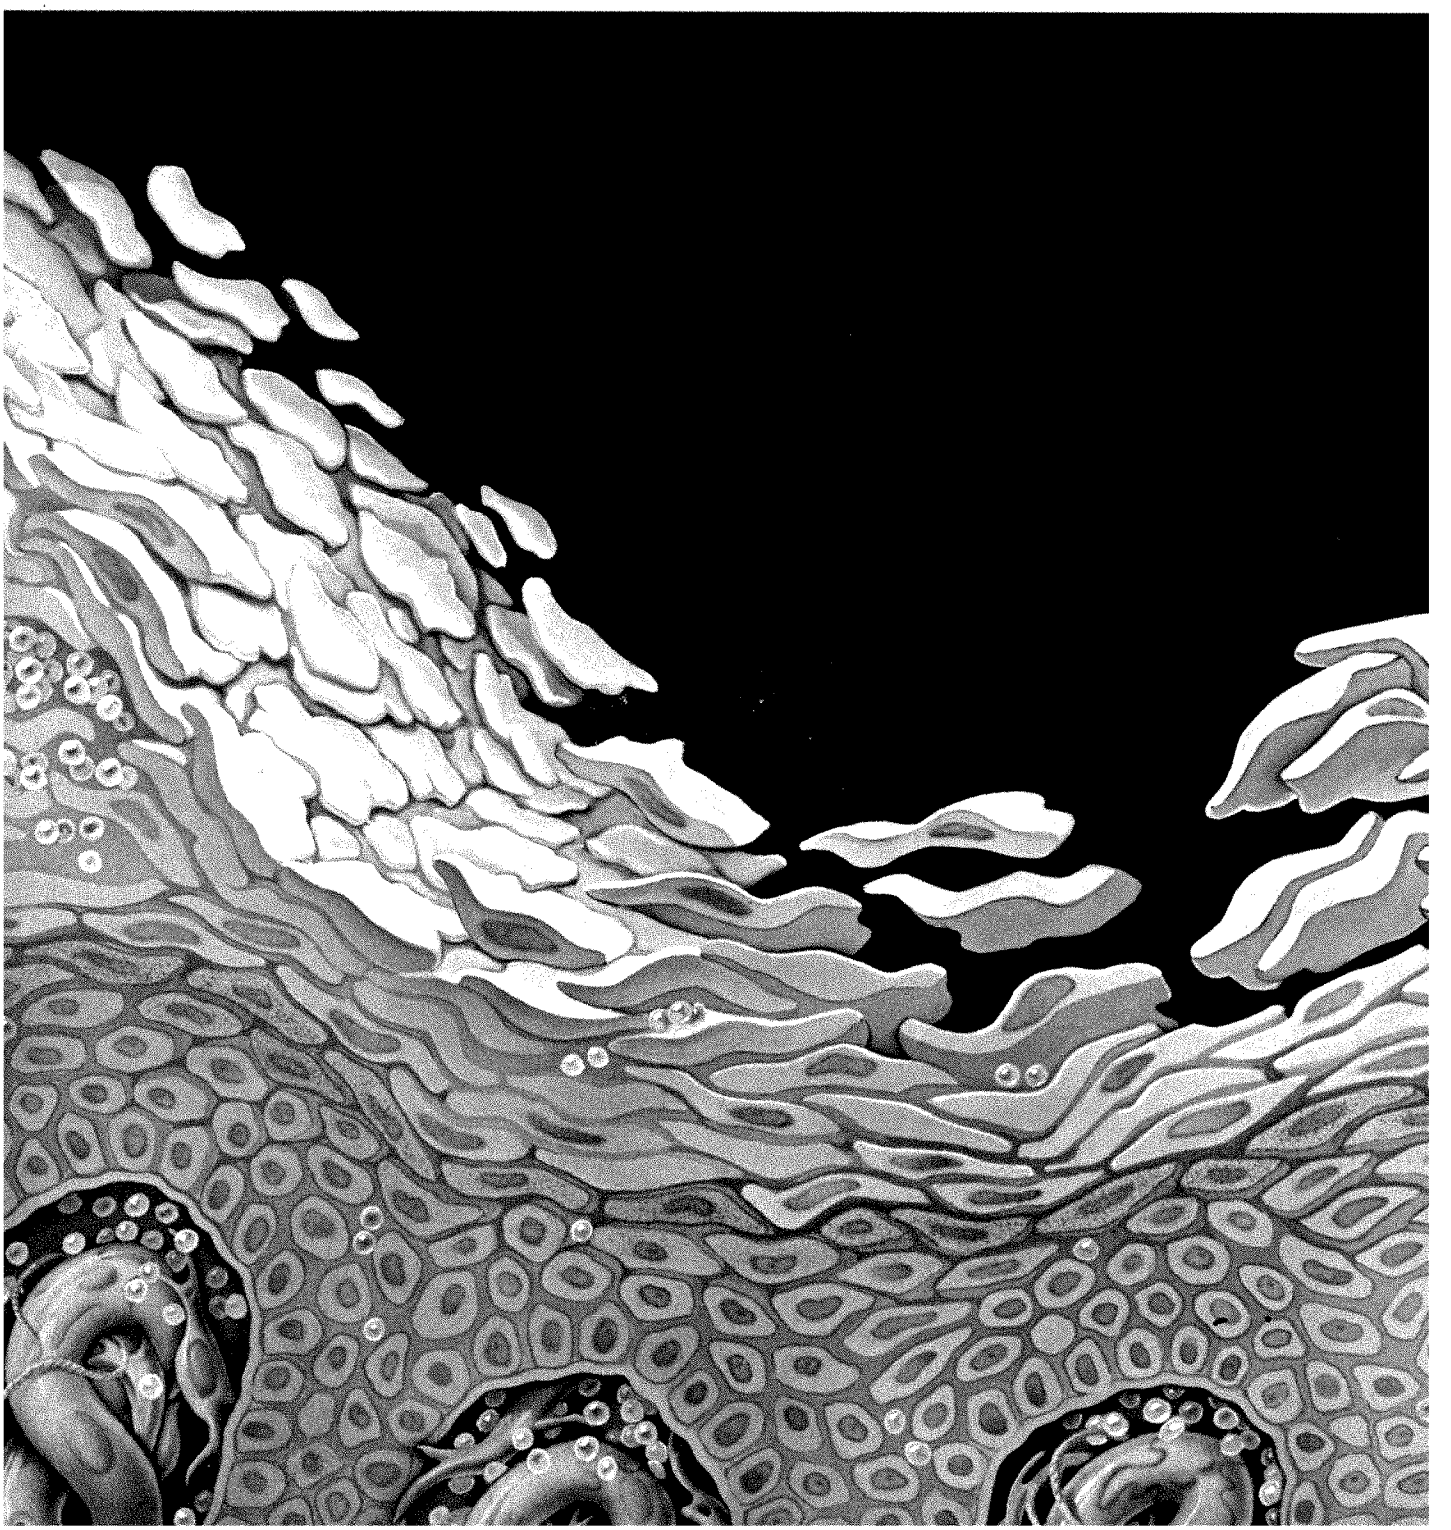
Fourth South African Dermatological Congress.—The Dermatological Group of the Medical Association of South Africa will hold its fourth congress in the Kruger National Park (Game Reserve), Aug 23 to 26, 1978. Principal speakers will be Dr Harry Arnold, from the United States, Professors Malcolm Greaves and Wilson Jones, from England, Dr Colin Ramsay, from Canada, and Dr Mali, from the Netherlands. In addition to topics on purely dermatological themes, there will be a symposium on skin diseases in and caused by animals, in which veterinarians who work in the game reserve will participate. Meeting times will be arranged so that there will be ample time for the viewing of wild game. For information contact the Congress Organizer, PO Box 6705, Johannesburg 2000, Republic of South Africa.

PSORIASIS
The Capricious Dermatosis

LIDEX® (fluocinonide) 0.05%
A Stabilizing Influence

Psoriasis. Mere mention of the word can make an afflicted patient cringe. And, because of the capricious, unpredictable nature of the disease, the patient rarely knows where or when it will recur.

Obviously, the goal is control. And, though varied treatment modalities are available today, none offers universal



efficacy for all patients, all of the time.

Yet, very often a highly effective topical steroid, like Lidex, (fluocinonide) can help stabilize psoriasis.

Lidex. A highly effective topical steroid with anti-inflammatory, vasoconstrictive, antipruritic actions.

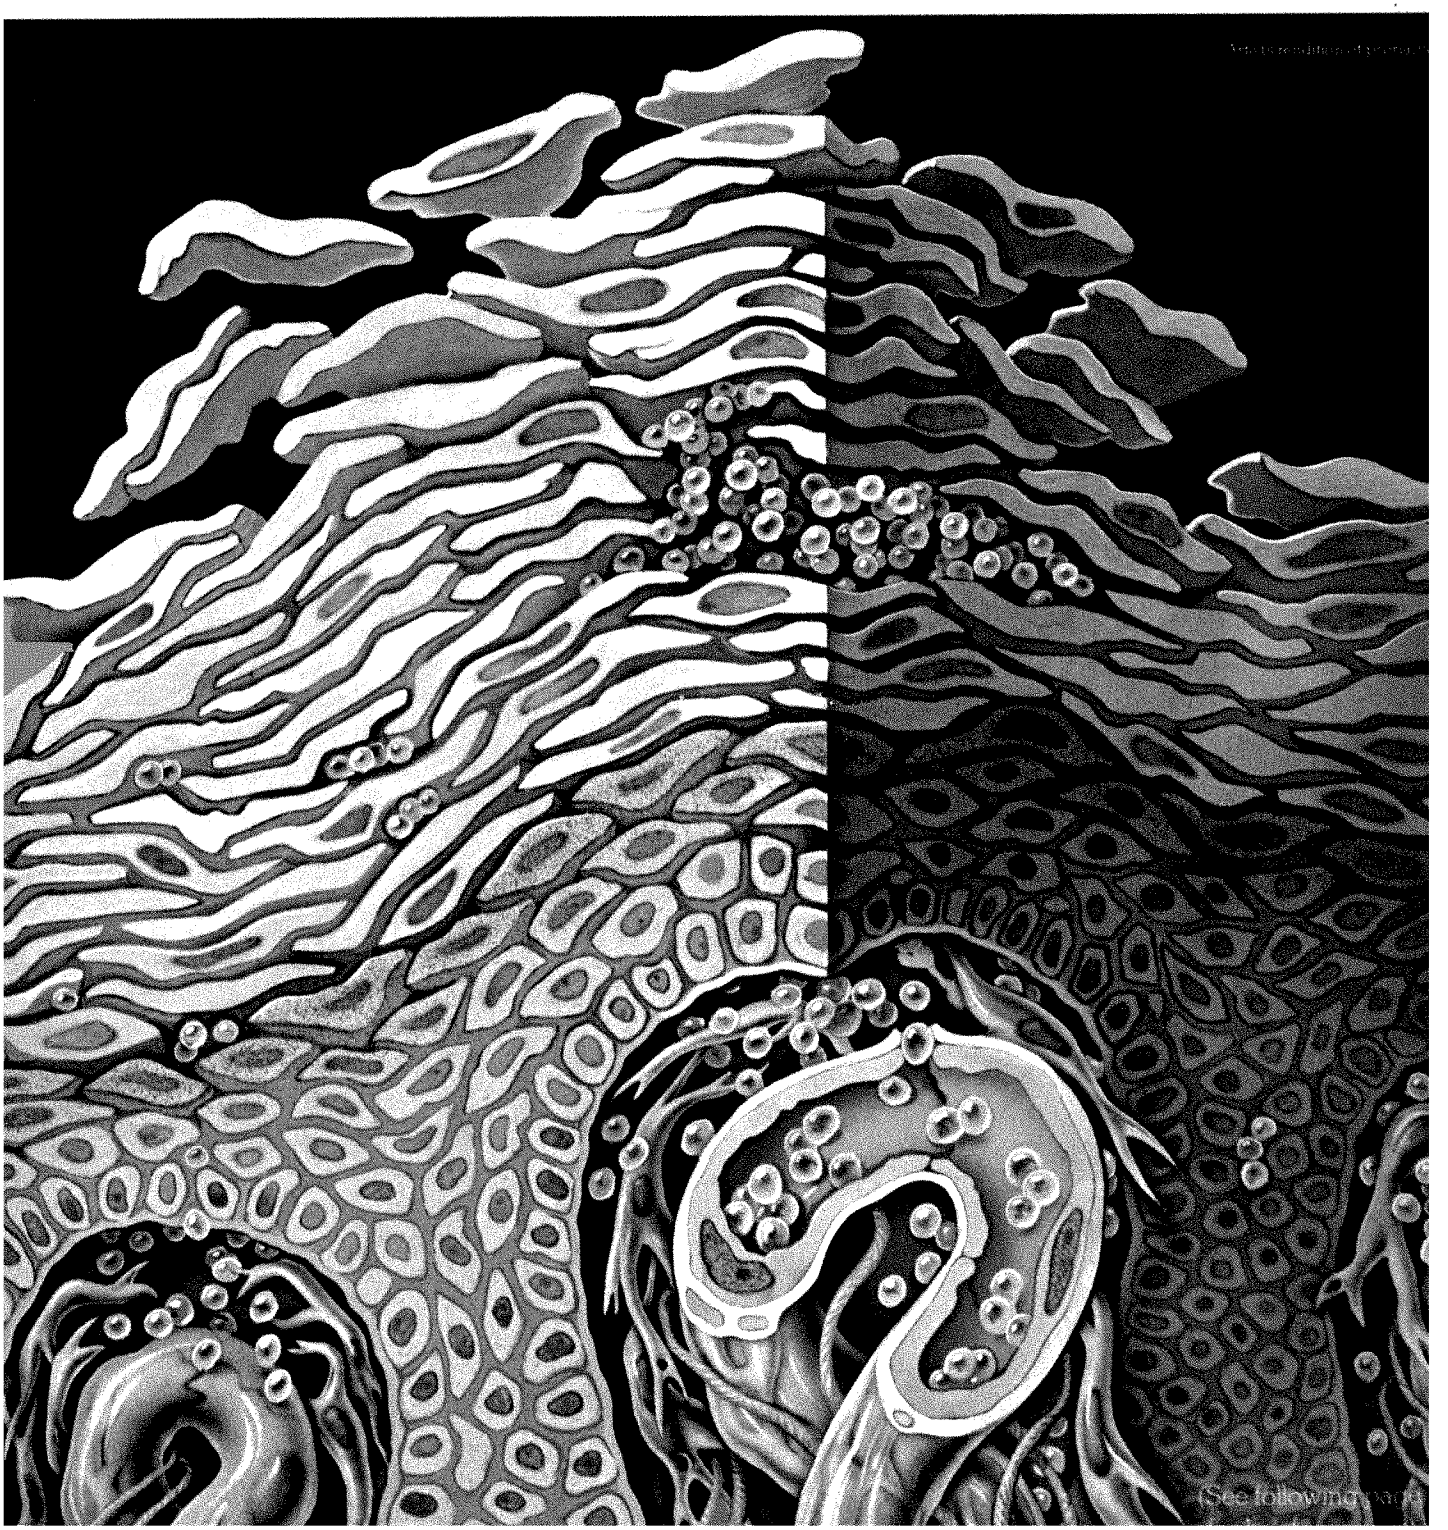
100% dissolved for optimal penetration, important in stages that exhibit thickened, scaly lesions.

Totally free of preservatives.

Available in cream, ointment, and Topsyn® (fluocinonide) gel.

SYNTEX

SYNTEX LABORATORIES, INC.
PALO ALTO, CALIFORNIA 94304



LIDEX® (fluocinonide)
0.05% Cream and Ointment

TOPSYN® (fluocinonide)
0.05% Gel

Summary of prescribing information

Description
LIDEX cream 0.05%, LIDEX ointment 0.05% and TOPSYN gel 0.05% contain the active compound fluocinonide. Fluocinonide, which is the 21-acetate ester of fluocinolone acetonide, has the chemical formula 6α, 9α, -difluoro-11β, 16α, 17α, 21-tetrahydroxypregna-1,4-diene-3, 20-dione, cyclic 16, 17-acetal with acetone 21-acetate. LIDEX cream contains fluocinonide in FAPG® cream, a specially formulated cream base consisting of stearyl alcohol, polyethylene glycol 6000, propylene glycol, 1, 2, 6-hexanetriol and citric acid. This white cream vehicle is greaseless, non-staining, anhydrous and completely water miscible. The base provides emollient and hydrophilic properties. In this formulation, the active ingredient is totally in solution.

LIDEX ointment contains fluocinonide in a specially formulated ointment base consisting of Amerchol CAB (mixture of sterols and higher alcohols), white petrolatum, propylene carbonate and propylene glycol. It provides the occlusive and emollient effects desirable in an ointment. In this formulation the active ingredient is totally in solution.

TOPSYN gel contains fluocinonide in a specially formulated gel base consisting of propylene glycol, propyl gallate, disodium edetate, and Carbopol 940 (carboxypolymethylene) with NaOH and/or HCL added to adjust the pH. This clear, colorless, thixotropic vehicle is greaseless, non-staining and completely water miscible. In this formulation, the active ingredient is totally in solution.

Indications
LIDEX cream and ointment and TOPSYN gel are intended for the relief of inflammatory manifestations of corticosteroid responsive dermatoses.

Contraindications
Topical steroids are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions
If irritation develops, the cream, ointment or gel should be discontinued and appropriate therapy instituted. In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted.

If a favorable response does not occur promptly, the corticosteroid cream, ointment or gel should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, the possibility exists of increased systemic absorption and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

LIDEX® (fluocinonide) cream and ointment and TOPSYN® (fluocinonide) gel are not for opthalmic use.

Adverse reactions
The following local adverse reactions have been reported with topical corticosteroids:

burning	folliculitis
itching	acneform eruptions
irritation	hypopigmentation
dryness	striae
secondary infection	skin atrophy

Dosage and administration
A small amount should be gently massaged into the affected area three or four times daily, as needed.

How supplied
LIDEX 0.05% Cream—15 g 30 g and 60 g tubes.
LIDEX 0.05% Ointment—15 g 30 g and 60 g tubes.
TOPSYN Gel 0.05% 15 g and 60 g tubes.

Dermik

Dermik Laboratories, Inc.
Fort Washington, Pa., U.S.A. 19034

SULFACET-R® LOTION

DESCRIPTION—Sulfacet-R* Acne Lotion contains (as dispensed) sodium sulfacetamide 10% and microsize sulfur 5% in a flesh-tinted lotion of purified water, alkyl-aryl sulfonic acid salts, hydroxyethylcellulose, propylene glycol, xanthan gum, lauric myristic diethanolamide, polyoxyethylene laurate, cyclohexanediamine tetraacetic acid, butylparaben, methylparaben, silicone emulsion, talc, zinc oxide, titanium dioxide, attapulgite, iron oxides, pH buffers and 2-bromo-2-nitropropane-1, 3-diol.

ACTIONS—Provides keratolytic, peeling, drying and antiseborrheic action.

INDICATIONS—An aid in the treatment of acne vulgaris, acne rosacea and seborrheic dermatitis.

CONTRAINDICATIONS—This product is contraindicated for use by patients having known hypersensitivity to sulfonamides, sulfur or any other component of this preparation. Not to be used by patients with kidney disease.

PRECAUTIONS—For external use only. Keep away from eyes. If irritation develops, discontinue use and consult physician. Sensitivity to sodium sulfacetamide may occur. Therefore, caution and careful supervision should be observed when prescribing this drug for patients who may be prone to hypersensitivity to topical sulfonamides. Particular caution should be employed if areas of denuded or abraded skin are involved. Patients should be carefully observed for possible local irritation or sensitization during long term therapy. Occasionally, certain individuals may be sensitive to one or more components of this preparation. The object of this therapy is to achieve desquamation without irritation, but sodium sulfacetamide and sulfur can cause reddening and scaling of the epidermis. These side effects are not unusual in the treatment of acne vulgaris, but patients should be cautioned about the possibility. Keep out of the reach of children.

ADVERSE REACTIONS—Previous toxic reactions such as agranulocytosis, acute hemolytic anemia, purpura hemorrhagica, drug fever, jaundice and contact dermatitis indicates hypersensitivity to sulfonamides.

DIRECTIONS—Shake well before using. Apply a thin film 1 to 3 times daily with light massaging to blend in each application in accordance with the physician's directions. Each package contains a "Dermik Color Blender" which enables the patient to alter the basic shade of the lotion so that it matches the skin color exactly.

[Important to the Pharmacist—At the time of dispensing, add contents of vial* to the bottle. Shake well and/or stir with a glass rod to insure a uniform dispersion. Place expiration date of four (4) months on bottle label.]

*"Sulfa-Pak" vial contains 2.4 grams of sodium sulfacetamide.

HOW SUPPLIED—Bottle, 1 oz.

CAUTION—Federal law prohibits dispensing without prescription.

...benzoyl peroxide gel from Owen

- Proven effective in reduction of total lesions
- Cosmetically elegant vehicle
- Promoted to dermatologists only

Description: benzac™ 5 contains benzoyl peroxide 5%, polyoxyethylene lauryl ether 6%, alcohol 30% (w/w), dimethicone, carbomer 940, di-isopropanolamine, citric acid, fragrance and purified water. benzac™ 10 contains benzoyl peroxide 10%, polyoxyethylene lauryl ether 6%, alcohol 30% (w/w), dimethicone, carbomer 940, di-isopropanolamine, citric acid, fragrance and purified water.

Actions: benzac™ is an effective aid in the topical treatment of acne vulgaris. benzac™ provides drying, desquamating action, and has been shown to have antibacterial effects against Propionibacterium (Corynebacterium) acnes.

Indications: An adjunctive topical therapy for the control of acne vulgaris.

Contraindications: Not to be used by patients having known sensitivity to benzoyl peroxide or any other ingredients of the preparation.

PRECAUTIONS: FOR EXTERNAL USE ONLY. Avoid contact with the eyes, eyelids, and other mucous membranes. May bleach hair and colored fabrics. **KEEP THIS AND ALL DRUGS OUT OF THE REACH OF CHILDREN.**

Dosage and Administration: After washing with a mild cleanser and water, apply once or twice daily. The degree of drying and peeling can be adjusted by modification of the dosage schedule.

How Supplied: benzac™ 5, 60 gram tubes benzac™ 10, 60 gram tubes

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

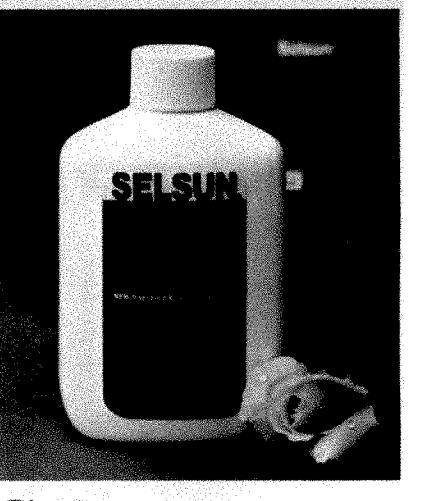
SUBSCRIPTION RATES: The yearly rate of the ARCHIVES OF DERMATOLOGY is as follows: United States and US Possessions, one year, $18; two years, $28; all other countries, one year, $28; two years, $38. Special yearly price to residents, interns and medical students in the United States and US Possessions, $9.

THE ARCHIVES OF DERMATOLOGY is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.



Selsun®
(SELENIUM SULFIDE LOTION, U.S.P.) ℞

Brief Summary

Contains:
Selenium sulfide, 2½%, w/v; bentonite; lauric diethanolamide; ethylene glycol monostearate; titanium dioxide; amphoteric—2; sodium lauryl sulfate; sodium phosphate (monobasic); glyceryl monoricinoleate; citric acid; captan; perfume; and water.

Indications:
For the treatment of dandruff and seborrheic dermatitis of the scalp.

Contraindications:
Should not be used by patients allergic to any of its components.

Warnings:
Safety for use on infants has not been established.

Precautions:
Cutaneous sensitization of the scalp or adjacent areas has been reported; if sensitivity reactions should occur, discontinue use. Chemical conjunctivitis may result if product enters the eyes. Do not use when acute inflammation or exudation is present as an increase in absorption may occur.

Adverse Reactions:
As with other shampoos, oiliness or dryness of the hair and scalp may occur following use; there have been occasional reports of an increase in the amount of normal hair loss. Hair discoloration may occur; can be avoided or minimized by thorough rinsing.

YOUR TEEN-AGE PATIENTS PROBABLY WON'T CARRY FACE CLOTHS... BUT THEY MIGHT CARRY

THERAPADS PLUS®

TO COMPLEMENT ANY ACNE REGIMEN

☐ CONVENIENT CLEANSING— ANYTIME, ANYWHERE

Therapads Plus provide effective cleansing and drying actions to remove excess surface oiliness... cleanse deeply, thoroughly, and antiseptically. Therapads Plus are pleasantly scented and saturated with a colorless solution of 70% ethyl alcohol, 1.5% salicylic acid, and 0.1% sodium alkyl aryl polyether sulfonate.

☐ HELP CONTROL OILY SKIN, BLACKHEADS, ACNE

Used 2 or 3 times a day—such as midmorning, midafternoon, and bedtime—Therapads Plus help keep skin clean, and free from oil between soap-and-water washings; also help dry existing blemishes.

Therapads Plus—available in boxes of 30 foil-wrapped pads. Therapads (regular)—available in jars of 40 and 100.

LENOX HILL HOSPITAL
Announces a Symposium on

TUMORS OF THE EYELIDS, ORBIT AND OCULAR ADNEXA

October 27, 28, 1977

This Symposium will be devoted to the diagnosis, pathogenesis and treatment of tumors of the eyelids and orbit, emphasizing basal cell carcinoma of the eyelids. The course will be presented by outstanding ophthalmologists, ophthalmic plastic surgeons, plastic surgeons, x-ray therapists, dermatologists, immunotherapists, cryosurgeons and pathologists.

The format will consist of lectures, panel discussions, surgical films and videotapes of surgery.

THE FACULTY WILL INCLUDE:
Albert Hornblass, M.D., Course Director
Crowell Beard, M.D.
Edgar Berry, M.D.
Charles Beyer, M.D.
Lazlo Biro, M.D.
Martin Bodian, M.D.

It's a distressing, disabling and costly disease

And, now there's a monograph that looks at all aspects of the disease from recent epidemiological data to advisable therapeutic regimens. Morton's **Gonorrhea** discusses all the advances made since the mid-1960's and provides references. Emphasis is placed on the sound scientific routines of clinical examination, laboratory methods, epidemiological follow-up of sex contacts and control measures. Each individual chapter is complete with references. Remember when the question concerns gonorrhea, the answer's in our book!

By **R.S. Morton**, MD. Consultant Venereologist, Royal Infirmary, Sheffield. About 300 pp. Illustd. About $25.00. Just Ready

Please address communications concerning accepted or published communications to: AMA Specialty Journals, 535 N Dearborn St, Chicago, IL 60610.

Conditions for Acceptance of Color Illustrations

Illustrations in full color are accepted for publication in ARCHIVES OF DERMATOLOGY if the editor believes that color will add significantly to the published manuscript.

When color illustrations are accepted, the American Medical Association will pay part of the expense of reproduction and printing, the remainder to be borne by the author or the institution with which he is affiliated. After deducting AMA's contribution, the author's share is $275 for up to six square finished illustrations. Additional illustrations and special effects, such as outlining, opaquing, or surprinting, will be billed to the author at cost.

Color transparencies must be submitted for evaluation. Do not send color prints unless accompanied by original transparencies. If transparencies are mounted in frames or glass, the material should be carefully packed in gauze and sent with the manuscript in a separate container or between two pieces of pressboard.

Advertising and Subscription Information

ADVERTISING OFFICES: 535 N Dearborn St, Chicago, IL 60610, Area Code 312, 751-6000; and 600 Third Ave, New York, NY 10016, Area Code 212-867-6640.

ADVERTISING PRINCIPLES: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

CHANGE OF ADDRESS: Please notify the publisher at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

Instructions for Authors

Send manuscripts by first-class mail to the Chief Editor, John H. Epstein, MD, 450 Sutter St, San Francisco, CA 94108. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

Author Responsibility.—All accepted manuscripts are subject to copy editing. The author will receive an edited typescript rather than galley proofs for approval. The author is responsible for all statements in his work, including changes made by the copy editor.

Designate one author as correspondent and provide his address and telephone number. Order reprints at the time the typescript is returned after editorial processing. Specify address to which requests for reprints should be sent.

Manuscript Preparation.—Submit an original typescript and two high-quality copies of the entire manuscript. All copy (including references, legends, and tables) must be typed double-spaced on 22 × 28-cm (8½ × 11-inch), heavy-duty white bond paper. Ample margins should be provided.

Refer to patients by number (or, in anecdotal reports, by fictitious given names). Real names or initials should not be used in the text, tables, or illustrations.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines, if possible. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Style of Writing.—The style of writing should conform to acceptable English usage and syntax. Slang, medical jargon, obscure abbreviations, and abbreviated phrasing are to be avoided.

Informed Consent.—Manuscripts reporting the results of experimental investigations of human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Abstract.—Provide an abstract (135-word maximum) of the article, including statements of the problem, method of study, results, and conclusions. The abstract replaces the summary.

References.—List references in consecutive numerical order (not alphabetically). Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communications should not be listed as references. References to journal articles should include (1) author, (2) title, (3) journal name (as abbreviated in *Index Medicus*), (4) volume number, (5) inclusive page numbers, and (6) year, in that order. References to books should include (1) author(s), (2) chapter title (if any), (3) editor (if any), (4) title of book, (5) city of publication, (6) publisher, and (7) year. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. The author is responsible for the accuracy and completeness of the references and for their correct text citation.

Metrication.—All measurements must be in metric units. English units may also be given parenthetically if the measurements were originally done in English units.

Illustrations.—Use only those illustrations that clarify and augment the text. Submit illustrations in duplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Magnification and stain should be provided when pertinent. Illustrations should preferably be in a proportion of 12.5 × 18 cm (5 × 7 inches).

An experienced medical illustrator should be employed whenever possible for the preparation of all artwork. Template lettering or preset type is preferred to hand-lettered labels. If halftone artwork with labels is submitted, affix type and leaders to a clear acetate overlay registered to the base drawing. Labels and leaders should be applied directly to the drawing board surface if the artwork consists only of line ink technique.

Illustrations in full color are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay part of the expense of reproduction and printing color illustrations, the remainder to be borne by the author or his sponsor. After deducting the ARCHIVES contribution, the author's share is $275.00 for up to six square-finished illustrations that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35 mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies. All transparencies should be carefully packed and sent with the manuscript.

Legends.—Legends should be typed double-spaced, beginning on a separate sheet of paper. Length should be limited to a maximum of 40 words.

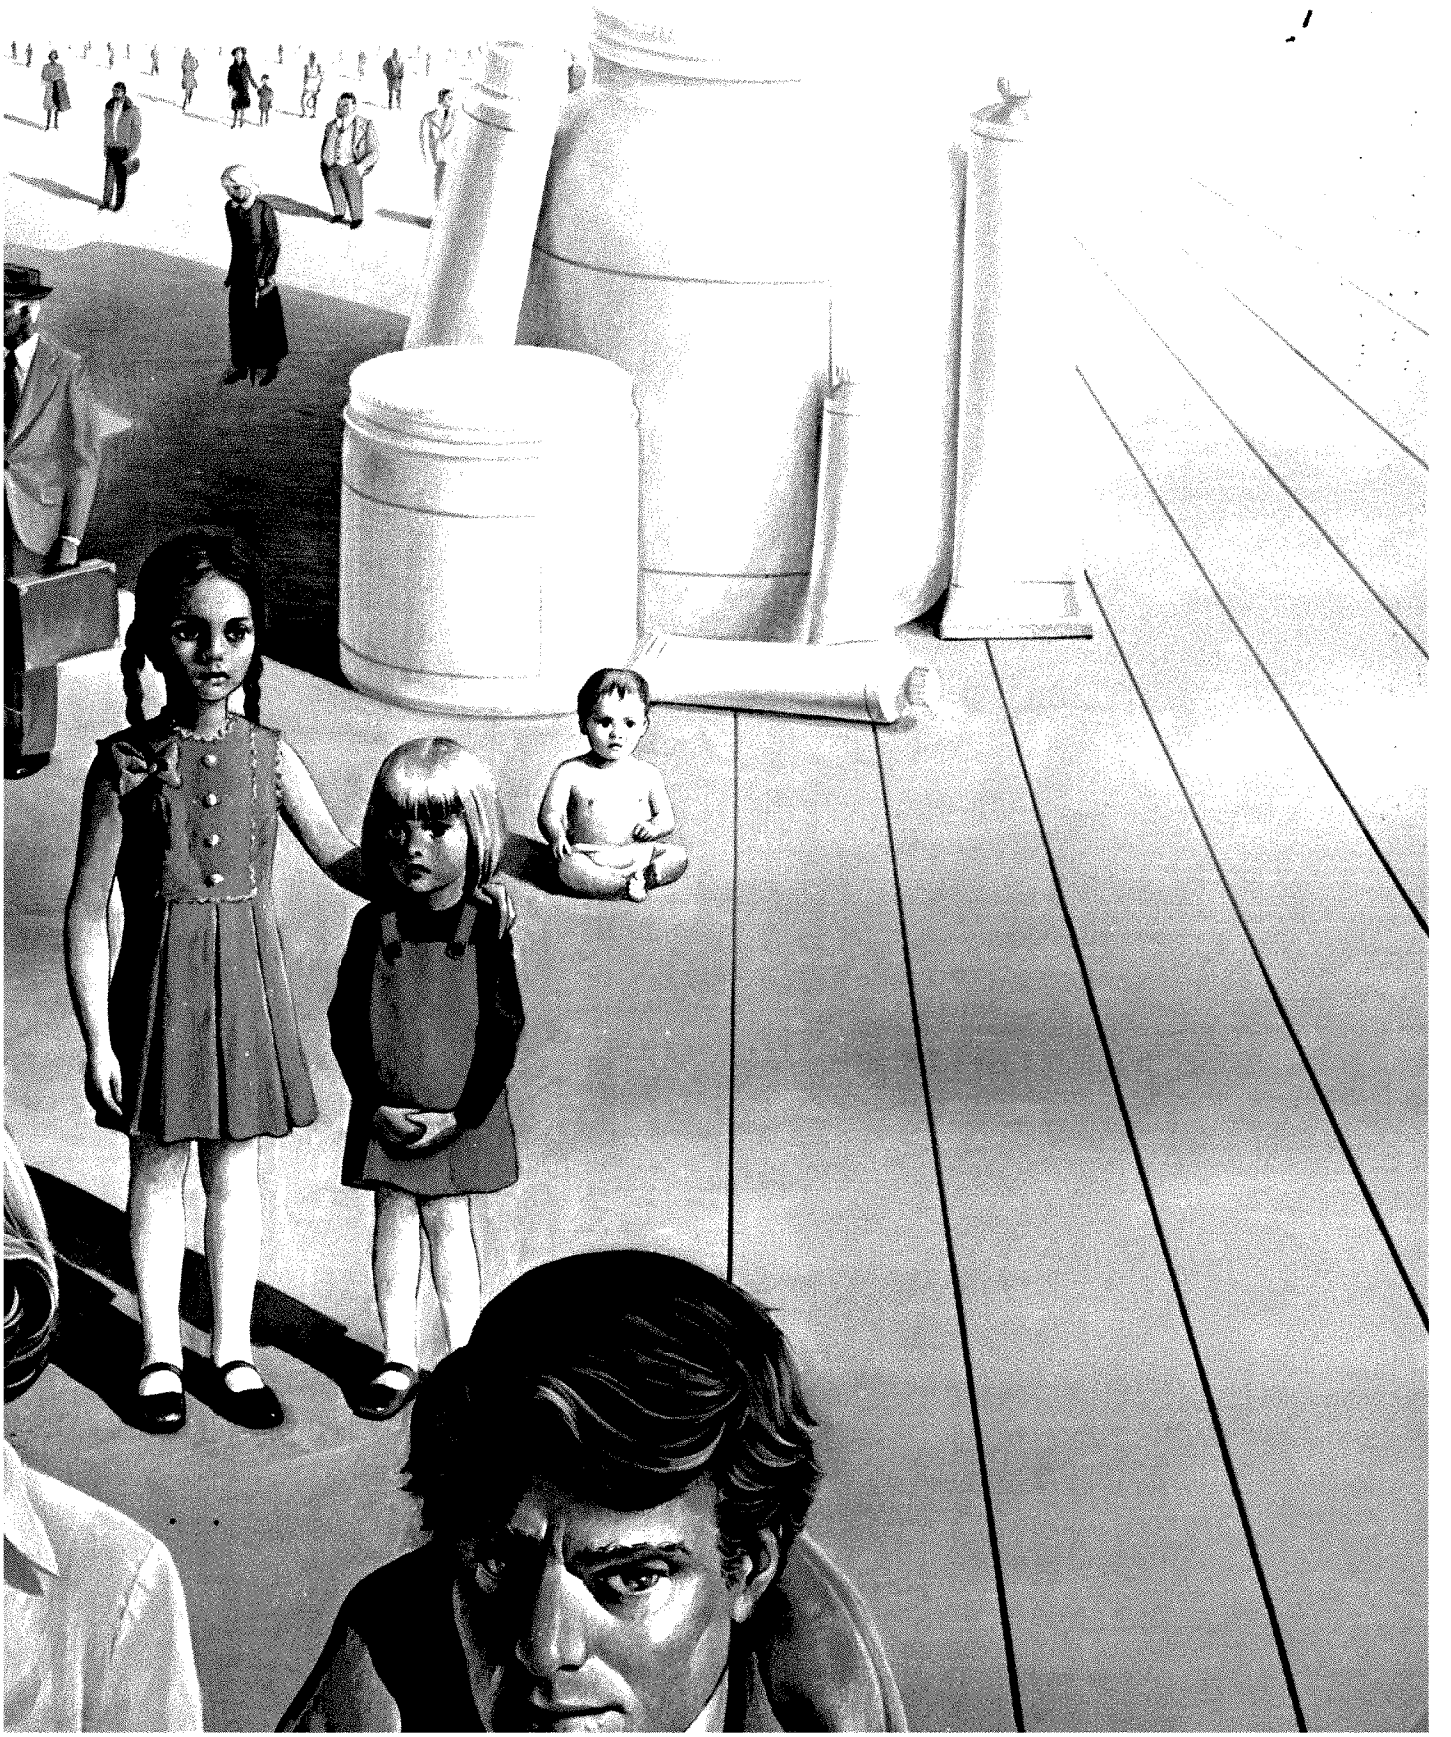
Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: author(s), title of article, title of journal or book, volume number, page(s), month, and year. The publisher's permission to reprint should be submitted to the ARCHIVES after the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluations should include the name and affiliation of the statistical reviewer.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm (8½ × 11-inch) paper. Do not use larger size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

They're individuals...
(with individual skin problems)



Aristocort® lets you treat them that way!

Triamcinolone Acetonide

Versatility

A dosage form and strength for every patient...every type of indicated steroid-responsive dermatosis

Economy

A variety of sizes to meet all therapeutic needs and maximize economy

Experience

Fluorinated topical effectiveness—confirmed over almost 20 years of clinical use

Elegance

Cosmetically pleasing. Without sensitizers, such as parabens, phenol preservatives and lanolin.

Supplied as:

0.1% and 0.025% Creams: in 15 and 75 Gm. tubes and ½ and 5¼ lb. jars
0.5% Cream: in 15 Gm. tubes and ½ lb. jars
0.1% Ointment: in 15 and 75 Gm. tubes and ½ and 5¼ lb. jars
0.5% Ointment: in 15 Gm. tubes and ½ lb. jars
ARISTOGEL® Triamcinolone Acetonide Gel 0.1%: in 15 and 75 Gm. tubes.

Indications: For relief of inflammatory manifestations of corticosteroid-responsive dermatoses.
Contraindications: Viral skin diseases, such as varicella and vaccinia; hypersensitivity to any component (not for ophthalmic use); when circulation is markedly impaired.
Warnings: Safety of use in pregnancy has not been absolutely established. Do not use extensively, in large amounts, or for prolonged periods of time in pregnant patients.
Precautions: If irritation develops, discontinue use and institute appropriate therapy. In infections, use appropriate antifungal or antibacterial agents; if a favorable response does not occur promptly, discontinue the corticosteroid until the infection is adequately controlled. If [illegible] areas are treated or the occlusive technique is used, increased systemic absorption of the corticosteroid may occur; take suitable precautions.
Adverse Reactions: (local) Burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.
Supplied: *Cream 0.5%*—Per Gm.: triamcinolone acetonide 5 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; *Cream 0.1%*—Per Gm.: triamcinolone acetonide 1 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; *Cream 0.025%*—Per Gm.: triamcinolone acetonide 0.25 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; all potencies are in a water base of mono and diglycerides, squalane, polysorbate 80 USP, polysorbate 60, cetyl esters wax NF, stearyl alcohol USP, Tenox II, and sorbitol solution USP, *Ointment 0.5%*—Per Gm.: triamcinolone acetonide 5 mg.; inactive ingredient: white petrolatum; *Ointment 0.1%*—Per Gm.: triamcinolone acetonide 1 mg.; inactive ingredient: white petrolatum. *ARISTOGEL® GEL 0.1%*—Per Gm.: triamcinolone acetonide 1 mg., 1.8% benzyl alcohol as preservative; inactive ingredients in a water base: polysorbate 80 USP, polyoxyethylene (20) cetyl ether, glycerin USP, and citric acid USP.

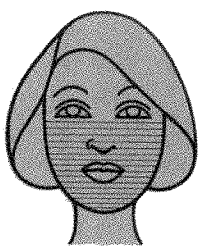
Four indications for Komed® HC Acne Lotion

Komed HC reduces inflammation as it keeps skin dry and desquamating with non-comedogenic sodium thiosulfate[1]

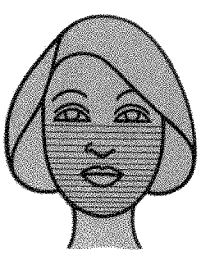
1.

When you wish to alternate severe acne medication with acne medication that will reduce erythema and irritation



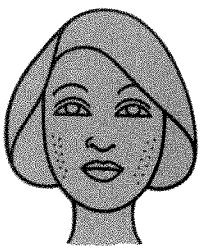
2.

When severe acne medication has been effective and you want to maintain acne control with minimal irritation



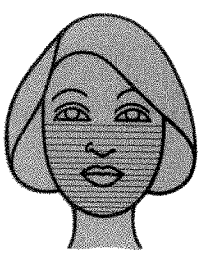
3.

When you determine that initial use of severe acne medication is not indicated



4.

When reducing the inflammation associated with acne vulgaris is an important consideration



Besides its ability to reduce inflammation, patients appreciate the invisibility of Komed HC. It dries rapidly to a transparent film to be worn unseen or used as the base for makeup.

Contraindications Contraindicated for herpes simplex, chickenpox, smallpox, tuberculous ulcers and fungal infections.
Warning Although there have been no reports of topical steroids having adverse effects on pregnant patients, the safety of their use has not been established. Therefore, they should not be used extensively, in large amounts, or for prolonged periods of time during pregnancy.
For acne conditions not requiring the anti-inflammatory effects of hydrocortisone, KOMED lotion or KOMED MILD lotion are recommended.
Precautions If signs of irritation or sensitivity develop, discontinue use. If infections due to bacteria or fungi appear during therapy, appropriate measures should be taken. The anti-inflammatory action of hydrocortisone may mask the presence of infection. Do not use on or about the eyes.
Caution U.S. Federal law prohibits dispensing without a prescription.

[1]Mills OH Jr, Kligman AM "Is Sulphur helpful or harmful in acne vulgaris?" Br J Derm 86:620, 1972

"Suspensions and creams containing elemental sulphur were shown to be capable of inducing comedones in the rabbit ear and on human backs."

Allergic
Dermatose

rat, and rabbit, induced fetal abnormalities in the rat at doses substantially above the human therapeutic range. Clinical data in human beings are inadequate to establish safety in early pregnancy. Until such data are available, hydroxyzine is contraindicated in early pregnancy.

Precautions: Hydroxyzine may potentiate the action of central nervous system depressants such as meperidine and barbiturates. In conjunctive use, dosage for these drugs should be reduced. Because drowsiness may occur, patients should be cautioned against driving a car or operating dangerous machinery.

Adverse Reactions: Drowsiness may occur; if so, it is usually transitory and may disappear in a few days of continued therapy or upon dosage reduction. Dryness of the mouth may occur with higher doses. Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with higher than recommended dosage

Supply: Tablets, containing 10 mg, 25 mg, or 50 mg hydroxyzine hydrochloride, 100's and 500's; Tablets, containing 100 mg, 100's; Syrup, containing 10 mg per teaspoonful (5 ml) and ethyl alcohol 0.5% v/v, pint bottles.

Before prescribing or administering, see package circular.

with strong emotional overlay

the cause can be obscure

Factors precipitating allergic dermatoses with strong emotional overlay, which can range from allergens to anxiety, can be difficult to identify.

successful treatment often includes

Atarax®
(hydroxyzine HCl)

TABLETS: 10 mg, 25 mg, 50 mg, and 100 mg

- rapid antianxiety action
- demonstrated antihistaminic activity

ROERIG Pfizer

gets to deep fungal infec

when topicals can't.

Potent, systemic fungistat

GRISACTIN provides the antifungal activity needed to control tinea infections, including onychomycosis, that invade the dermis and deeper regions. Systemic action penetrates where topical action often fails.

GRISACTIN is effective against a wide range of fungi: *Trichophyton rubrum, T. mentagrophytes, T. tonsurans, T. interdigitalis, T. verrucosum, T. megnini, T. gallinae, T. crateriform, T. sulphureum, T. schoenleini, Microsporum canis, M. audouini, M. gypseum,* and *Epidermophyton floccosum.*

Peak serum levels are usually produced in about four hours with a single 500 mg. tablet. To meet the requirements of different patients—depending on body weight, age, severity, and location of infection—dosage is easily individualized with 125 mg. and 250 mg. capsules, and 500 mg. tablets.

Brand of
Griseofulvin (microsize)

Indications: Griseofulvin is indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: *Tinea corporis, Tinea pedis, Tinea cruris, Tinea barbae, Tinea capitis, Tinea unguium* (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, T. tonsurans, T. mentagrophytes, T. interdigitalis, T. verrucosum, T. megnini, T. gallinae, T. crateriform, T. sulphureum, T. schoenleini, Microsporum audouini, M. canis, M. gypseum, Epidermophyton floccosum.*
NOTE: Prior to therapy, the type of fungi responsible for the infection should be identified.
The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone.
Griseofulvin is *not* effective in the following: Bacterial infections, candidiasis (moniliasis), histoplasmosis, actinomycosis, sporotrichosis, chromoblastomycosis, coccidioidomycosis, North American blastomycosis, cryptococcosis (torulosis), *Tinea versicolor,* nocardiosis.
Contraindications: This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of hypersensitivity to griseofulvin.
Warnings: *Prophylactic Usage*—Safety and efficacy of griseofulvin for prophylaxis of fungal infections has not been established.
Animal Toxicology—Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin, once a week, during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorigenicity, these studies were not of adequate design to form a basis for conclusions in this regard.
In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals.
Usage in Pregnancy—The safety of this drug during pregnancy has not been established.
Animal Reproduction Studies—It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress.
Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this.
Precautions: Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic, and hematopoietic, should be done.
Since griseofulvin is derived from a species of Penicillium, the possibility of cross-sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty.
Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated.
Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy.
Barbiturates usually depress griseofulvin activity and concomitant administration may require a dosage adjustment of the antifungal agent.
Adverse Reactions: When adverse reactions occur, they are most commonly of the hypersensitivity type such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities.
Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs.
When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.
Dosage and Administration: Accurate diagnosis of the infecting organism is essential. Medication must be continued until the infecting organism is completely eradicated as indicated by appropriate clinical or laboratory examination. General measures in regard to hygiene should be observed to control sources of infection or reinfection. Concomitant use of appropriate topical agents is usually required, particularly in treatment of *tinea pedis.*
Dosage should be individualized, depending on age and severity of infection. *Adults*—0.5 Gm. daily (125 mg. q.i.d., 250 mg. b.i.d., or 500 mg./day). *Children*—10 mg./kg. daily is usually adequate (from 30 to 50 lb., 125 mg. to 250 mg. daily; over 50 lb., 250 mg. to 500 mg. daily, in divided doses).
How Supplied: GRISACTIN [griseofulvin (microsize)]—No. 442—GRISACTIN 125, each capsule contains 125 mg., in bottles of 100 and 500. No. 443—GRISACTIN 250, each capsule contains 250 mg., in bottles of 100 and 500. No. 444—GRISACTIN 500, each tablet (scored) contains 500 mg., in bottles of 60.

The American Retired Physicians Association:

Here's how it can help you plan—and have—a more rewarding retirement

The American Retired Physicians Association (ARPA) is the first and only national organization created specifically to serve the special needs and interests of retired, semi-retired, and soon-to-retire physicians and their spouses. It offers a wide variety of benefits that can significantly contribute to making your retirement everything you hoped for. They include:

- Group travel
- Insurance programs
- Discount information
- Retirement lifestyles
- Expert financial advice
- Opportunities for service
- Information resource bank
- Current medical news
- Bi-monthly *Newsletter*

To be eligible for membership, you must be a physician —or physician's widow—at least 55 years of age. Annual dues are only $20 for a voting member (MDs); $15 for a non-voting member (non-MD, widow-widower). For more information and/or to join, return this coupon today!

IS AQUACARE®/HP TOO MUCH FOR EVERYDAY DRY SKIN?

IF IT WEREN'T SO SAFE AND COSMETICALLY ELEGANT THE ANSWER MIGHT BE YES.

AQUACARE®/HP HYDRATES, SOFTENS AND SOOTHES CHRONIC, SCALING, PRURITIC CONDITIONS . . . WHETHER MILD OR SEVERE.

The keys to a more efficient medical practice

AMA Practice Management Publications

An efficient medical practice requires sound business management. By applying proven management techniques, you can improve the efficiency and profitability of your practice and--most important of all--have more time to devote to your patients.

These AMA Practice Management Publications, developed with the help of medical management consultants, are designed to provide you with the latest techniques and procedures in the management of your practice. Whether you are a new physician who must make immediate decisions about setting up your practice or an established physician who wants to increase the efficiency of your practice, these publications are an invaluable source.

TO ORDER: Write Order Department, American Medical Association, 535 N. Dearborn, Chicago, IL. 60610. Please specify title, OP number, and include payment with your order.

Publications

1 **The Business Side of Medical Practice** (OP-410) $2.00
Guide to basic management principles. Includes: deciding how to practice; selecting a location; setting up an office; financing; legal hurdles; insurance; mechanics of providing good medical service; billings and collections; human relations.

2 **Planning Guide for Physicians' Medical Facilities** (OP-439) $2.00
Provides guidelines and general principles to help you determine the criteria for selecting a medical office that best suits your needs. Includes: basic planning before building; office construction, inside and out; your office interior; office condominiums.

3 **Medicolegal Forms with Legal Anaysis** (OP-109) $1.25
Contains medicolegal forms, with legal analysis and citations of court decisions, for the more common interactions between patients and their physicians and hospitals, such as: consent and informed consent; patient's right to privacy; confidentiality of records; physician-patient relationship.

4 **Preparing a Patient Information Booklet** (OP-441) $.30
A guide for preparing a general information booklet for your patients on your specialty and type of practice.

5 **Talking with Patients** (OP-450) $.30
Provides proven psychological principles and specific examples on how to improve office-patient relations in telephone communications.

6 **Medical Collection Methods** (OP-448) $25.00
A "how to" cassette/workbook program designed to train medical assistants in the most effective collection techniques.
Extra Workbooks (OP-449) $2.00 each

7 **Professional Corporations in Perspective** (OP-102) $3.25
1977 publication which features: economic factors, advantages and disadvantages of incorporation; effect of ERISA on professional corporations; choosing a retirement plan; and managing a professional corporation.

8 **New Doctor's Kit** (OP-458) $10.00
Contains: **The Business Side of Medical Practice; Planning Guide for Physicians' Medical Facilities; AMA Publications Lists; Group Practice Guidelines; Current Procedural Terminology** order form; Uniform Health Insurance Claim Form; **Medicolegal Forms; Talking with Patients; Preparing a Patient Information Booklet;** AMA membership information; Placement Service; and bibliography on billing systems, recording keeping systems, etc.

9 **Group Practice Kit** (OP-457) $7.50
Contains: **Group Practice Guidelines; Professional Corporations in Perspective;** medicolegal reprints on such subjects as: professional liability, confidentiality, informed consent, etc.; samples of model legal agreements for a physician and employed associate, office sharing, medical partnerships, and forming a corporation.

wash it. dry it. peel it.

Fostex,® the flexible therapeutic acne wash that degreases, dries, and peels. Easily integrated with all topical or systemic therapy for acne Grades I, II, and III. Convenient and economical Fostex Liquid and Cream are also effective anti-seborrheic shampoos for oily scalps associated with acne. Available as Fostex Cream in 4½ oz. jars, Fostex Cake in 3¾ oz. bars, and Fostex Liquid in 5 oz. plastic bottles.

Fostril,® the flesh-tinted drying and peeling lotion that conceals as it heals. Adaptable to Grades I, II, or III acne, Fostril is available in 1 oz. plastic tubes.

Transact,® the transparent medicated acne gel. A thin film of Transact will dry the oiliest of skin and is ideal for acne on chest, shoulders, and back. Greaseless, nonstaining, with a fresh clean fragrance. In 1 oz. plastic tubes.

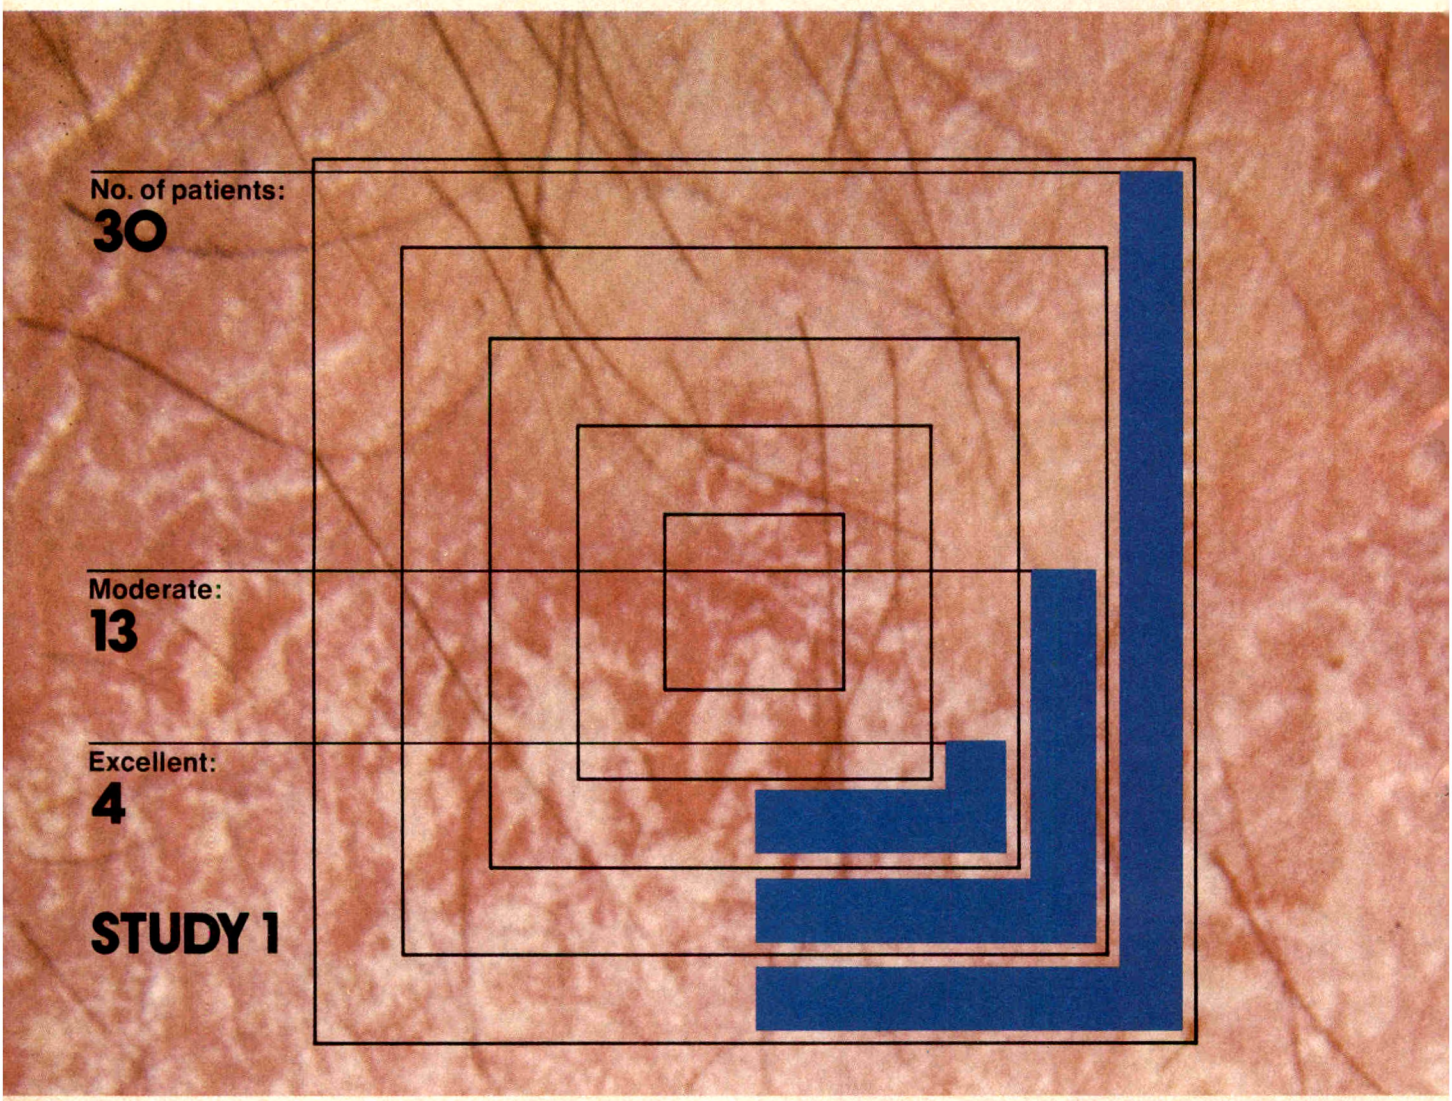
New measures of response in psoriasis patients



■ ARISTOCORT-A (Triamcinolone Acetonide 0.1%) Cream was applied t.i.d. without occlusion for 14 days, by a total of 60 patients with psoriasis, in 2 similar studies.*

■ The % of moderate or excellent response was 57% in Study 1 and 50% in Study 2. A combined overall response rate of 90% was achieved if 22 patients showing slight response are included.*

■ Overall patient acceptance of the Cream in both these studies was high, when evaluated against 10 criteria.

*Data on file, Lederle Laboratories, Dept. of Medical Research

New studies show 50-57% moderate or excellent response in 14 days

INDICATIONS: For relief of inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS: Viral skin diseases, such as varicella and vaccinia; hypersensitivity to any component (not for ophthalmic use); when circulation is markedly impaired.

WARNINGS: Safety of use in pregnancy has not been absolutely established. Do not use extensively, in large amounts, or for prolonged periods of time in pregnant patients.

PRECAUTIONS: If irritation develops, discontinue use and institute appropriate therapy. In infections, use appropriate antifungal or antibacterial agents; if a favorable response does not occur promptly, discontinue the corticosteroid until the infection is adequately controlled. If extensive areas are treated or the occlusive technique is used, increased systemic absorption of the corticosteroid may occur; take suitable precautions.

ADVERSE REACTIONS: (local) Burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.

ARISTOCORT A CREAM: Each gram of ARISTOCORT A contains 0.25 mg. (0.025%), 1 mg. (0.1%) or 5 mg. (0.5%) of the highly active steroid, Triamcinolone Acetonide (a derivative of triamcinolone) in AQUATAIN, a specially formulated base composed of emulsifying wax NF, isopropyl palmitate, glycerin USP, sorbitol solution USP, lactic acid, 2% benzyl alcohol and purified water. AQUATAIN is non-staining, water-washable, paraben-free, spermaceti-free and has a light texture and consistency.

ARISTOCORT A OINTMENT: Each gram of ARISTOCORT A Ointment contains 1 mg. (0.1%) or 5 mg. (0.5%) of the highly active steroid, Triamcinolone Acetonide (a derivative of triamcinolone) in a specially formulated base composed of emulsifying wax NF, white petrolatum, and propylene glycol. In addition, the 0.1% Ointment contains Tenox II and lactic acid.

An excellent blend of clinical efficacy and cosmetic acceptance. Now indicated for seborrheic dermatitis.

Obviously, efficacy is foremost in your mind when you recommend a therapeutic shampoo. And efficacy, coupled with cosmetic acceptability, usually guarantees a successful therapeutic course.

That's why Head & Shoulders is so highly regarded in the treatment of dandruff.

Clinically effective

For years, Head & Shoulders has proved effective in the treatment of dandruff—whether for initial therapy or long-term control. And now, research shows that Head & Shoulders is effective in the treatment of seborrheic dermatitis.*

Cosmetically pleasing

Head & Shoulders lathers well, has a pleasant odor and appearance, and need not be left on the scalp for an extended period of time. Also, it leaves hair clean, manageable, and attractive.

Head & Shoulders®

You'll like it for its therapeutic benefits. Your patients will like it for its cosmetic appeal.

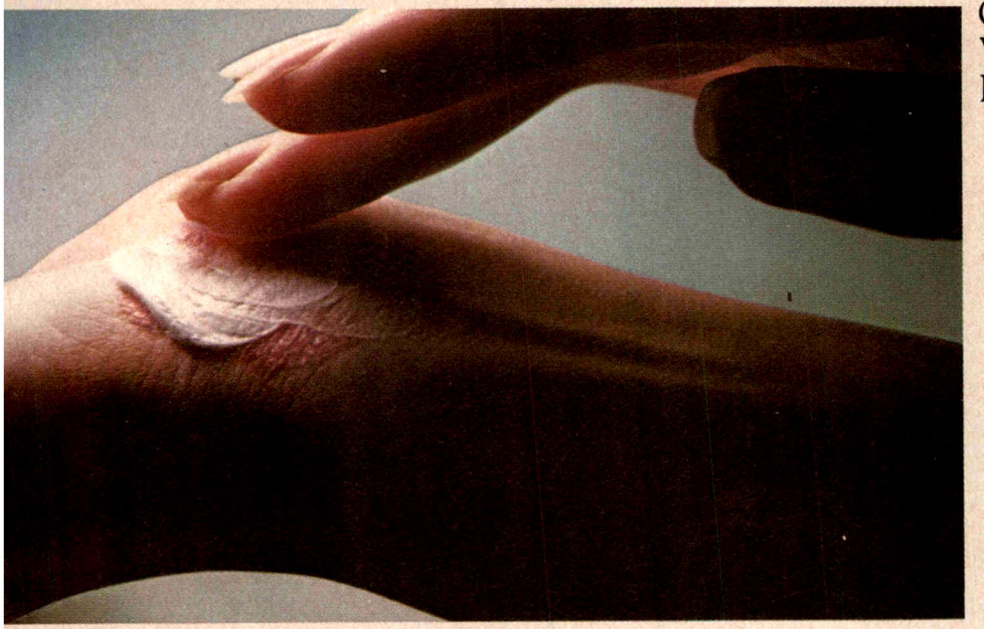
HOECHST-ROUSSEL PHARMACEUTICALS INCORPORATED

Announces a New topical fluorinated corticosteroid in a Unique Emollient Cream Base

NEW TOPICORT
(DESOXIMETASONE)

THE SPECIALLY DEVELOPED, PRESERVATIVE-FREE BASE COMBINES THE EMOLLIENCE OF AN OINTMENT WITH THE COSMETIC ACCEPTABILITY OF A CREAM IN A WATER-IN-OIL EMULSION.



Well-documented efficacy and safety: Anti-inflammatory, antipruritic, vasoconstrictive Topicort (desoximetasone) has been demonstrated safe and effective in relieving the inflammatory manifestations of corticosteroid-responsive dermatoses.

Worldwide clinical experience: For up to 4 years, Topicort (desoximetasone) has been marketed by Hoechst in over 30 foreign countries. Extensive clinical trials in the United States, conducted by 23 investigators under a wide variety of climatic conditions, confirm the many years of worldwide experience.

A wide range of conditions in corticosteroid-responsive dermatoses: Topicort (desoximetasone) is useful on wet as well as dry lesions, in both acute and chronic cases, with a profile of adverse reactions similar to that seen with other topical corticosteroids.

Emollient Cream 0.25%

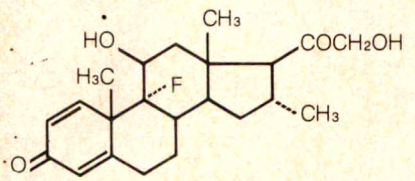
Available: 15-gram tubes.
In corticosteroid-responsive dermatoses
Convenient B.I.D. dosage.

Please consult full prescribing information on following page.

Q7103J-677

TOPICORT®(desoximetasone) EMOLLIENT CREAM 0.25%

Description: Topicort® (desoximetasone) Emollient Cream 0.25% contains the active synthetic corticosteroid desoximetasone. The chemical name of desoximetasone is 9α - fluoro - 11β, 21 - dihydroxy - 16α - methylpregna - 1,4 - diene-3,20-dione. The chemical structure is:



Each gram of Topicort® (desoximetasone) Emollient Cream 0.25% contains 2.5 mg desoximetasone in an emollient cream consisting of isopropyl myristate, cetylstearyl alcohol, white petrolatum, mineral oil, lanolin alcohol and purified water.

Actions: Topicort® (desoximetasone) Emollient Cream is primarily effective because of its anti-inflammatory, antipruritic and vasoconstrictive actions.

Indications: Topicort® (desoximetasone) Emollient Cream is indicated for the relief of inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications: Topical steroids are contraindicated in vaccinia, varicella and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

Precautions: If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled.

Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time, or if occlusive technique is used.

If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Adverse Reactions: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria.

Dosage and Administration: Apply a thin film of Topicort® (desoximetasone) Emollient Cream 0.25% to the affected skin areas twice daily. Rub in gently.

How Supplied: Topicort® (desoximetasone) Emollient Cream 0.25% is supplied in 15-gram tubes.

Sulfoxyl® Lotion Regular ℞
Sulfoxyl® Lotion Strong
Composition: Sulfoxyl Lotion Regular contains 5% benzoyl peroxide and 2% sulfur; Sulfoxyl Lotion Strong contains 10% benzoyl peroxide and 5% sulfur, each in a lotion base formulated with polyethylene glycol monostearate, stearic acid, glycerol monostearate, isopropyl palmitate, propylene glycol, zinc soap and purified water.
Indications: Use as a topical aid in the treatment of acne.
Dosage and Administration: After cleansing the skin, smooth Sulfoxyl Lotion gently into the affected areas, once daily for three days. If no discomfort is felt, frequency of application can then be increased to twice daily. The amount of drying and desquamation can be modified by adjusting the dosage schedule.
Contraindications: Patients with a known sensitivity to benzoyl peroxide, sulfur or any of the other formulation ingredients should not use these medications.
Precautions: For external use only. Avoid contact with eyes, mucous membranes and sensitive areas of the neck. Notify physician if excessive dryness or irritation occurs or increases.
Keep from heat.
Caution: Patients should be warned that these formulations may bleach colored linens, towels and apparel.
How Supplied: 1.0 ounce plastic bottles.
Caution: Federal law prohibits dispensing without prescription.

Benoxyl® 5 and 10 Lotion: Benoxyl 5 contains 5% benzoyl peroxide and Benoxyl 10, 10% benzoyl peroxide in a grease-free washable lotion base.
How Supplied: 1 oz. and 2 oz. plastic bottles.

PanOxyl® 5, PanOxyl® 10 ℞
Composition: PanOxyl 5 contains 5% Benzoyl Peroxide. PanOxyl 10 contains 10% Benzoyl Peroxide. PanOxyl 5 and PanOxyl 10 also contain 6% polyoxyethylene lauryl ether and 40% ethyl alcohol in a gel base formulated with colloidal magnesium aluminum silicate, hydroxypropylmethylcellulose, citric acid and purified water.
Action and Uses: The topical use of PanOxyl 5 and PanOxyl 10 provides therapeutic control of acne through drying and desquamative action, as well as providing antiseptic activity.
Indications: Use as an aid in the treatment of acne.
Dosage and Administration: Apply 1 or more times daily to affected areas. Washing the face with soap and water prior to application greatly enhances the efficacy of the medication.
Contraindications: Patients with a known sensitivity to Benzoyl Peroxide should not employ these medicatons.
Precautions: For external use only. Avoid contact with the eyes or mucosal membranes. Very fair individuals should always be started on a single application at bedtime, allowing the medication to remain on the skin overnight. PanOxyl may bleach colored fabrics.
How Supplied: 2 oz. and 4 oz. plastic tubes.
Caution: Federal law prohibits dispensing without prescription.

Three Dimensions of Acne Care

The widest range of benzoyl peroxide formulations gives you maximum therapeutic flexibility

New Sulfoxyl® Lotion

The drying and desquamating effects of sulfur added to benzoyl peroxide can be particularly valuable in acne complicated by excessive oiliness. "...Sulfur with benzoyl peroxide ...produces a greater keratolytic effect than either substance alone."[1] The exfoliative properties of sulfur can help benzoyl peroxide to penetrate deeper into sebaceous follicles.

Two Strengths:
Sulfoxyl® Lotion Regular (5% benzoyl peroxide and 2% sulfur) and Sulfoxyl® Lotion Strong (10% benzoyl peroxide and 5% sulfur) in a grease-free washable base.

Benoxyl® Lotion

A good way to start benzoyl peroxide therapy. Benzoyl peroxide alone has been described as "a triple action drug: (1) it suppresses *C. acnes* in vivo; (2) it is comedolytic and (3) it is a counter-irritant."[3]

Two Strengths
Benoxyl® 5 Lotion (5% benzoyl peroxide) and Benoxyl® 10 Lotion (10% benzoyl peroxide) in a grease-free washable base.

PanOxyl® Gel

"The most potent forms of benzoyl peroxide are the new alcohol gels such as PanOxyl. Once the gel is applied to the skin, the solvent evaporates and deposits a concentrated form of depot free-radical oxygen which...is capable of penetrating into the sebaceous follicles and suppressing the *C. acnes*. This topical agent is much more effective in suppressing the fatty acids and the bacterial counts than systemic tetracycline and also produces a more rapid clinical improvement... No new lesions usually appear after 3 weeks and after 2 months the patient is usually free of the acne problem."[2]

Two Strengths:
PanOxyl® 5 Gel (5% benzoyl peroxide) and PanOxyl® 10 Gel (10% benzoyl peroxide) in an alcohol gel base.

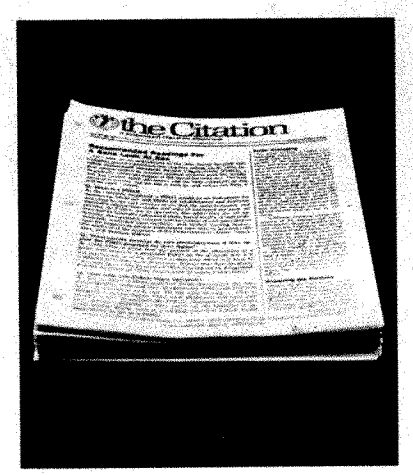
The $25 investment that could save you from a malpractice suit

One in every 10 physicians now faces a malpractice suit, and 40% will lose their cases, according to a study by a major insurance company. And every fourth doctor can count on at least one malpractice suit during his career.



What you can do to protect yourself

If you know your legal obligations to your patients and are aware of the problem areas that can lead to potentially dangerous situations, you could significantly reduce the odds of a malpractice suit.

You get exactly that kind of vital information from THE CITATION, a twice monthly publication of the American Medical Association's Office of the General Counsel. The price: only $25 for a year's subscription of 25 issues.

Learn prevention from the experience of others

THE CITATION brings you summaries of actual malpractice cases involving claims of abandonment, negligence, mistaken diagnosis, therapeutic procedure, lack of consent, and many more. Each summary is a concise report of a case, including background, evidence, defense, and decision.

Here's what reading THE CITATION regularly can mean to you:

- Learning the problem areas and from the experience of others so you can avoid similar situations.
- Developing a keener insight into situations that can create trouble.
- Being aware of the kinds of medical cases for which you should seek consultation.
- Gaining a better understanding of the laws, and their applications to specific cases.

In addition, THE CITATION provides information on every kind of legal problem you can expect to encounter in your practice.

Can you afford to be without it?

The odds being what they are for a malpractice suit, the physician who doesn't know how to take every possible precaution is courting trouble. *Prevention* is the best possible defense against a malpractice suit; and THE CITATION is the *best* way to learn how to avoid the problem areas.

A one-of-a-kind publication

THE CITATION is the only publication, at any price, that provides comprehensive coverage, on a nationwide basis, of all areas of the law that have impact on the practice of medicine.

The wisest $25 investment you can make

When you think of the money, time, and aggravation THE CITATION could save you, $25 for a one year subscription is a very small price indeed. Take a minute right now to subscribe. Fill out the form below and send it, along with your payment, to the address indicated.

Uticort™

(betamethasone benzoate)

a highly effective topical steroid in a special base

UTICORT contains the fluorinated corticosteroid ester — betamethasone benzoate 0.025% — in a specially formulated, clear, self-liquefying gel base to increase steroid activity.

Patients with seborrheic dermatitis treated with UTICORT improved 86% in an average of 11.6 days.

liquefies on application for better surface contact

UTICORT is especially valuable in the treatment of seborrheic dermatitis on hairy areas of the body.

cosmetically acceptable

UTICORT dries to a clear film and can be used confidently on either smooth or hairy skin areas. Moreover, it is greaseless, nonstaining, and nonsticky.

preservative free

Contains no parabens or other potentially sensitizing preservatives.

Brief summary of prescribing information

INDICATIONS. Uticort Gel (betamethasone benzoate) is intended for relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS. Topical steroids are contraindicated in viral diseases of the skin, such as varicella and vaccinia. Topical steroids are contraindicated in patients with a history of sensitivity to any of the components of the preparation.

This preparation is not for ophthalmic use.

PRECAUTIONS. If irritation develops, the gel should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid, and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, or in large amounts, or for prolonged periods of time.

Due to the alcohol content of the vehicle, Uticort Gel (betamethasone benzoate) may cause mild, transient stinging without irritation if used on excoriated skin.

ADVERSE REACTIONS. The following local adverse reactions have been reported with topical corticosteroids: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruptions, and hypopigmentation.

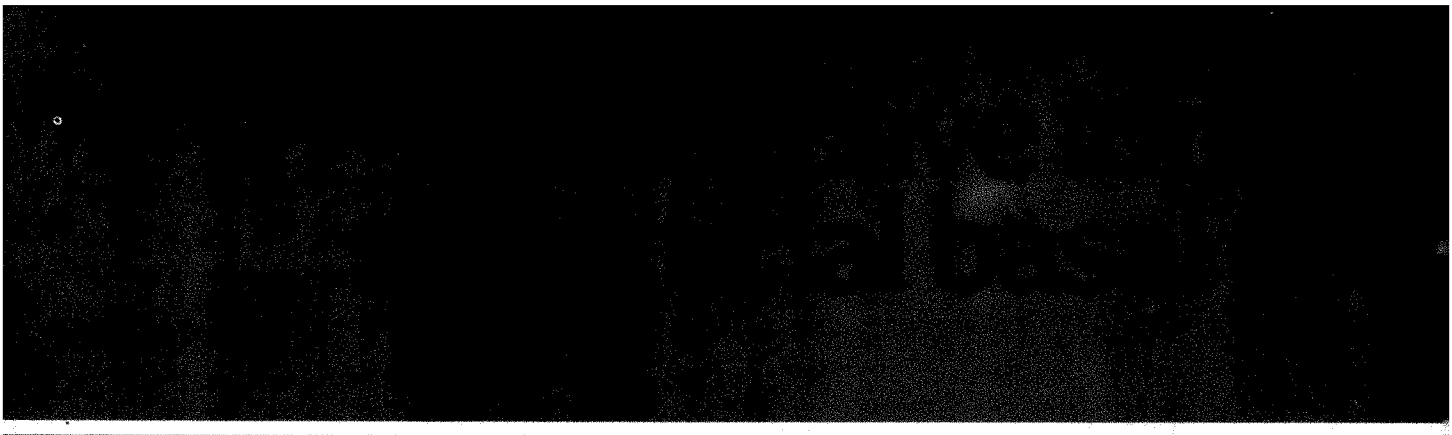
DOSAGE AND ADMINISTRATION. Apply to affected areas two to four times daily as needed.

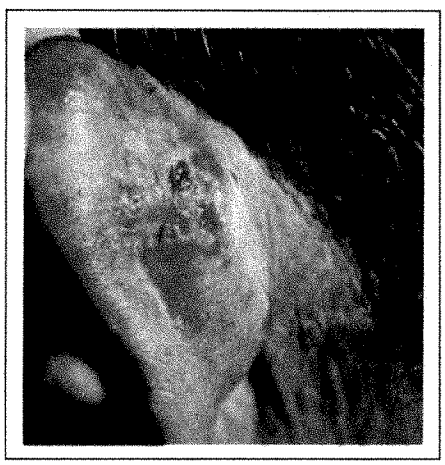
HOW SUPPLIED. N 0071-3025 Uticort Gel is supplied in 15-g and 60-g tubes.

Caution: Federal law prohibits dispensing without prescription.

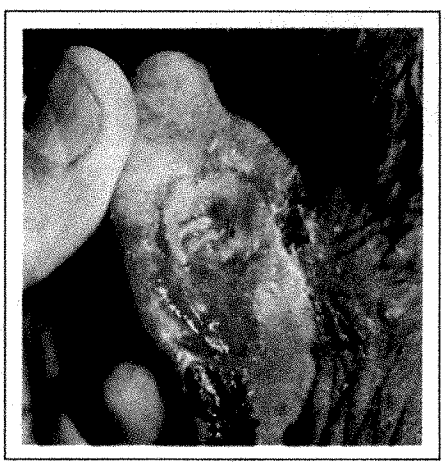
PARKE-DAVIS

PARKE, DAVIS & COMPANY, Detroit, MI 48232





2/6/70—Before treatment a 3.0 cm lesion was present behind left ear. Biopsy revealed it to be a superficial basal cell carcinoma. Treatment with Efudex (fluorouracil) 5% Cream was begun.



5/1/70—After 11 weeks' therapy, lesion site was necrotic and escharified; surrounding skin showed minimal inflammation. Treatment was terminated 4/24/70.

9/10/70—Area completely healed; posttreatment biopsy revealed no further carcinoma.

6/15/72—Patient 25 months posttreatment. No evidence of recurrence.

Management of superficial basal cell carcinoma is often complicated by multiple lesions which extend over large areas of the body. Until now, primary treatment has been surgery or radiation therapy. However, these modalities may be followed by scarring and disfigurement.

Topical chemotherapy with Efudex (fluorouracil) 5% is a valuable alternative when conventional methods are impractical. For example, it is an effective agent for the concurrent treatment of superficial lesions over large areas of the body, or for use on difficult treatment sites.

Although during treatment with Efudex the lesion and some of the surrounding skin may become inflamed and blistered temporarily, final results are cosmetically gratifying, with minimal or no scarring.

Efudex 5% Cream offers the dermatologist:

- An effective topical alternative to surgery for multiple lesions and difficult treatment sites.
- Cosmetically gratifying results, with minimal or no scarring. No systemic toxicity.
- Convenient, economical b.i.d. application. Apply with care near eyes, nose and mouth; wash hands immediately afterward if applied with fingers.

Efudex® 5% Cream
fluorouracil/Roche
An exclusive Roche formulation
Also available as 5% Efudex Solution

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Multiple actinic or solar keratoses; superficial basal cell carcinomas when conventional methods are impractical (5% strength only).

Contraindications: If occlusive dressing is used, may increase inflammatory reactions in adjacent normal skin. Avoid prolonged exposure to ultraviolet rays. Safe use in pregnancy not established.

Precautions: If applied with fingers, wash hands immediately. Apply with care near eyes, nose and mouth. Solar keratoses failing to respond should be biopsied; perform follow-up biopsies in superficial basal cell carcinoma.

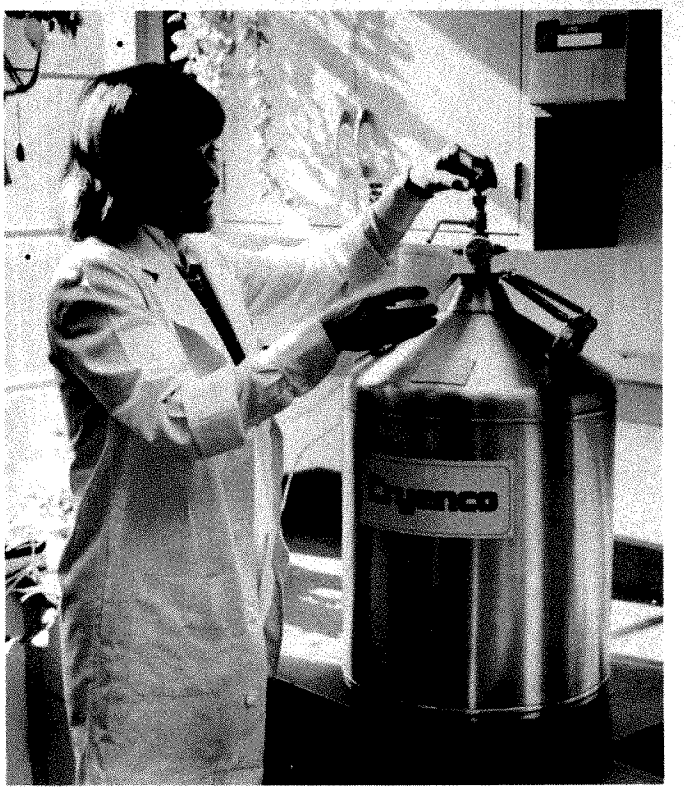
Adverse Reactions: Local—pain, pruritus, hyperpigmentation and burning at application site most frequent; also dermatitis, scarring, soreness, tenderness, suppuration, scaling and swelling. Also reported—insomnia, stomatitis, irritability, medicinal taste, photosensitivity, lacrimation, telangiectasia, leukocytosis, thrombocytopenia, toxic granulation and eosinophilia.

Dosage and Administration: *Actinic or solar keratosis*—apply sufficient quantity to cover lesions, twice daily. Usual length of therapy is 2 to 4 weeks. *Superficial basal cell carcinomas*—apply sufficient quantity (only 5% strength recommended) to cover lesions, twice daily. Continue treatment for at least 3 to 6 weeks, but possibly as long as 10 to 12.

How Supplied: Solution, 10-ml drop dispensers containing 2% or 5% fluorouracil on a weight/weight basis. Cream, 25-Gm tubes containing 5% fluorouracil in a vanishing cream base.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110



Let's dispense with unusual amenities.

Cryo-surgery is a highly specialized science and surgical skill. And of course liquid nitrogen storage is especially critical.

Cryenco Biostat® Model 350 LN_2 dispensing dewars are unsurpassed in the field for efficiency, durability and dependability.

Each Model 350 is hand-crafted with long-life stainless steel outer shell construction and a 2-year warranty.

Engineered for consistant service, Model 350 dispenses LN_2 conveniently and efficiently for dermatological use and boasts a working duration of up to 3 months, without a refill.

Engineering, service and design features all add up to a storage facility with truly unusual advantages. Write today for a free catalog or contact your local Cryenco representative.

KENALOG® SPRAY
Triamcinolone Acetonide Aerosol N.F.

DESCRIPTION: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) provides 3.3 mg. triamcinolone acetonide per 50 grams in an isopropyl palmitate vehicle with alcohol (4.7%) and propellants.

INDICATIONS: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) is indicated for relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS: Topical steroids are contraindicated in viral diseases of the skin, such as vaccinia and varicella, and in patients with a history of hypersensitivity to any product component. This preparation is not for ophthalmic use. Topical steroids should not be used when circulation is markedly impaired.

WARNINGS: Usage in Pregnancy— Although topical steroids have not been reported to have an adverse effect on the fetus, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

PRECAUTIONS: Administer suitable antifungal or antimicrobial therapy if infection exists; if there is not a prompt, favorable response, discontinue the corticosteroid until the infection has been adequately controlled. Discontinue the drug and institute appropriate therapy if irritation develops. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. When used about the face, the eyes should be covered and inhalation of the spray avoided.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids either with or without occlusive dressings: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, miliaria, hypertrichosis, acneform eruptions, maceration of the skin and hypopigmentation; contact sensitivity to a particular dressing material or adhesive may occur occasionally. Some patients (particularly those with very dry skin or dry lesions) may find the cooling effect of the spray objectionable or complain of a transient burning or stinging sensation.

For full prescribing information, consult package insert.

HOW SUPPLIED: Kenalog Spray (Triamcinolone Acetonide Aerosol N.F.) is available in spray dispenser cans of 50 and 150 g. with adapter.

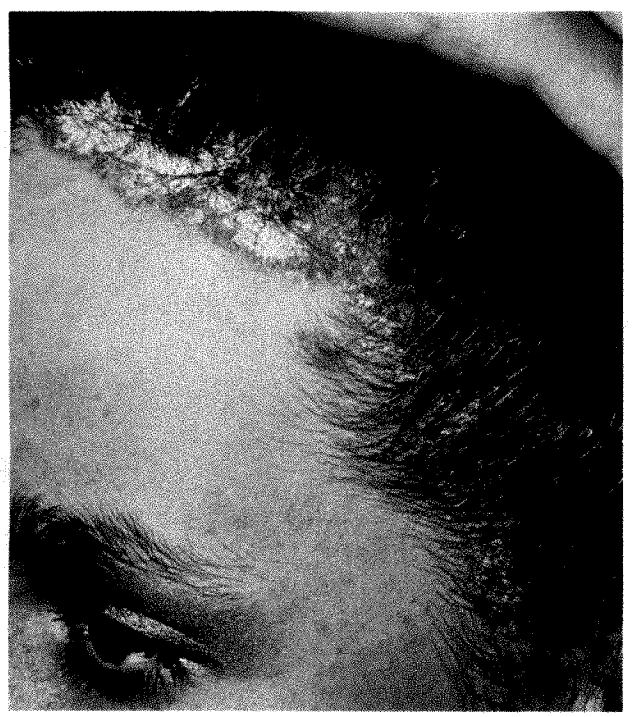
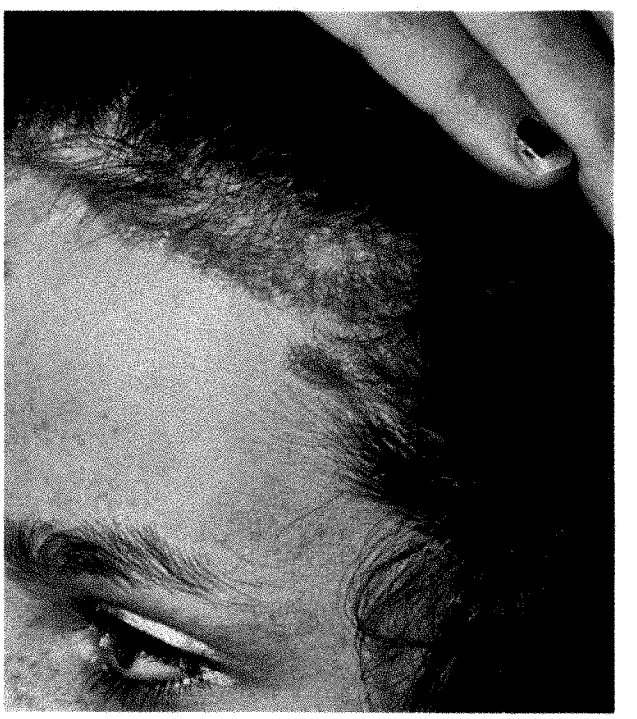
ANOTHER CASE FOR KENALOG®
TRIAMCINOLONE ACETONIDE

"INTRACTABLE" SCALP PSORIASIS



MARCH 4, 1977

A 15-year-old patient complaining of severe, intractable psoriasis of the scalp. Previous therapy with tar shampoo, keratolytic agents and fluorinated topical steroids had been unsuccessful. Because prior topical agents had been difficult to apply, Kenalog® Spray b.i.d. was prescribed.



AFTER 1 WEEK

Patient reported that pruritus had been relieved promptly. Marked improvement observed at this time: absence of scales, decrease in erythema and central clearing of plaques. Patient continuing on Kenalog® Spray b.i.d.
Case history on file at Squibb Institute for Medical Research.

A CASE FOR KENALOG® SPRAY

TRIAMCINOLONE ACETONIDE AEROSOL N.F.

See adjacent column for brief summary.

For dry skin care on a day-to-day basis, consider the soothing, softening, nondetergent cleansing properties of Alpha Keri Soap.

- Excellent cleansing properties eliminate harshness and irritation
- Contains Alpha Keri® therapeutic bath oil to soothe and soften skin
- Rich lather and delicate scent create outstanding patient acceptance

PUVA Statement

The Task Forces on Psoriasis and Photobiology of the American Academy of Dermatology (AAD) met in Chicago during the annual meeting of the academy, December 1976, to discuss PUVA therapy. The following statement was developed by these two task forces and accepted by the AAD Board of Directors. It was issued as a special notice at the AAD meeting and published in the AAD Bulletin.

A number of papers on PUVA therapy for psoriasis have appeared in the ARCHIVES *or are in press. In addition, the journal will continue to evaluate and accept manuscripts related to the scientific aspects of PUVA. However, the editors would like to emphasize that they are in complete agreement with the academy's position that is presented in the following statement.*—EDS.

The Psoriasis and Photobiology Task Forces of the American Academy of Dermatology make the following statement concerning PUVA therapy for psoriasis. Because of initial success of PUVA therapy, its use may become widespread before completion of investigative evaluation. The following considerations are unanswered:

1. Determination of the lowest effective irradiation dose to minimize potential long-term damage
2. Determination of maintenance irradiation requirements, with consideration of potential for chronic cutaneous changes
3. Evaluation of histopathological data that may be of prognostic importance
4. Determination of necessary protective measures to prevent ocular, as well as cutaneous, injury
5. Further observation to determine if the treatment may produce serious threats relating to carcinogenesis, including melanoma formation and malignancies of circulating blood elements

Therefore, this form of photochemotherapy cannot be recommended until the above questions have been evaluated by controlled analytical procedures.

Topical Halcinonide and Betamethasone Valerate Effects on Plasma Cortisol

Acute and Subacute Usage Studies

Edward C. Gomez, MD, PhD; Lewis Kaminester, MD; Phillip Frost, MD

• **The effect of topical application of halcinonide cream and betamethasone valerate cream on plasma cortisol was studied in an acute usage study as well as a subacute study, which more closely approximated common clinical usage. In the acute study, halcinonide cream caused a marked decrease in plasma cortisol, both with and without occlusion, in patients with extensive psoriasis, but only with occlusion in normal subjects. Betamethasone valerate cream decreased plasma cortisol levels in patients with extensive psoriasis when applied with occlusion and, to a lesser extent, without occlusion. In a double-blind subacute usage study without occlusion, two of 23 patients treated with halcinonide cream showed decreased plasma cortisol levels during the treatment period, while none of the 21 patients treated with betamethasone valerate cream showed such decreases. Three patients in the halcinonide group developed striae. Clinical response to halcinonide was superior to that with betamethasone valerate cream, but a similar number of patients were resistant to treatment with each medication.**

(*Arch Dermatol* **113:1196-1202, 1977**)

The effects of topical application of potent fluorinated adrenal corticosteroid preparations, with or without occlusion, have been well documented.[1,2] In the presence of an abnormal barrier to percutaneous absorption or with the increased percutaneous absorption produced by occlusion, sufficient absorption of a variety of corticosteroid preparations occurs to produce suppression of endogenous production of cortisol. Such studies have usually been acute usage experiments.[1-5] The extrapolation from these studies to the common, usually longer term use of corticosteroid preparations in clinical practice is less clear.

In the course of evaluating adrenal effects of a new and potent topical corticosteroid preparation, halcinonide cream, we have compared the effects obtained with such an acute usage protocol to those obtained with subacute usage protocol, which more closely approximated the usual clinical situation. This article reports the adrenal effects of halcinonide cream, 0.1%, and betamethasone valerate cream, 0.1%, when applied for five days with and without occlusion to both normal and diseased skin, in comparison to the effects of the same preparations when used on an outpatient basis over a four- to six-week period without occlusion.

Accepted for publication Nov 22, 1976.

that had been approved by the Research and Human Rights Committees of Mount Sinai Medical Center. One patient had atopic dermatitis; the other patients psoriasis.

Patients participating in the acute usage study had more than 30% of the total body surface involved and had not received systemically administered corticosteroids during the prior three months or topically administered corticosteroids during the previous month. Patients participating in the subacute usage study had at least 5% of the body surface involved and had not received systemically administered corticosteroids for the prior three months or topically administered corticosteroids for two weeks prior to beginning therapy. All patients in the acute usage study had normal pituitary-adrenal reserve as measured by a 24-hour oral metapirone test during the pretreatment period.

Experimental Design

Acute Usage Protocol.—The study was divided into a pretreatment period (days −4 to −1), a treatment period (days 1 to 5), and a post-treatment period (days 6 to 13). During the pretreatment period, a five-hour (100 gm) oral glucose tolerance test was done on day −4 and a metapirone test on day −3. Urine was collected daily to determine 17-hydroxysteroid and plasma cortisol levels. Specimens to determine blood glucose levels were taken two hours after breakfast on day −2.

During the treatment period, daily two-hour postprandial glucose determinations, plasma cortisol determinations, and 24-hour urine collections for urinalysis and 17-hydroxysteroid levels were performed.

During the post-treatment period, plasma cortisol determinations and 24-hour urine collections for urinalysis and 17-hydroxysteroid determinations were performed daily. Two-hour postprandial glucose determinations were done on days 6 and 11. The five-hour glucose tolerance test was repeated on day 10.

Fifteen grams of cream were applied to approximately 50% of the body twice daily at approximately 10 AM and 10 PM, by a nurse. When occlusion was indicated, the application of the cream was immediately followed by application of a plastic film held in place with tape and/or panty hose. The occlusive plastic film was left in place

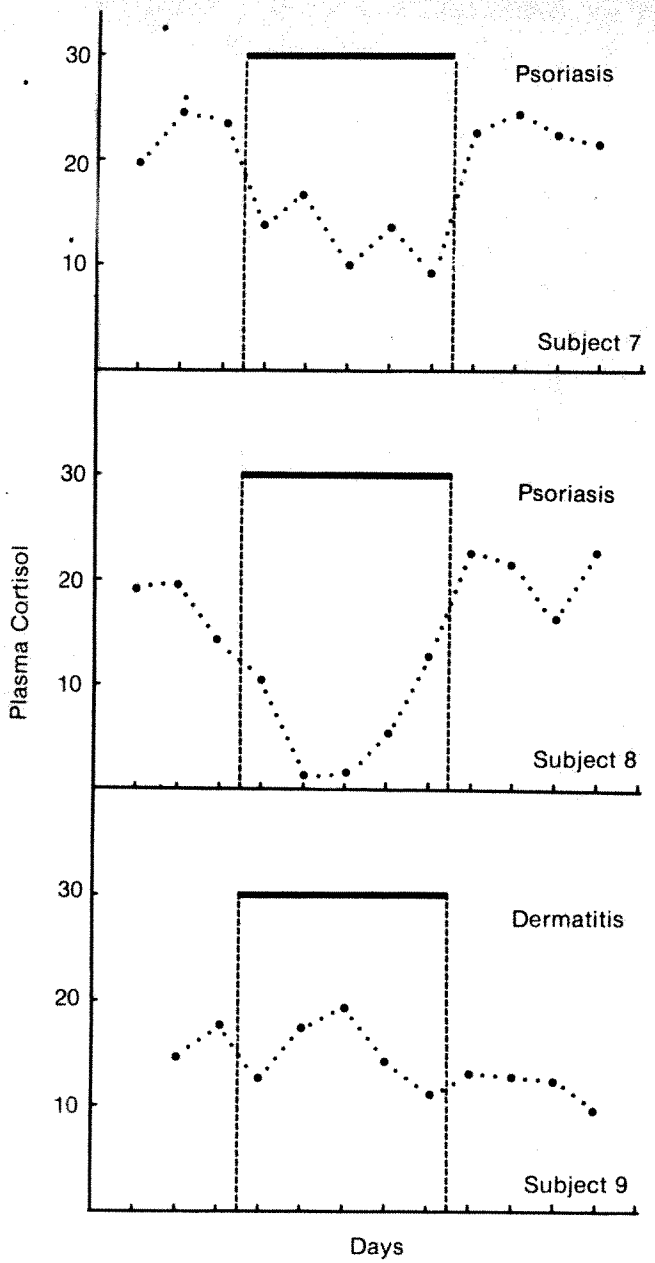

Fig 3.—Application of halcinonide cream, 0.1%, to subjects 7 through 9. Points in rectangle indicate values of plasma cortisol on mornings after treatment days.

for ten hours after each application and then removed for two hours to allow the patient to bathe and dry prior to the next application.

Subacute Usage Protocol.—This was a double-blind study comparing halcinonide cream, 0.1%, and betamethasone valerate cream, 0.1%, applied three or four times a day, without occlusion. Patients were examined at weekly intervals for four to six weeks. On the initial visit blood was drawn for hematologic studies, chemical analyses of the blood, and duplicate plasma cortisol determinations. At the weekly visits these studies were evaluated. Drugs were assigned according to a randomized schedule and were coded so that neither the investigator nor the patient was aware whether halcinonide cream or betamethasone valerate cream was used. To minimize the effect of diurnal variations of cortisol, patient visits were scheduled at the same time of day for each patient, but the time of day varied from patient to patient.

Cortisol and Steroid Excretion Measurements

Specimens for plasma cortisol determination were collected in tubes treated with heparin. Specimens were collected between 8 AM and 8:30 AM each day in the acute usage study. Twenty-four-hour urine specimens were collected from 8 AM each morning to 8 AM the following day and stored in a refrigerator until the analyses were to be done. Cortisol determinations were done by the method of Kitabchi and Kitchell.[6] To insure that the topical corticosteroids did not interfere with the fluorescence measurement of cortisol, the lack of reactivity of halcinonide and betamethasone valerate in this assay was confirmed (Table 1). The 17-hydroxycorticoid levels were determined by the method of Porter and Silber.[7]

RESULTS

Acute Usage Study

Application of Halcinonide Cream to Normal Skin.—Three normal subjects had halcinonide cream, 0.1%, applied to 50% of the body surface area,

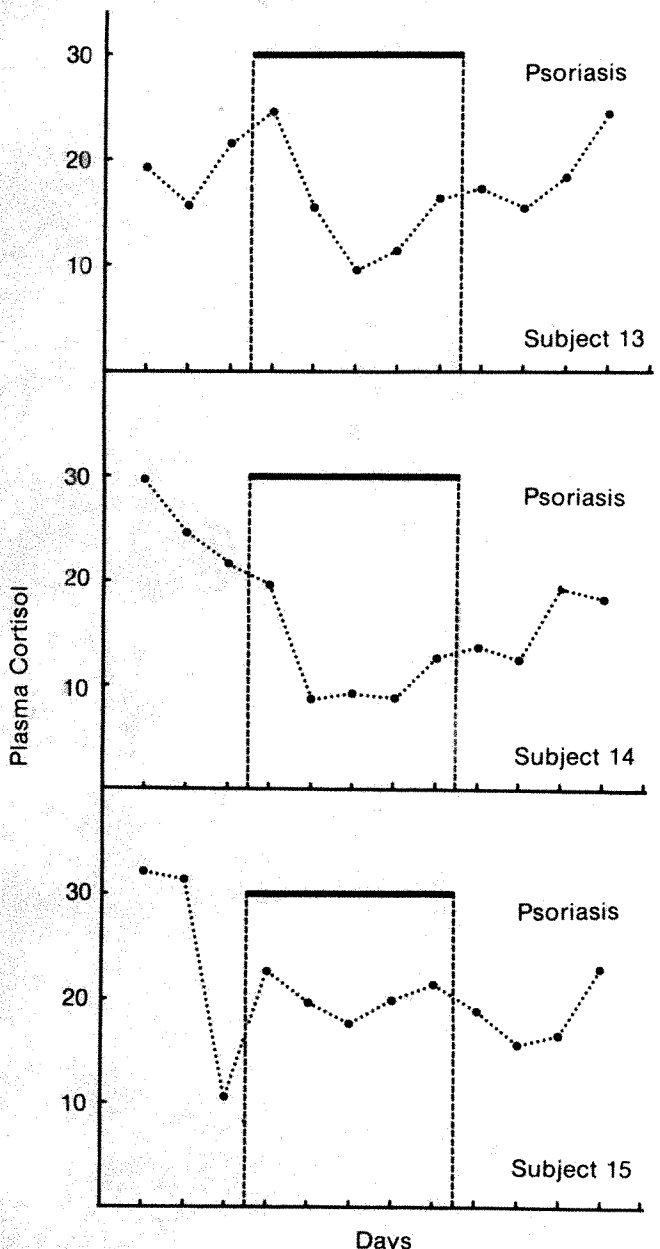

Fig 5.—Application of betamethasone valerate cream, 0.1%, to subjects 13 through 15. Points in rectangle indicate values of plasma cortisol on mornings after treatment days.

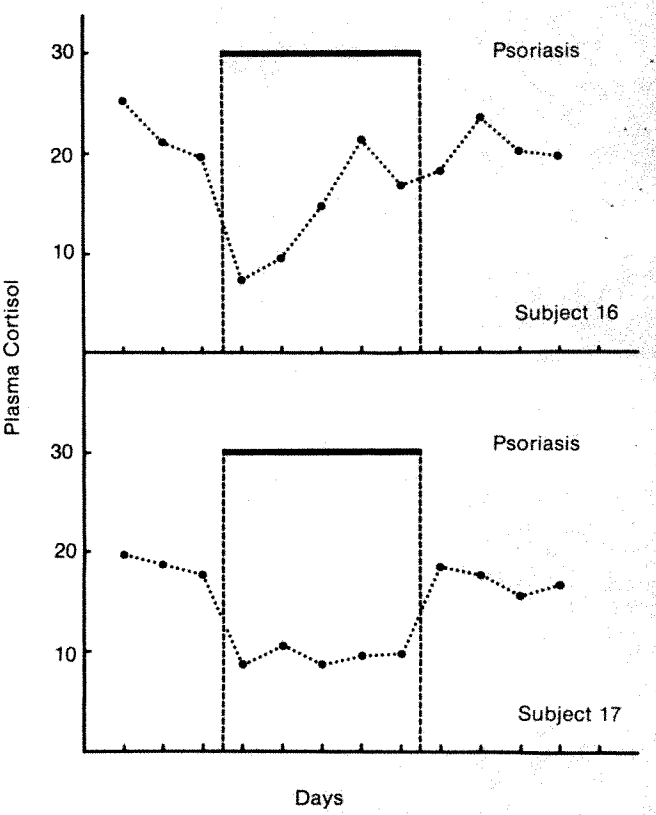

Fig 6.—Application of betamethasone valerate cream, 0.1%, with occlusion, to subjects 16 and 17. Points in rectangle indicate values of plasma cortisol on mornings after treatment days.

without occlusion, according to the acute usage protocol described above. Daily plasma cortisol determinations showed no evidence of adrenal suppression (Fig 1). Measurement of 17-hydroxysteroid excretion showed no evidence of adrenal suppression, except in subject 3, in whom 17-hydroxysteroid excretion was slightly lower on days 4, 5, and 6 than during the pretreatment days.

Three additional normal subjects had halcinonide cream, 0.1%, applied with occlusion, in a similar manner. Each of the subjects showed suppression of plasma cortisol during the treatment period (Fig 2). Subjects 4 and 5 showed progressive decrease in plasma cortisol until the morning after the final treatment. By the following morning, plasma cortisol levels in both of these patients had increased, indicating that the adrenal suppression was rapidly reversible. Subject 6 showed marked depression of plasma cortisol on only one of the treatment days. This value was definitely outside the normal range, but in view of the normal values found on the preceding and succeeding days, the possibility of a technical error must be considered.

Application of Halcinonide Cream to Diseased Skin.—Three subjects with widespread cutaneous involvement were treated with halcinonide cream, 0.1%, without occlusion. Two of the subjects had psoriasis and one had atopic dermatitis. The two subjects with psoriasis showed definite decreases of plasma cortisol on the mornings after treatment and a rapid increase to pretreatment values the days after the discontinuation of treatment (Fig 3). Subject 8 showed a marked decrease in plasma cortisol on the second morning after the initiation of treatment with a rise toward normal during the treatment period despite continued therapy. The rise in plasma cortisol during the treatment period was temporally related to an extremely rapid improvement in the patient's lesions. Subject 9, who had atopic dermatitis, showed no evidence of suppression of plasma cortisol during treatment.

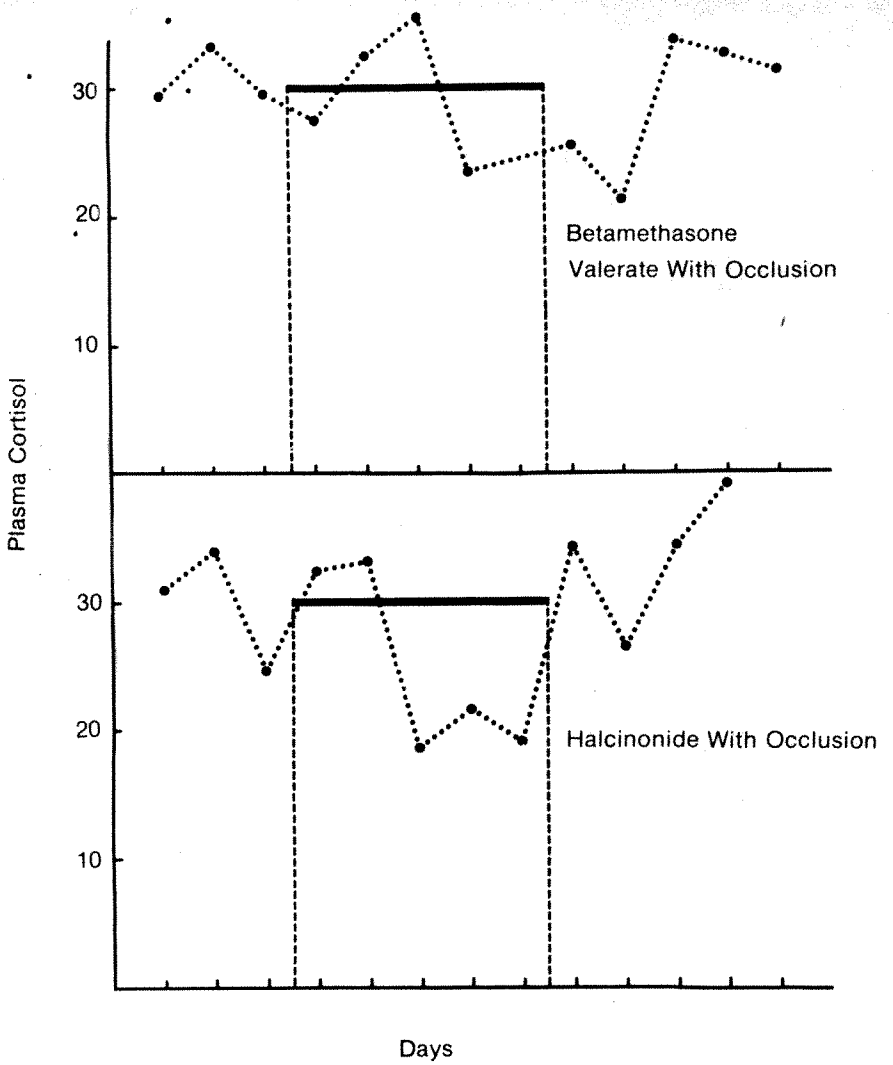

Fig 7.—Application of halcinonide cream, 0.1%, with occlusion and betamethasone valerate cream, 0.1%, with occlusion to subject 18. Points in rectangle indicate values of plasma cortisol on mornings after treatment days.

Three additional subjects with widespread psoriasis were treated with halcinonide cream, 0.1%, with occlusion (Fig 4). All three showed a marked decrease in plasma cortisol values, which persisted throughout the treatment period despite the clinical improvement of the skin lesions. After the discontinuation of treatment, the plasma cortisol values rose rapidly to the pretreatment level.

Application of Betamethasone Valerate Cream to Diseased Skin.—Three subjects with widespread psoriasis were treated with betamethasone valerate cream, 0.1%, without occlusion (Fig 5). Subject 13 showed a mild decrease in plasma cortisol values only during the middle of the treatment period, while subject 14 showed a mild decrease in plasma cortisol values during the treatment period, which persisted for two days after discontinuation of treatment.

Subject 15 showed no evidence of suppression during the treatment period. Three patients were treated with betamethasone valerate cream, 0.1%, with occlusion. Figure 6 shows the plasma cortisol values obtained for two of these patients. Both show a decrease in plasma cortisol during the treatment period. Subject 16 showed a rise in plasma cortisol despite continued therapy with occlusion, while subject 17 showed a persistent decrease in plasma cortisol until the termination of therapy. The third patient (subject 18) treated with betamethasone valerate cream, 0.1%, with occlusion, showed no evidence of adrenal suppression (Fig 7). This same patient was also treated with halcinonide cream, 0.1%, with occlusion, and again failed to show a suppression of plasma cortisol or 17-hydroxysteroid excretion during the treatment. Plasma cortisol in this patient was in the high normal range with some values above the normal range.

Effects on Glucose Metabolism.—Four of the subjects tested had abnormal results to pretreatment glucose tolerance tests. Of these only one of the subjects demonstrated abnormal glucose metabolism in the course of the study, and these data have been reported separately.[8]

Subacute Usage Protocol

Fifty-one outpatients between 9 and 76 years of age with psoriasis were treated with halcinonide cream, 0.1%, or betamethasone valerate cream, 0.1%, without occlusion, according to the double-blind subacute usage protocol described above. Of these patients, 44 patients completed four to six weeks of therapy. There were 31 male and 13 female patients. Involvement with psoriasis varied from approximately 5% (1/18) of the body surface to more than 50% (9/18) of the body surface. Of 44 patients completing the four to six weeks of therapy, nine had severe psoriasis, 26 moderate psoriasis, and nine mild psoriasis. Patients used between 225 and 900 gm of cream during the course of the study with an average usage of 472 gm.

A summary of the results of the study are shown in Table 2. Twenty-three of the patients completing the study were treated with halcinonide cream, 0.1%, and 21 were treated with betamethasone valerate cream, 0.1%. Of the patients treated with halcinonide cream, two showed mild, reversible adrenal suppression, and three developed striae. Of the patients treated with betamethasone valerate cream, none showed either adrenal suppression or striae formation.

Clinical response was graded at each visit and an overall clinical response assigned at the end of the study. Of the 23 patients treated with halcinonide cream, 13 had excellent responses. Only one of the 21 patients treated with betamethasone valerate cream had an excellent response. Both treatment groups had a similar number of patients who showed only fair or poor responses.

The plasma cortisol findings in the two patients showing adrenal suppression are shown in Fig 8. One patient was treated for four weeks with an excellent clinical response and showed a persisting decrease in plasma cortisol level as compared to the pretreatment and post-treatment values. Only 5% of the body surface was involved in this patient, much less than in many patients who showed no

Table 2.—Summary of Results of Subacute Usage Study

	Halcinonide	Betamethasone Valerate
No. of Patients	23	21
Adrenal suppression	2	0
Striae formation	3	0
Clinical response		
Excellent	13 (57%)	1 (4%)
Good	3 (13%)	12 (57%)
Fair	4 (17%)	6 (29%)
Poor	3 (13%)	2 (10%)

evidence of adrenal suppression. The second patient evidencing adrenal suppression was treated for six weeks with an excellent response and a moderate decrease in plasma cortisol values compared to pretreatment and post-treatment values. This patient also had a smaller percentage (10%) of the body surface involved than did other patients who did not show adrenal suppression. Neither patient developed any notable side effects during the study period.

All three patients developing striae were in the group treated with halcinonide cream. Two of the patients developed the striae at sites of natural occlusion, one near the axillae and the second in the intergluteal fold. The third patient developed a band of striae around the waist, exactly matching the area under a wide leather belt that he customarily wore.

COMMENT

The suppression of adrenal function by topically applied corticosteroid preparations is amply demonstrated in the dermatologic literature. Most studies have used patients with widespread involvement with psoriasis or other dermatoses known to have an abnormal barrier to percutaneous penetration and in many cases have used occlusion to augment penetration of the corticosteroid preparation. Such studies are now performed to evaluate the safety of new corticosteroid preparations prior to marketing. Since the routine use of corticosteroid preparations in dermatologic practice is much different from the use of such preparations in the studies reporting adrenal suppression, it is of interest to monitor corticosteroid effects on the adrenal pituitary axis under conditions more closely resembling actual clinical usage.

The studies described here indicate

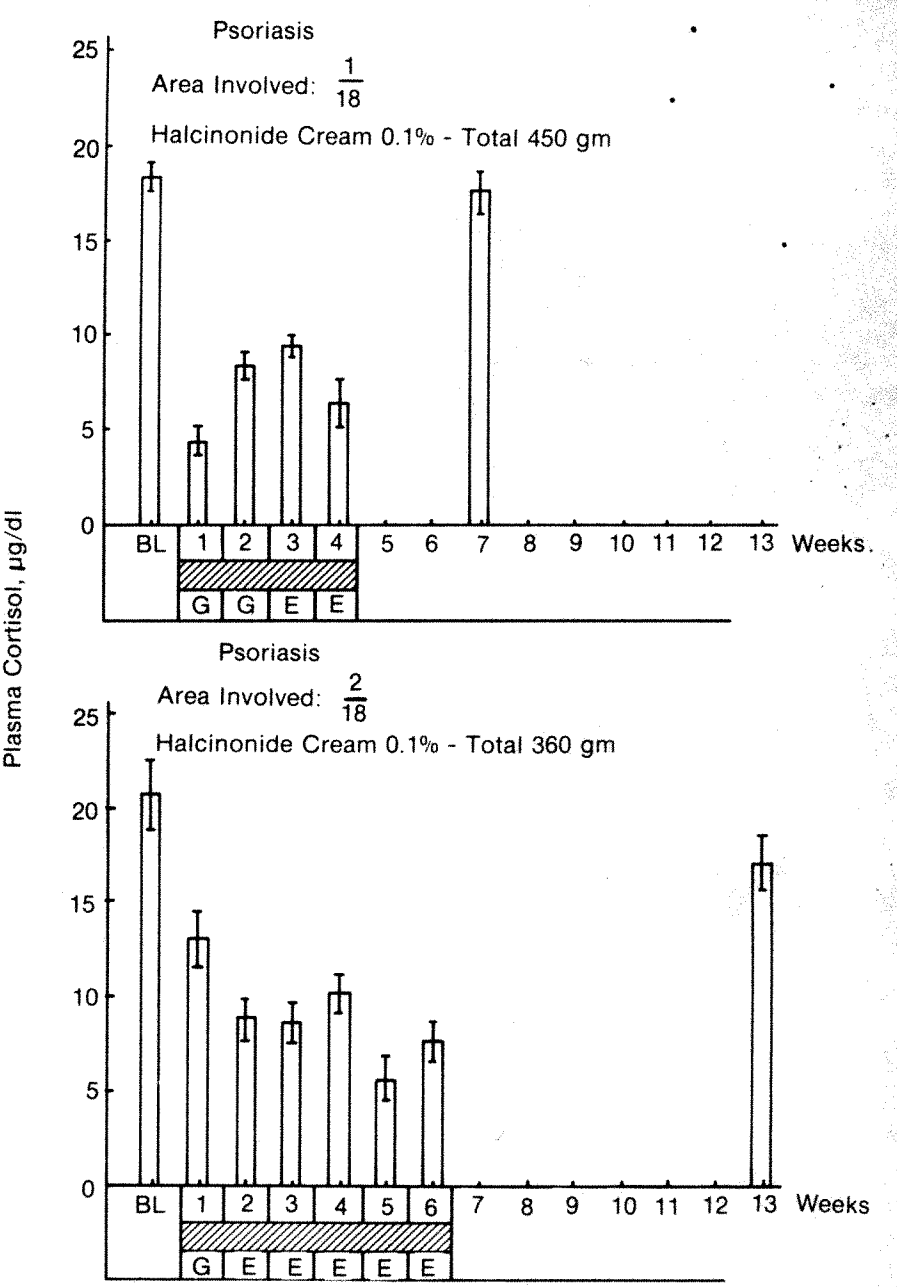

Fig 8.—Suppression of plasma cortisol of two subjects in subacute usage study. Shaded area indicates values while under treatment. BL indicates baseline or pretreatment specimen. Lower letters indicate grading of clinical response at each visit (G, good and E, excellent). Cortisol values are average of determinations on two separate specimens (indicated by brackets).

that halcinonide cream, like other recently introduced corticosteroid preparations, has a suppressive effect on the adrenal-pituitary axis, as measured by a decrease in plasma cortisol levels after topical application to patients with widespread psoriasis, with or without occlusion. In addition, application to normal skin also causes a decrease in plasma cortisol levels, provided the area of application is occluded with a plastic film. No evidence of adrenal effects was noted when halcinonide cream was applied to 50% of the body surface of normal individuals without occlusion.

Betamethasone valerate cream also caused suppression of the plasma cortisol level in individuals with widespread psoriasis, both with and without occlusion. One individual with widespread psoriasis did not show adrenal suppression with either betamethasone valerate cream or halcinonide cream applied under occlusion. This individual had a relatively high cortisol level, including many values above the upper limit of normal, and

may have abnormal adrenal function. One patient developed a temporary alteration of glucose metabolism while under treatment with halcinonide and has been reported elsewhere.[8]

In contrast to the findings with the acute usage protocol, only two of 44 patients completing the subacute usage study showed evidence of adrenal suppression, both patients being in the halcinonide group. Three patients who developed striae were also in the halcinonide group. The finding of more side effects in the halcinonide treatment group than in the betamethasone valerate treatment group is not surprising since the clinical evaluations in this study, as well as reports of others,[9] indicate that halcinonide cream is a more potent preparation than is the betamethasone valerate cream used for comparison.

The contrast between the acute usage study and the subacute usage study is striking. The data suggest that in routine clinical usage there is less adrenal suppression than would be expected from the acute usage studies. Assessment of pituitary-adrenal reserve might have revealed additional patients with effects from subacute usage, but the large number of patients involved precluded studies not easily performed on an outpatient basis.

The reliance solely on plasma cortisol values during the subacute usage study is not considered an important factor since the additional examination of 17-hydroxycorticoid excretion in the acute usage study yielded no additional information. Indeed, the difficulty of obtaining reliable 24-hour excretion values over a three-week period far exceeded the usefulness of these determinations. It is, of course, essential that the method used to determine plasma cortisol not measure the topical corticosteroids under study.

The potency of present-day preparations makes the performance of adrenal function tests of patients having widespread psoriasis during acute usage studies, with or without occlusion, of questionable value in the evaluation of new corticosteroid preparations. Most present-day steroids easily cause adrenal suppression in the majority of subjects so treated. More meaningful information can be obtained by studying subjects with an unaltered barrier, either with or without occlusion. Such studies would detect topical corticosteroid preparations having even greater potential for suppression of adrenal function, such as clobetasol proprionate ointment, which was recently reported to cause profound decrease in plasma cortisol when applied to normal subjects without occlusion.[10]

More recently, Carruthers et al[11] have studied clobetasol proprionate cream and ointment in normal subjects over a two-week period and found marked and persisting suppression of plasma cortisol during the treatment period, providing sufficient corticosteroid was applied (90 gm of preparation per week). Cortisol returned to normal on discontinuation of therapy. Patients under treatment for periods of ten weeks to 18 months with more than 50 gm per week also showed decreased plasma cortisol or reduced peak insulin stress test levels. Carruthers and associates also encountered a subject who showed no evidence of adrenal suppression at dosages causing suppression in other subjects (a situation similar to the patient in Fig 7). Their finding of diminished reserve on insulin stress is probably related to the prolonged periods of therapy and might have been overlooked in an acute usage study.

Long-term studies with patients having altered barriers are also logical in that they more closely approximate clinical usage and may provide some indication of additional side effects, such as striae formation, which would not be observed in short-term studies for the evaluation of acute effects or the determination of efficacy.

This investigation was supported in part by National Institutes of Health grant AM16232. E. R. Squibb and Sons provided the halcinonide cream (Halog) and betamethasone valerate cream (Valisone).

Mycophenolic Acid for Psoriasis

William S. Lynch, MD, Henry H. Roenigk, Jr, MD

• Mycophenolic acid is an antimetabolite used experimentally for the treatment of psoriasis. Thirty-eight patients were treated with mycophenolic acid. A double-blind, placebo-controlled study demonstrated the efficacy of mycophenolic acid ($P < .01$). A long-term safety study showed the occurrence of hematologic abnormalities, viral infections, and carcinoma. The position of mycophenolic acid in the therapeutic treatment of psoriasis must await the results of a multicenter cooperative study.

***(Arch Dermatol* 113:1203-1208, 1977)**

Despite continuous investigative efforts, the cause of psoriasis remains an enigma. In the past decade it has been confirmed that an increased epithelial proliferation explains many of the clinical and histologic features of a psoriatic lesion.[1,2] Because of this, various chemotherapeutic agents have been employed in resistant cases.[3] Theoretically, most of these compounds function by interrupting hyperkinetic cellular function.

Methotrexate has proved to be an invaluable agent for psoriasis, and psoriatic arthritis,[4,5] but substantial potential toxicity[5,6] has necessitated a continuing search for a safe and efficacious drug. Cyclophosphamide,[7] nitrogen mustard,[7] mercaptopurine,[7,8] thiguanosine,[9] fucidin,[10] azathioprine,[11] levodopa,[12] fenfluramine hydrochloride,[13] and psoralen plus UVA[14] are among the agents that have been or are being evaluated. Hydroxyurea[15,16] and azaribine[17,18] have also proved beneficial in controlled series, but have shown significant toxic side effects.

More recently, mycophenolic acid, an inhibitor of purine synthesis, has given encouraging results.[19] Of the 29 patients treated by Jones et al[19] in their initial clinical trial, one patient's condition cleared completely, 14 showed almost complete clearing, 13 exhibited definite improvement, and one did not respond. A cooperative study was subsequently designed to judge both the efficacy and long-term safety of orally given MPA in psoriasis. Ten medical centers and approximately 375 patients are participating in the study (written communication, E. L. Jones, MD, September 1976). Our preliminary report comprises a portion of this cooperative effort.

METHODS

Thirty-eight patients with psoriasis were enrolled in the study. All types of psoriasis were eligible (plaque, guttate, inverse, pustular, palmar-plantar, arthritic). The subjects must have been unable to control their skin condition with nonsystemic measures. All participants were fully informed as to possible adverse reactions, alternative treatment available, and the design of the study. Writen consent was obtained.

Exclusion from the study included the following: women of childbearing potential unless using adequate contraception; children under 12 years of age; patients who received methotrexate or other antimetabolic drugs in the previous four weeks; patients with a preexisting leukopenia (WBC, 3,500 cm mm); men planning conception; chronic alcoholics and persons exposed to toxic chemicals; patients with liver disease.

The investigation was divided into separate portions: (1) double-blind, placebo-controlled parallel study to judge efficacy; and (2) long-term follow-up study to judge safety.

Medications

Mycophenolic acid was supplied in 400-mg capsules. The placebo medication consisted of capsules identical in appearance to the active medication, but containing starch only. The medication was started initially at a dosage of 2,400 mg/day in two to three divided doses. Dosages were increased at a rate no faster than every week. The maximum dosage was 96 mg/kg/day. The dosage was adjusted to maintain the desired clinical response.

If an appreciable adverse reaction occurred, the drug was either temporarily discontinued or the dose was lowered. The therapy was interrupted temporarily if infection, fracture, surgery, infarction, thrombosis, vaccination, or hazardous medication affected the patient. A patient was released from the study protocol if a neoplasm was diagnosed. Concurrent medication, including topical therapy, was kept at a minimum. Close surveillance was maintained for a possible drug interaction.

Clinical and Laboratory Observations

All patients were observed as outpatients or inpatients in the Cleveland Clinic.

Accepted for publication Nov 24, 1976.

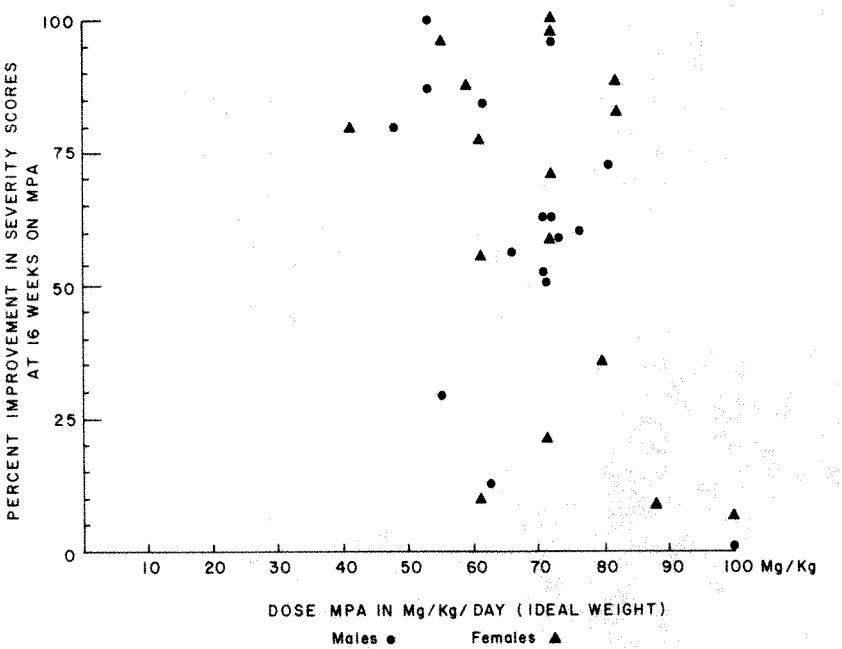

Fig 2.—Improvement in severity scores vs dosage (ideal weight) and sex. Mycophenolic acid indicated by MPA.

Initial evaluation included a detailed history and physical examination, including an ophthalmologic examination, and photographs. Patients were seen at weekly intervals for the first eight weeks, every other week for four weeks, then every four weeks. At each visit the severity of the disease was graded at six skin sites using the following scale of 0 to 6 for lesion thickness, scaling, and erythema: 0, absent; 1, trace; 2, mild; 3, mild to moderate; 4, moderate; 5, moderate to severe; and 6, severe. The maximum possible severity score was, therefore, 108. The percent of body area affected was recorded initially and at 12 weeks.

Interpretation of response to mycophenolic acid and placebo was done in the following manner: (1) Efficacy study: The mean severity scores of the mycophenolic acid-treated and the placebo-treated groups were evaluated at each visit and at the end of the 12 weeks. These data were then analyzed for statistical significance. (2) Safety study: Severity scores were tabulated at each visit. At 16 weeks the percent improvement in the individual severity score was calculated and placed into one of the following categories: excellent, 75% to 100%; good, 50% to 74%; fair, 25% to 49%; poor, 0 to 24%; and worse, condition flared.

Patients with psoriatic arthritis were graded on their subjective feelings, the amount of anti-inflammatory medication taken, grip strength, and/or the time it took to walk 14.9 meters (50 ft).

At each visit a complete blood count, platelet count, urinalysis, and automated chemical analyses profile were done. If symptoms or laboratory tests indicated, additional appropriate laboratory tests were performed.

The ophthalmic examination was repeated at 28 weeks, 52 weeks, and at the end of the study. Follow-up photographs were taken at various intervals during the treatment.

Efficacy Study (Part 1)

This portion of the investigation was a double-blind, placebo-controlled parallel study. The patients were randomly selected for treatment with mycophenolic acid or the placebo for the first 12 weeks. Neither the patients nor the grading physician was aware of which medication was being used. At the end of 12 weeks, the patients who were receiving the placebo were switched to the active mycophenolic acid, and the patients initially taking the active drug continued with it. All patients were then continued in the study as part of the safety study.

Safety Study (Part 2)

This portion of the investigation was designed to judge the long-term safety of mycophenolic acid. The protocol was identical to that outlined for part 1, except all the patients were taking the active drug. In this portion of the study both the patient and the evaluating physician knew the medication used. This part of the study included patients started as safety study patients from the beginning and those from the efficacy study after they were given the active mycophenolic acid regimen. The study was designed to last a period of two years.

STUDY POPULATION

Thirty-eight patients, 20 females and 18 males, were included in the safety study group. Of these, 25 patients were initially enrolled in the efficacy portion of the investigation. The characteristics of the entire group are listed in Table 1.

Thirty-seven patients had moderate-severe psoriasis of the plaque form. One patient had severe involvement of the palms and soles only. Three patients had moderate-severe arthritis, and in two of these the arthritis was the prominent feature of the disease. No patients with pustular psoriasis were treated.

A large percentage of patients had taken methotrexate or other antimetabolites previously. Of the 26 patients who had received methotrexate, 22 had shown definite improvement. Discontinuance of the medication was prompted by a severe side effect or inadequate control of the disease.

Twenty-four patients were judged to be in good general health. Concurrent medical problems existed in the study group, including hypertension, diabetes mellitus, arteriosclerotic heart disease, hyperlipidemia, thalassemia minor, and an inactive duodenal ulcer. One patient, a 43-year-old woman, had had a mastectomy in 1967 for carcinoma of the breast without evidence of recurrence. This same patient has had numerous basal cell carcinomas and had just completed successful Mohs' chemosurgery for a squamous cell carcinoma of the right temporal scalp. One 65-year-old woman was found to have a suspicious pigmented retinal lesion on the initial ophthalmic examination. She refused to have an enucleation and was included in the study after consultation with a panel of ophthalmologists and full understanding on her part of the risks involved.

Three patients were eliminated from the efficacy portion of the study prior to accumulating important data for inclusion in the efficacy statistics. (Two patients found that frequent visits were too inconvenient and one patient developed an anemia, leukopenia, and thrombocytopenia).

Three patients were also released from the safety portion of the investigation prior to complete evaluation of the response. Two patients developed a vaginitis and requested to be discontinued. One patient was lost to follow-up. It was

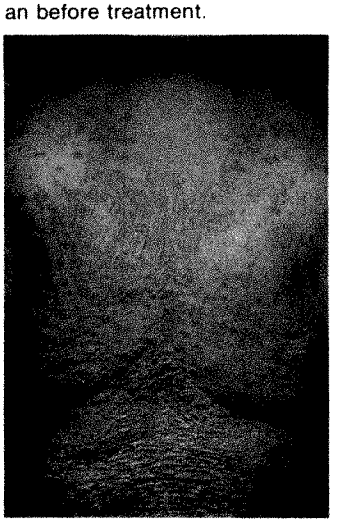

Fig 8.—Same patient seen in Fig 7 after 16 weeks of mycophenolic acid treatment (maximum dose, 4,800 mg/day).

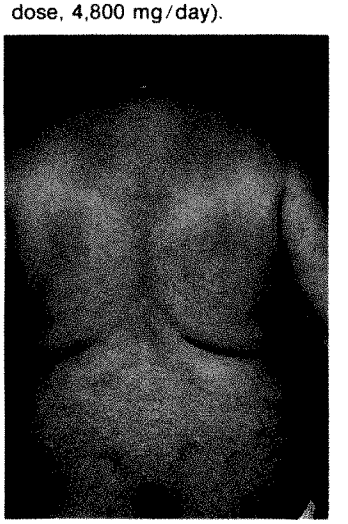

learned later that he died and an autopsy showed the presence of subdural hematoma, presumably secondary to a fall. This was five weeks after last taking the drug; at the time of his last clinic visit all laboratory test results were within normal limits.

RESULTS

In the efficacy portion of the investigation 10 patients reached at least ten weeks on the placebo regimen and 12 patients were randomly started and continued with the active medication. Figure 1 demonstrates the weekly difference in the severity scores of the two groups. Although intentional pairing of severity scores were not done for each group, the average initial severity score for the placebo and active groups was identical. The group receiving mycophenolic acid showed a statistically significant ($P < .01$) change in the severity score when compared to the group receiving the placebo. Interestingly, there were two placebo responders. These two patients continued with the placebo until the psoriasis flared (one at 26 weeks, and the other at 40 weeks), and then were given the active medication.

In the safety portion of the study, 32 patients completed at least 16 weeks with mycophenolic acid. The results are tabulated in Table 2; a total of 13/32 (41%) patients exhibited an excellent response; 11/32 (34%) had a good response; 2/32 (6%) showed a fair response; 5/32 (12.5%) had a poor response, and 1 patient's condition worsened. This patient was a 60-year-old man who took the medication for 20 weeks, with a maximum dosage of 7,200 mg/day. Mycophenolic acid was discontinued because of a lack of response and severe gastrointestinal side effects.

The average time to show maximum response was 9.1 weeks, with a range of 3 to 14 weeks. Of the three patients with psoriatic arthritis, one showed subjective improvement and no patient exhibited substantial objective improvement.

Figure 2 illustrates the improvement in severity scores compared to dosage (per ideal weight) and sex. The response appeared to be dose-related with no sex predilection. The maximal response seemed to vary between 50 mg/kg/day and 72 mg/kg/day (or 3,600 mg/day and 4,800 mg/day). There seemed to be no sex predilection to the degree of the response.

Photographs of the clinical response in three patients are shown in Fig 3 through 8.

Adverse Reactions

The adverse reactions encountered in the study of 38 patients receiving large doses of mycophenolic acid are listed below:

Side Effects Attributed To MPA	
Gastrointestinal	
Nausea	24
Abdominal cramps	23
Diarrhea	17
Melena or bloody stools	3
Soft bowel movements	13
Vomiting	12
Urinary tract symptoms	
Burning on urination	5
Urgent or frequent urination	2
Other	
Weak or tired feeling	18
Difficulty sleeping	8
Vaginal burning	2
Tender fingertips	1
Mouth ulcers	1
Events of Uncertain Association With MPA	
Carcinoma	
Adenocarcinoma of breast	1
Squamous cell carcinoma of epiglottis	1
Recurrent squamous cell carcinoma of skin	1
Infections	
Viral	
URI	5
Warts	4
Verrucae vulgaris	2
Condyloma accuminata	2
Herpes simplex	6
Herpes zoster	2
Gastroenteritis	1
Bacterial	
Urinary tract infection	4
Pharyngitis	4
Septicemia *(Staphylococcus)*	2
Otitis media	1
Furunculosis	1
Bronchitis	1
Fungal	
T. cruris (KOH [+])	2
Other	
Dizziness	2
Epistaxis	1
Angina	2
Laboratory Abnormalities	
Hematologic	
↓ Hb (> 2 gm)	4
Leukopenia (WBC, <3,500/cu mm) (2 patients with absolute neutropenia)	4
Thrombocytopenia	2
Other	
Transiently abnormal liver function tests	3
↑ Cholesterol	1
↑ Uric acid	1
Pyuria (sterile)	14

In general, the side effects appeared to be dose-related and were particularly common above a dosage of 4,800 mg/day. Usually, the reaction could be alleviated by decreasing the dosage or temporarily discontinuing the drug.

Gastrointestinal manifestations were the most frequent. Severe abdominal cramps or evidence of blood in the stools prompted cessation of the drug and the performance of a complete gastrointestinal evaluation in six cases (including proctologic examination and roentgenograms of the stomach, gallbladder, small intestine, and colon). No specific abnormality was found and the patients were able to tolerate lower doses of mycophenolic acid.

A weak or tired feeling was another common complaint. This could not be related to any specific hematologic abnormality, and seemed to be less of a problem after eight to ten weeks receiving the medication.

The occurrence of infections in the study group was quite common, with viral infections predominating. Two patients developed classic herpes zoster. One 12-year-old boy developed herpes zoster on the left thorax and painful mouth ulceration at ten weeks into the study. He had previously been taking methotrexate, 7.5 mg/week, but discontinued it two months prior to inclusion in the study. The dose of mycophenolic acid was 2,400 mg/day. The drug was discontinued for two weeks and restarted without occurrence of signs or symptoms. The zoster site healed with keloid formation. Another was a 33-year-old man who developed zoster in the left sacral area. Prior to the study he had received no systemic medication for psoriasis. His medication was discontinued for two weeks and reinstituted without difficulty after normal healing occurred. Six additional patients developed clinically obvious and/or culture-proved herpes simplex, and four patients developed warts. None of these patients had exhibited a propensity for these infections prior to taking MPA.

Three of our patients were discovered to have a neoplasm: one patient, a 43-year-old woman, discussed previously, had a recurrent squamous cell carcinoma of the scalp, which developed after having been successfully treated with Mohs chemosurgery; she also developed numerous basal cell carcinomas on her face, trunk, and extremities. The dosage of mycophenolic acid received was 3,600 mg/day during a 16-week period. She had also taken methotrexate (20 to 25 mg/week) from 1964 to 1972.

A 49-year-old woman was found to have a large mass in the right breast after 38 weeks on mycophenolic acid therapy. She had a modified radical mastectomy performed and a stage I signet ring cell carcinoma was diagnosed. She had received an average daily dosage of 4,000 mg of mycophenolic acid. Prior to inclusion in the

study she had a negative result from a breast examination at our institution, although mammograms were not done. She had taken methotrexate (20 to 25 mg/week) for five years before taking mycophenolic acid.

A 59-year-old woman was found to have a squamous cell carcinoma of the epiglottis. She had received an average daily dosage of 3,600 mg/day of mycophenolic acid for 46 weeks, and had discontinued the mycophenolic acid five months prior to detection of the tumor to try psoralen and black-light therapy. Before taking mycophenolic acid, she had taken azaribine for five months, without a substantial response. She is currently undergoing radiation therapy, and will possibly have a radical neck operation.

The laboratory abnormalities are listed in Table 3. A pertinent finding was the paucity of liver abnormalities. Although a number of our patients had been receiving other antimetabolic agents, routine liver biopsies were not done as a part of our investigation.

Hematologic abnormalities did occur: One 44-year-old woman developed anemia, leukopenia, and thrombocytopenia that recurred after stopping and restarting the drug therapy. She was released from the study and all measurements returned to normal.

Of particular interest were two siblings who developed a selective neutropenia (a 13-year-old girl and 15-year-old boy). They developed this at 16 weeks into the study, but because of the different starting dates, the onset of symptoms were separated by an interval of one month. Presenting symptoms included sore gums, fever, chills, and headache. Both patients were hospitalized and treated with parenteral antibiotics for bacteremia. Bone marrow aspirate showed a pronounced diminution in the granulocytic series. Additional normal laboratory tests included the following: immunoglobulins, chromosome analysis, leukocyte agglutinins, peripheral blood T-cell and B-cell levels, and lymphocyte transformation tests to phytohemagglutinin, pokeweed mitogen, and concanavalin A.

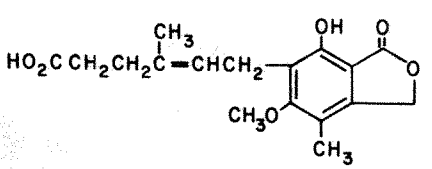

Fig 9.—Structure of mycophenolic acid.

COMMENT

Mycophenolic acid was isolated by Gosio in 1896 as a fermentation product of a penicillin mold. The finding was duplicated in 1913 by Alsberg and Black, who named the substance.[20] It was not until 1952 that the structural formula was fully elucidated (Fig 9).[21]

The compound has been shown to have antibacterial[22] and antifungal[23] activity. In vitro antiviral properties were also noted but could not be demonstrated in vivo.[24,25]

Laboratory evidence from experiments with animals indicated that mycophenolic acid may be effective against certain virally induced tumors.[26] Because of its seemingly low toxicity, the compound was utilized in clinical trials with humans in the treatment of neoplastic diseases. The results were disappointing.[27,28]

Toxicity studies in animals have implied relative safety. One study reported no clinical, laboratory, or autopsy evidence of toxic reactions in rabbits that received 320 mg/kg/day for one year.[19] There have been no reports concerning the possible carcinogenic potential of mycophenolic acid. Likewise, the studies pertaining to the effects of mycophenolic acid on the immune response are inconclusive. Another study describes the immune response to sheep red blood cells of mice treated with mycophenolic acid. With the method used it was believed that mycophenolic acid had immunosuppressive effects equipotent to 6-mercaptopurine with use of the same study format.[29]

The mechanism of action of mycophenolic acid appears to be an enzymatic inhibition of the purine precursors of RNA and DNA. Specifically, the drug blocks the enzymatic interconversion of the nucleotides inosine-5′-phosphate (IMP) to quanosine-5′-phosphate (GMP) (Fig 10). The enzymes involved are IMP dehydrogenase and GMP synthetase.[30,31] It does not appear that adenosine monophosphate synthesis is inhibited by the drug. Furthermore, it has become apparent that the enzymatic blockage can be bypassed by DNA synthesis from free guanine, the so-called guanine salvage pathway (Fig 6). This pathway can be blocked by 6-mercaptopurine, thereby potentiating the effect of mycophenolic acid.[27]

The metabolism of mycophenolic acid has been delineated by Lintrup et al.[32] After oral administration the drug is rapidly absorbed from the gastrointestinal tract and metabolized in the liver to mycophenolic acid glucuronide. In humans the peak level of free mycophenolic acid is one hour after ingestion and the glucuronide fraction reaches its highest concentration at two hours. Essentially, mycophenolic acid all is excreted as the glucuronide form, and it is predominantly found in the urine.

Mycophenolic acid glucuronide is considered inactive and it is felt that only those tissues with a high level of the enzyme β-glucuronidase can generate sufficient levels of the active drug. The epidermis and dermis had been shown to possess ample concentration of this enzyme,[33] and it is theorized that such a property may account for its specificity in certain tumors and in hyperproliferative diseases such as psoriasis.[34]

As mentioned, the initial clinical trial of mycophenolic acid in psoriasis[19] was encouraging. As the early reports of individual medical centers are published, it appears that the preliminary results are being duplicated. Twenty-seven of the 35 patients at Duke University showed clearing of more than half their lesions (written communication, W. H.

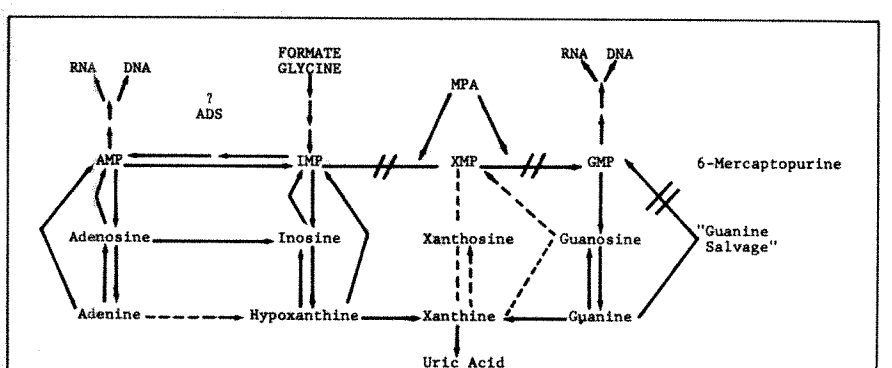

Fig 10.—Metabolic pathways affected by mycophenolic acid. Inosine-5′-phosphate indicated by IMP; guanosine-5′-phosphate, GMP; adenine monophosphate, AMP; and xanthosine-5′-phosphate, XMP.

Turner, MD, •September 1976). In patients treated at the Brown University College of Medicine, 12 of 19 patients showed greater than 50% improvement.[35] In our series, 24 of 32 patients (75%) exhibited greater than 50% improvement. Furthermore, analysis of the efficacy study showed a statistically significant response ($P < .01$) to mycophenolic acid when compared with the placebo. Undoubtedly, a higher degree of statistical significance would have been achieved had it not been for the two placebo responders. This response may help account for the close proximity in severity scores at week 9 (Fig 1).

We have not observed enough patients who have discontinued the drug for a lengthy interval before starting again to make a valid statement regarding the time it takes for the condition to relapse. Likewise, only a small group of patients have reached 52 weeks on mycophenolic acid treatment, but it appears there may be some tolerance to the drug exhibited.

The adverse reactions encountered in our series tend to temper the enthusiasm for use of mycophenolic acid in psoriasis. The majority of the problems were consistent with those being reported in other series.[19] However, the apparent increase in viral infections, the cases of neutropenia, and the associated carcinoma are of concern. The viral infections have been a problem at other institutions, and to date there have been 11 cases of herpes zoster (written communication, E. L. Jones, MD, September 1976). It is entirely possible that the two siblings who developed neutropenia may have done so secondary to a viral process. This theory is tenable, as a reinstitution of mycophenolic acid has failed to exhibit any suppressive bone marrow effects. It is also conceivable that the associated malignancies could have been a chance occurrence. Certainly, the patient with the squamous cell carcinoma of the scalp could be considered "malignancy prone."

Nonetheless, we feel that these occurrences demand additional investigative efforts. As mentioned, there is some evidence that mycophenolic acid can alter both humoral and cellular immunity.[29] Further toxicity studies should be designed to clearly elucidate the drug's effect on the immune system, and the possible carcinogenic potential. Only with such studies can the true safety of mycophenolic acid for the treatment of psoriasis be evaluated.

Spontaneous Regression of Plane Warts After Inflammation

Clinical and Histologic Studies in 25 Cases

Hachiro Tagami, MD; Masahiro Takigawa, MD; Atsuhiko Ogino, MD; Sadao Imamura, MD; Shigeo Ofugi, MD

• Based on clinical and histological studies in 25 patients, we have confirmed that plane warts show a characteristic phenomenon of spontaneous regression totally distinct from that described in common warts.

This regression developed during various treatments in nine cases, and in 16 cases, it occurred spontaneously. In all the patients, there was a sudden and systemic onset of inflammation in every flat wart. Within two to six weeks, all the warts completely involuted.

Histologically, there were variable degrees of epidermal changes depending on the stage of inflammation. However, a mononuclear cell infiltration with epidermal invasion was demonstrated in every biopsy specimen. This evidence further supports the earlier concept that this regressive phenomenon of plane warts is mediated by cellular immunity. It represents a natural experimental model of rejection of tumors induced by papovavirus in humans.

(*Arch Dermatol* 113:1209-1213, 1977)

Plane warts or flat warts usually involve exposed parts of the skin and appear as numerous small pigmented patches or papules. Characteristically, these numerous warts will suddenly and spontaneously redden and cause severe pruritus and then within several weeks, completely disappear as inflammation subsides. Histologically, in ten such cases, we observed a dense mononuclear cell infiltration in the upper dermis and epidermis, a feature suggestive of the involvement of cellular immunity in this phenomenon.[1]

We are surprised, however, to find that there have been only a few reports about regression of plane warts from other countries,[2,3] in contrast to a number of recent studies concerning regression of common warts.[4-7] Moreover, Matthews and Shirodaria[6] and Brodersen and Genner[8] pointed out that regressing common warts associate clinically with pain and blackish discoloration and histologically with the lack of lymphohistiocytic infiltration.

In the present article, we present an additional 25 cases with clinically and histologically diagnosed flat warts that subsequently showed a characteristic regression.

MATERIAL AND METHOD

Twenty-five patients were examined. Nine of them visited us seeking treatment for their flat warts that then became inflamed during various types of treatment. Another 16 patients saw us because of the sudden and spontaneous appearance of inflammation in their flat warts. Summary of their clinical features are listed below:

Nine Patients Treated for Flat Warts

Age: 6-38 yr (mean 24.1)
Male/female: 3/6
Duration of presence of warts: 1-11 yr
Distribution of warts: face, 8; neck, 2; upper limbs, 2; dorsa of hands, 2; lower limbs, 1
Immediate preceding therapy:
- intradermal injection of purified vaccine lymph 1
- pearl barley powder (Yokuinin [Japan]; no comparable US product) orally 3
- fluorouracil ointment topically 2
- 0.05% vitamin A acid ointment topically 1
- moroxydine hydrochloride (Virustat) orally 1
- sensitization with 2% dichlorobenzene in acetone on the left upper arm 1

Duration of the preceding therapy: 3 days to 3 wk (mean 9.7 days)
Severity of pruritus: mild, 1; moderate, 7; severe, 1
Signs of inflammation:erythematous swelling, 9
Time required for resolution of warts:
2 wk, 1
3 wk, 2
4 wk, 5
6 wk, 1
(mean, 3.8 wk)

16 Patients With Spontaneously Inflamed Flat Warts

Age: 12-51 yr (mean 27.8)
Male/female: 3/13
Duration of presence of warts: unnoticed until the occurrence of sudden inflammation (2 cases)–6 yr
Distribution of warts: face, 11; dorsa of hands, 2; lower limbs, 3
Special preceding events to the occurrence of inflammation: abortion, 1; hard labor under the sun, 1; sea-bathing, 1
Severity of pruritus: mild, 3; moderate, 11; severe, 2
Signs of inflammation: erythematous swelling, 16; crusting, 3; vesiculation, 2
Time required for resolution of warts:
2 wk, 4
3 wk, 5
4 wk, 1
5 wk, 5
6 wk, 1
(mean, 3.6 wk)

Biopsies of the inflamed warts were done, but in case 7, biopsies were done both before and after the development of inflammation. Histological sections were prepared in the usual way and stained with hematoxylin-eosin. Serial sections were examined since the inflammatory changes were not uniform even in the same wart.

RESULTS

Clinical Observations

All 25 cases had similar clinical findings of erythema, swelling, and pruritus. Since inflammation occurred even in quite tiny warts on different parts of the body than had previously been noted, patients were frightened by the fact that their warts had suddenly increased in number. The pruritus ranged from mild to severe and could not be influenced either by intake of antihistamines or by topical application of steroids such as 0.1% triamcinolone acetonide and 0.025% fluocinolone acetonide. In some cases, inflammation became so severe that clearly visible vesiculation or crust formation appeared (Fig 1). After two to six weeks, the reddened warts gradually became scaly, and the inflammation subsided with complete disappearance of all the warts, occasionally leaving a slight pigmentation.

The detailed clinical courses of two representative cases follow:

CASE 7.—A 31-year-old man had suffered from numerous brownish papules on the forehead for the past two years. Diagnosis of verruca plana was made clinically and histologically (Fig 2). He was treated by provoking contact dermatitis with dichlorobenzene at the affected areas after artificial sensitization to it. Pearl barley powder, 4 gm, was also given daily. Both regimens were ineffective. Three months later, he was treated with topical application of fluorouracil ointment twice daily. Within a few days, all the warts became pruritic and prominent due to the appearance of erythema and swelling. Histological studies performed two weeks later on one of the reddened warts showed the characteristic mononuclear cell invasion in wart tissue (Fig 3). The warts gradually became scaly and flattened and disappeared within four weeks without any special treatment.

CASE 20.—A 29-year-old woman, in her fifth month of pregnancy, had been aware of an asymptomatic brownish, wart-like papular eruption over the face and dorsa of the hands for eight years. She visited us because the warts suddenly became pruritic, reddened, and enlarged in size three days before. Under the diagnosis of verruca plana with spontaneous inflammation, she was given cyanocobalamin, 500 μg subcutaneously, and oral gastric antacids. However, the pruritus continued to exacerbate and within five days, they became vesiculated (Fig 1). Similar vesicular changes also appeared in the warts on her forearms, which so far had been unnoticed by her. A biopsy of one of the vesicular lesions on the face was done that showed diffuse eosinophilic necrosis of the epidermis with subepidermal vesiculation and a dense mononuclear cell infiltration. In two days, without any further treatment, they became crusty, scaly, and less pruritic, and within two weeks, all the lesions involuted completely.

Histopathological Features

Table 1 summarizes the histopathological data from 25 patients. The characteristic feature observed in all the biopsy specimens was a dense

mononuclear cell infiltration accompanied by epidermal invasion.

Epidermis.—In the lesions representing early phases of the inflammation, the upper epidermis still retained the histopathologic condition of ordinary flat warts such as the basket weave-like appearance of the stratum corneum and vacuolated cells (44%) in the stratum granulosum. However, in the lower epidermis, beginnings of mononuclear cell invasion caused basal spongiosis and histological pigmentary incontinence (Fig 4).

Fig 1.—Extreme of inflammatory changes in flat warts; vesiculation in flat warts of a 29-year-old woman (case 20) eight days after the sudden onset of spontaneous inflammation.

In specimens that appeared to represent more advanced stages, the epidermis became extensively spongiotic and diffusely invaded by mononuclear cells, being far different from the typical histological feature of plane warts (Fig 3). Occasionally, there was even focal spongiotic vesicle formation. Necrotic epidermal cells, stained strongly with eosin, were noted in 76% of the specimens. They usually scattered in the area of epidermis with spongiosis (Fig 5). In a few cases, the upper epidermis became extensively eosinophilic. Prominent upper dermal edema or subepidermal bullae were observed beneath such diffusely necrotic epidermis.

Focal parakeratotis was prominent in the portions representing fairly advanced stages, sometimes showing eosinophilic homogeneously round bodies that were perhaps remnants of those necrotic epidermal cells interspersed within the parakeratotic scales.

The epidermal changes were not uniform, however, even in the same wart. Sometimes vacuolated cells in the stratum granulosum existed beside the area where a focal parakeratotic mound was present above the spongiotic epidermis.

Dermis.—The infiltrating cells consisted of mononuclear cells or lymphohistiocytic cells. (Smear preparations of these infiltrating cells made from the content of vesicular lesions of case 10 showed approximately an equal number of small lymphocytes and

Table 2.—Comparison of Clinical and Histological Features in Regressing Common Warts and Flat Warts

	Common Warts*	Flat Warts
Clinical features	Subjectively very painful and acutely tender	Subjectively pruritic
	Warts become dark or present dark spots or lines, together with redness of the surroundings	Systemically, all the warts become erythematous, swollen, scaly and occasionally vesiculated or crusted
Histopathological changes	Epidermis retains changes typical of common wart	Epidermal architecture characteristic for plane wart is almost replaced by spongiosis, exocytosis of mononuclear cells and eosinophilic necrotic cells
	No cellular infiltration in the dermis	Dense mononuclear cell infiltration in the upper dermis
	Blood vessels occluded with thrombosed blood	No thrombosed blood vessels but occasionally extravasation of erythrocytes from dilated capillaries

*Summarized from the data of Matthews and Shirodaria[4] and Brodersen and Genner[6].

medium-sized lymphocytes intermingled with several monocytes). Neutrophils or eosinophils were rarely seen. Since ordinary flat warts showed hypermelanosis in the basal cell layer, in the inflamed warts melanin-laden macrophages were sometimes found in the upper dermis due to the destruction of the lower epidermis.

COMMENT

It is a rather well-known fact among Japanese dermatologists that when flat warts become reddened and pruritic, they respond to any kind of treatment. There was no clinical and histological difference between spontaneous regression of flat warts and warts treated topically, eg, with fluorouracil ointment. Therefore, it seems to be reasonable to assume that various treatments carried out for flat warts were only effective for the induction of the same mechanisms as those that operate in the spontaneous regression of flat warts. We believe that this phenomenon would be more frequently observable in other nations if every patient with flat warts was closely observed.

In our 25 cases, biopsy was performed at various intervals after the onset of the regression phenomenon. Nevertheless, the characteristic mononuclear cell infiltration was invariably noted in every specimen. This observation confirmed our previous studies and suggests that infiltrating mononuclear cells mediate the regression of plane warts. In an early stage, the mononuclear cells accumulate in the lower epidermis, while the upper epidermal cells still retain the histological changes typical for verruca plana. The inflammatory cellular reactions may occur not against intranuclear wart virus but against the whole epidermal cell. These cells may have been antigenically altered as a result of infecting virus, ie, virus-transformed cells.

As the epidermal damage caused by invasion of mononuclear cells proceeds, there develops extensive spongiosis associated with focal vesiculation and scattered cell necrosis. Occasionally, the upper or whole epidermis becomes diffusely necrotic without any appreciable number of invading mononuclear cells. The almost absolute lack of neutrophils and eosinophils seems to mitigate against the major role played by humoral immunity. One speculative view is that some toxic factors such as lymphokines are released massively from infiltrating mononuclear cells.

Even after the damaged epidermal cells change into thick parakeratotic layers and the epidermal architecture characteristic for the plane wart is no longer observable, there still persists epidermal invasion of mononuclear cells. Inflammatory response may continue until the last single virus-transformed cell is eliminated.

The clinical and histological changes reported in regressing common warts[6,8] were not seen in our 25 cases (Table 2). Although Morrison[7] recently found spontaneous involution in patients who had a positive leukocyte migration inhibition test to human wart tissue antigen, other studies by Matthews and Shirodaria[6] and Brodersen and Genner[8] assigned only a minor role to cellular immunity in rejection of common wart because of the absence of a lymphoid cell infiltration in their histological specimens. If the same interpretation can be applied to explain the sudden and systemic involution of numerous plane warts, cellular immunity seems to play a major role in this disease. The reason why there is such a great difference in the clinical and histological features of spontaneous resolution between the common wart and flat wart is not clear. It is of interest that patients with a cell-mediated immune deficiency state appeared more prone to wart infection and that plane warts were by far the most common type in these patients.[9]

The phenomenon of spontaneous regression of plane warts resembles that noted in Shope papilloma of rabbit that is induced by a relative virus. Here, the phenomenon of regression also has the characteristic of an actively acquired immune response, ie, systemic and specific.[10] Regression of a flat wart may represent a human model of rejection of tumors induced by papovavirus.

Recovery Processes During Regression of Plane Warts

Masahiro Takigawa, MD; Hachiro Tagami, MD; Susumu Watanabe, MD; Atsuhiko Ogino, MD; Sadao Imamura, MD; Shigeo Ofugi, MD

• The regressing process of plane warts can be divided into two phases: initial changes of wart virus-infected cells that later result in degeneration of warts, and recovery phase in which degenerating warts are rejected from the level of the basal layer followed by regeneration of normal epidermal cells from the surrounding epidermis. Electron microscopic observations of recovery phase of wart regression showed (1) the epidermal lesion was clearly divided into degenerating wart possessing altered viruses and regenerating epidermis; (2) melanocytes were demonstrated in degenerating warts; and (3) a new granular layer was evident beneath regressing wart in late recovery. Throughout the recovery process, infiltration of lymphocytes and macrophages was observed only in regenerating epidermis.

(*Arch Dermatol* 113:1214-1218, 1977)

Spontaneous regression is not uncommon in plane warts.[1,2] Previous studies[2,3] demonstrated an inflammatory mononuclear cell infiltrate within epidermal lesions as a characteristic finding in regressing plane warts in contrast to the lack of lymphocytic infiltration in regressing common warts.[4] These studies,[2,3] however, did not detail the entire course of wart regression. The present study is concerned with the ultrastructure of regressing warts and regenerating epidermis to elucidate the morphological process of regression of plane warts.

MATERIALS AND METHODS

Five patients with regressing plane warts and two patients with nonregressing, persistent plane warts were studied. Clinical details are summarized in the Table. Diagnosis of plane warts before the onset of regression was based on clinical features and/or histopathological findings. The first obvious clinical signs of the regression were inflammatory reactions occurring suddenly and simultaneously in all the warts. Pruritus occurred to a variable degree. The reaction lasted a few weeks and was followed by complete disappearance of all warts (Fig 1 and 2). The course of regression was divided arbitrarily into three stages based on objective changes in the lesions, since each wart at one time during regression showed similar clinical features. In the early stage, erythema was a predominant sign. In the intensely inflammatory stage, swelling and scaling in addition to erythema were observed. In the late stage, inflammatory signs decreased, and scaling was prominent. When inflammation was severe, lesions appeared crusted.

Clinical Details of Patients With Regressing and Nonregressing Plane Warts*

Case No.	Age, yr/Sex	Duration†	Distribution	Clinical Features	Time for Resolution, wk
1	40/F	6 mo	Face	Ordinary plane warts	. . .
2	28/F	12 mo	Face	Ordinary plane warts	. . .
3	49/F	15 mo	Face, forearm	Itchy and reddish papules	2
4	8/F	2 mo	Face, forearm	Itchy, reddish and swollen papules	3
5	26/F	3 wk	Face	Itchy, reddish and swollen papules	3
6	31/M	12 mo	Face	Itchy and crusted papules	2
7	26/M	1 wk	Face	Itchy and crusted papules	3

*All patients were Japanese.
†Duration indicates time after the diagnosis was made and, in the last five cases, until the onset of regression.

Light and Electron Microscopy

The specimens were obtained from facial lesions of all patients. One half of each specimen was fixed in 10% formaldehyde solution and processed for routine histopathology. For electron microscopy, the other half was cut into pieces, fixed in cold 2.5% glutaraldehyde in 0.1M phosphate buffer, pH 7.4, for one hour, rinsed overnight at 4 C in the same buffer containing 0.2M sucrose, postfixed in cold 1% osmium tetroxide in the phosphate buffer for one hour, dehydrated in graded alcohol, and embedded in an epoxy resin. Thin sections were cut by glass knives on a microtome, mounted on grids coated with carbonized Formvar, stained with uranyl acetate and lead citrate, and examined in an electron microscope at 100 kV or 75 kV, respectively.

RESULTS

Light Microscopic Findings

The specimen from nonregressing plane warts (cases 1 and 2) showed typical changes of a viral wart.[3] In the early stage (case 3), the horny layer showed parakeratosis at the lowermost part. Cells in the upper portion of epidermis next to this parakeratotic area displayed a slightly eosinophilic cytoplasm, pyknotic nuclei, and ill-defined cellular outlines. Dyskeratotic cells were scattered. Spongiosis and exocytosis of mononuclear cells were noted in the lower portion of the epidermis. The upper dermis showed vascular dilation and a perivascular mononuclear cell infiltrate (Fig 3). In the intensely inflammatory stage (cases 4 and 5), parakeratosis was

LIBRARY

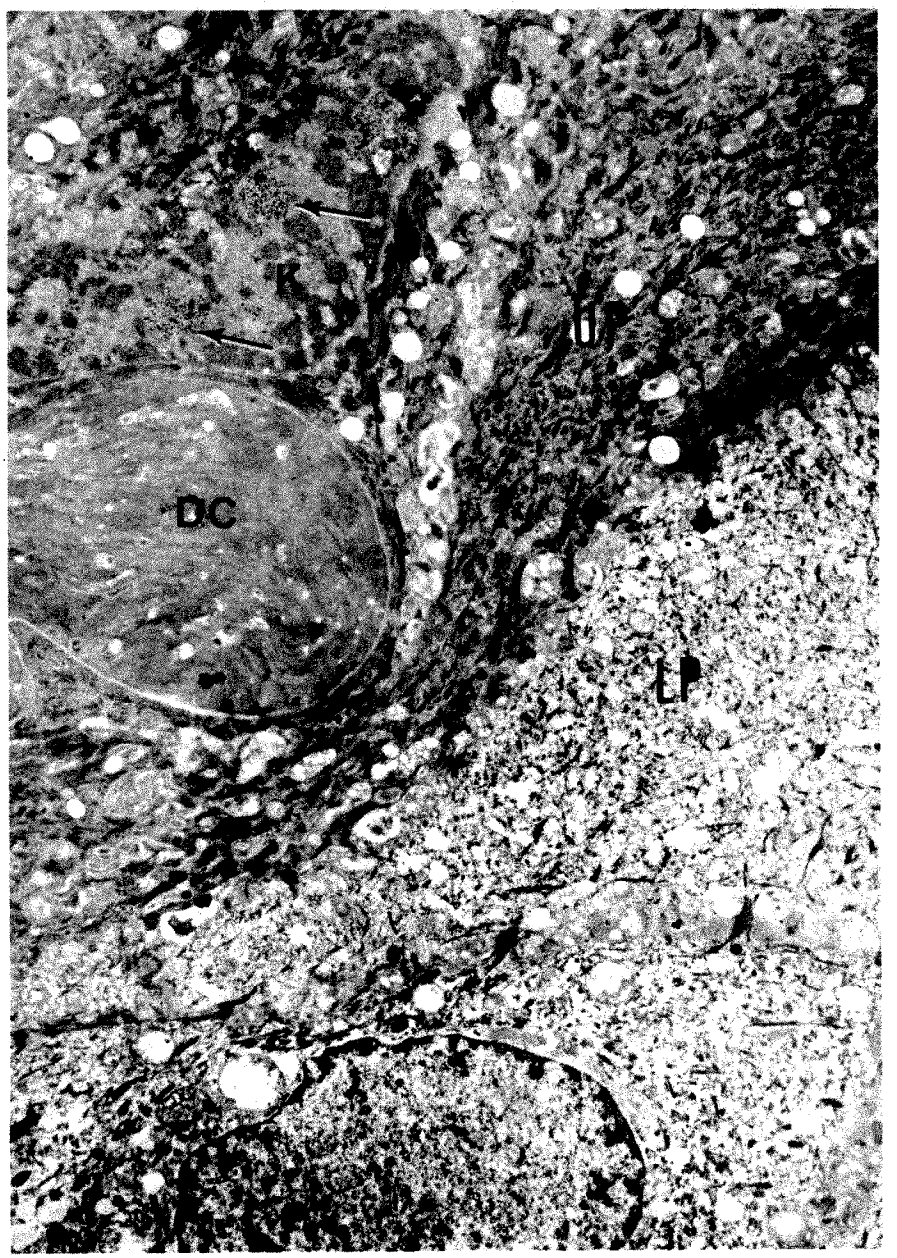

Fig 8.—Clear delineation of upper portion (UP) and lower portion (LP) of epidermis in early stage of recovery (case 3). Keratinocytes (K) with increased electron density and intranuclear particles (arrows), and dyskeratotic cell (DC) in UP are evident (original magnification, ×7,700).

more prominent throughout the entire horny layer, and mononuclear cells infiltrated a spongiotic epidermis. Cells with eosinophilic cytoplasm and dyskeratotic cells were not seen (Fig 4). Granular cells were only occasionally seen as single cells beneath the parakeratotic horny layer (Fig 5). In the late stage (cases 6 and 7), a definite, continuous granular layer had reappeared. Exocytosis of mononuclear cells was less intense than previously (Fig 6).

Electron Microscopic Findings

In control specimens (cases 1 and 2), viral particles were exclusively localized within the nuclei of cells in and adjacent to the horny layer. They were mostly spherical in shape, measured 30 to 37 mμ in diameter, and had a tendency to crystalline formation (Fig 7). Other ultrastructural findings were essentially the same as described by Lutzner[6] and Almeida et al.[7]

In the early stage (case 3), the upper portion of the epidermis had a dark appearance due to an overall high electron density of keratinocytes and could clearly be distinguished from the lower portion (Fig 8). In the dark portion, electron-dense particles giving a diameter of 22 to 44 mμ were present within the nuclei of keratinocytes (Fig 8 and 9 and inset). In their cytoplasm, mitochondria were disrupted and tonofilaments tended to clump, sometimes to form a dyskeratotic cell (Fig 8 and 9).[8] Vacuoles with and without membranes were seen commonly. Melanocytes appeared frequently within the degenerating mass of epidermal cells (Fig 10). Parakeratotic stratum corneum cells showed vacuolation and degenerative nuclei in which electron-dense particles could be recognized. No definite inflammatory cells were seen in the upper portion.

On the other hand, relatively normal-appearing keratinocytes occurred in the lower portion (Fig 8). Neither intranuclear electron-dense particles nor wart virus was observed in cells of the lower portion. In the basal and successive several layers, infiltrating lymphocytes and macrophages with lysosomes were observed in the widened intercellular spaces (Fig 11). No plasma cells or polymorphonuclear leukocytes were seen. The basement membrane and the dermal components appeared normal. These ultrastructural observations suggested that the dark, upper portion was degenerating wart while the lower portion was regenerating epidermis.

In the intensely inflammatory stage (cases 4 and 5), ultrastructural changes confirmed the light microscopic observations as follows: (1) the dead warty tissue had migrated outward into the horny layer; and (2) some high level cells contained very small keratohyalin granules (Fig 12). In addition, numerous membrane coating granules occupied the intercellular spaces of uppermost layer of regenerating epidermis.

In the late stage (cases 6 and 7), three to four layers of the granular cells were evident beneath the vacuolated horny layer (Fig 13). Infiltration of lymphocytes and macrophages in the spongiotic epidermis persisted. The appearance of many granular cells indicated that regenerating epidermal cells had resumed normal keratinization.

COMMENT

The ultrastructural observations of the early stage of wart regression showed a clear distinction between degenerating wart and regenerating epidermis. Degenerating wart contained keratinocytes with a high electron density and also many melanocytes. As the process advanced, regenerating epidermis resumed normal keratinization as indicated by the appearance of granular cells in the uppermost layer. These data imply that regression is represented by extrusion of all virus-infected cells.

Based on the finding of melanocytes in the dying tissue, we suggest that the whole lesion, including the basal layer, is rejected as the main event in wart regression. Healing would then occur by inward migration of new, uninfected basal cells from the surrounding epidermis or appendages. Alternatively, all but the basal and spinous layers are rejected, and melanocytes are drawn upward with the necrotic tissue and crowd together. The answer to this question may reflect on whether basal cells are infected with wart virus. The RNA-wart virus DNA hybridization studies of Croissant et al[9] in Shope papilloma of rabbits, the counterpart of human wart in animal experiments, suggest that the viral genome appears only in cells of the granular layer and above; but the sensitivity of their technique measured no less than 6 grains per genome. Many investigations,[10-12] on the other hand, have supported the view that proliferating cells of the basal and spinous layers contain a small number of viral genomes, probably in a provirus state.

The demonstration of regenerating epidermis in the early stage implies that recovery was already underway despite the clinical appearance. In the present study, it was not possible to detect the earliest changes of rejection, suggesting they occurred before obvious clinical signs of inflammation were noted.

Taking these observations into consideration, the regression of plane warts can be divided into two phases: (1) initial changes of wart virus-infected cells; and (2) recovery phase, although both phases might overlap. The initial changes seem to occur in almost all epidermal cells of the wart and later resulted in their degeneration. The recovery phase was composed of rejection of the degenerating wart and regeneration of normal

epidermis. In terms of the recovery, wart regression is likely to represent a type of epidermal wound healing.[13]

Recently, regression of warts has been considered to be mediated by immune responses, and several mechanisms that possibly occur have been suggested.[14-16] Prominent infiltration of mononuclear cells in the lesions may imply that cellular immunity plays an important role in the regression of plane warts.[2] Our present electron microscopic study, however, clearly demonstrated that an infiltrate composed of lymphocytes and macrophages in the epidermal lesion was restricted to the regenerating normal epidermis and at no time were inflammatory cells observed in the degenerating wart tissue. Further electron microscopic and other studies of the initial changes of regression of plane warts are needed to elucidate the exact role of infiltrating cells in regression.

S Uchida, M Fujioka, and K Akada prepared the specimen.

Flat Warts Undergoing Involution

Histopathological Findings

Alexander Berman, MD, Richard K. Winkelmann, MD

• **Patients with multiple flat warts were observed during the period of involution, shortly before regression of the warts. The histopathological process was characterized by mononuclear cell infiltration around subpapillary blood vessels, exocytosis of mononuclear cells into the epidermis, and a spectrum of degenerative epidermal changes that culminated in focal areas of necrosis within the epidermis. Lesions near the end stage of involution did not show the histopathologic features of flat warts. The mononuclear cell-associated injury to the epidermis resembles that seen in delayed cutaneous hypersensitivity responses and suggests that regression of flat warts may be due to a cell-mediated rejection reaction.**

(*Arch Dermatol* 113:1219-1221,1977)

Tagami et al,[1] in 1974, published the first report in the English language describing the histopathologic changes in plane warts undergoing spontaneous regression. Though histologic inflammatory changes in flat warts had been described in the earlier German[2,3] and Japanese[4] literature, Tagami et al[1] correlated the development of mononuclear cell infiltration with regression of the flat warts.

We became interested in the involution of flat warts after observing three patients with typical flat warts on the extremities whose lesions disappeared in a remarkably short period of time. In each instance, mononuclear cell infiltration of the lesions, with degeneration and necrosis in the epidermis, was found on microscopic examination. It became apparent that mononuclear cell infiltration and presumably destruction of the virus-infected epidermis characterized the final stage of involution, immediately prior to regression of the warts.

To define the histopathological findings during the early phases of involution, patients with multiple flat warts were observed at regular intervals over long periods of time. We found that occasionally, the onset of involution could be recognized clinically. When the onset of involution was suspected, biopsy of the lesions was done, and the patients were then observed to establish whether the remaining flat warts would subsequently regress.

Our observations on flat warts during the stage of involution constitute the basis of this report.

REPORT OF CASES

Case 1.—A 19-year-old woman was seen on July 2, 1975, with multiple flat warts on the dorsum of the left hand, thighs, and legs. In the past two weeks, many new, extremely pruritic, lesions had developed on the thighs and legs. She decided to seek medical attention because she became alarmed at the appearance of new lesions and the sudden development of itching of the warts. A total of 60 flat warts were counted. She recalled that four years previously, she had periungual warts on her fingers that disappeared without treatment. Her two brothers have warts.

A typical lesion on her thigh was excised for microscopic examination, and she was given a 6% salicylic acid-propylene glycol gel formulation (Keralyt) to rub into the warts morning and night. She returned 13 days later. The warts had all disappeared. The skin at the sites of application of the gel showed only erythema and scaling.

Case 2.—A 27-year-old woman was seen on June 27, 1975, with multiple discrete and grouped flat warts on the left thigh and knee and both legs. A plaque of flat warts was seen also on the chin. Most lesions had been present at least two years, but in the past month, many new lesions had suddenly appeared and, "in the last two weeks all the warts started to itch constantly." She had had a plantar wart removed surgically approximately ten years ago. Her brother had a wart at the age of 12 years and her mother had recently had a wart removed from her finger. A biopsy was done on a typical lesion, and she was given the 6% salicylic acid-propylene glycol gel as patient to rub into the warts. She returned 14 days later. All the warts had disappeared. Only scaling and a few excoriations on the legs were seen.

Case 3.—A 22-year-old woman had multiple discrete flat warts on the arms, thighs, and legs. Typical flat warts were present also on the left side of the forehead. She estimated that the lesions had been present approximately 1½ years.

She was given 6% salicylic acid-propylene glycol gel to rub into the warts. After approximately three months, the flat warts became erythematous, edematous, and were surrounded by halos of depigmentation. A biopsy was done on a lesion on the left leg. Five weeks later, all the flat warts had disappeared.

Histopathological Findings:

The basic pathologic process in all cases is identical. Mononuclear cells in the upper dermis infiltrate the epidermis and produce varying degrees of degeneration and necrosis within the epidermis (Fig 1).

There is hyperkeratosis, focal parakeratosis, focal crust formation, and acanthosis. The epidermis is infiltrated by inflammatory cells. Exocytosis may be focal so that collections of exocytotic mononuclear cells resemble a Pautrier abscess (Fig 2) or may be massive, producing epidermal necrosis. Degenerative changes include intracellular and intercellular edema,

Fig 1—Mononuclear cell infiltration in upper dermis, exocytosis into epidermis, and spongiosis and degeneration within epidermis. Top, Patient 1; center, patient 2; and bottom, patient 3 (hematoxylin-eosin, original magnifications ×160 [top], ×240 [center], and ×160 [bottom]).

homogenization and necrosis of groups of epidermal cells, and focal areas where epidermal architecture is lost and only fragments of cells remain. Extravasated RBCs are seen in some necrotic areas. Individually hyalinized epithelial cells are seen at all levels in areas of epidermal injury.

The upper dermis is edematous, and the subpapillary and papillary vessels are dilated and are surrounded by accumulations of mononuclear cells.

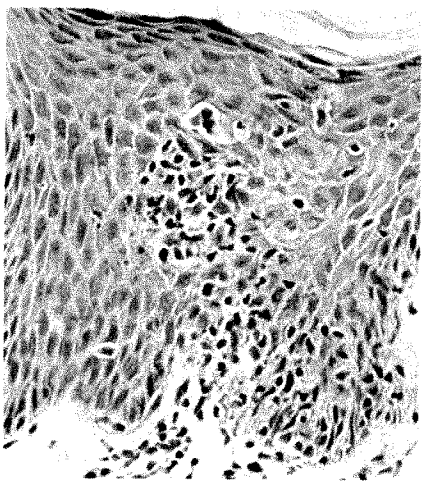

Fig 2.—Collection of exocytotic mononuclear cells and early degenerative changes in surrounding epidermis in patient 3 (hematoxylin-eosin, original magnification ×475).

These cells are remarkably uniform in size and appearance and are presumed to be lymphocytes. Larger mononuclear cells, presumably histiocytes, and plasma cells are occasionally seen. Focal areas of hemorrhage are seen around papillary blood vessels.

HISTOPATHOLOGICAL FINDINGS EARLY IN INVOLUTION

Two histologic specimen reports of flat warts were found in the files of the Mayo Clinic that showed a perivascular mononuclear cell infiltration in the upper dermis as well as characteristic histopathologic features of flat warts. The warts in these patients disappeared in a short period of time. We suspected that the mononuclear cell infiltration represented the early changes of involution.

To study the process of involution, patients with multiple flat warts were observed at regular intervals over long periods of time. Only 6% salicylic acid-propylene glycol gel was applied to the warts. We found that, occasionally, the onset of involutionary changes in the warts could be recognized clinically. When the onset of involution was suspected, lesions were excised for microscopic study, and the patients were then observed to establish whether the remaining warts would regress. In one patient studied in this manner (Fig 3), when the onset of involution was suspected by the development of an edematous appearance of the warts, five lesions were excised for microscopic study. Within one week, the warts were noted to be "getting smaller," and when she returned 25 days later, all

*Three of the five specimens (60%) showed histologic changes sufficiently well-developed to permit recognition of stage of involution. Two specimens (40%) failed to show evidence of involution.

flat warts had disappeared.

Microscopic examination of the five specimens showed histopathologic changes characteristic of flat warts: acanthosis, basket-weave hyperkeratosis, thickening of the granular cell layer, and vacuolation of the epithelial cells in the upper spinous and granular cell layers.

Specimen 1 (Fig 4) shows early but well-developed mononuclear cell infiltration in the upper corium and focal exocytosis and spongiosis in the lower epidermis. Specimen 5 (Fig 5) shows a similar pattern of mononuclear cell infiltration and spongiosis in the lower epidermis. Specimen 2 (Fig 6) demonstrates probably the earliest changes of involution. A mild perivascular infiltration of mononuclear cells in the upper dermis, a few mononuclear cells within the epidermis, and prominent intercellular edema separating the epithelial cells is seen. Specimens 3 and 4 show only mononuclear cell cuffing around the subpapillary vessels; there is no exocytosis and no epidermal injury. Involution cannot be suspected in these specimens. Apparently, involutionary changes do not develop at the same rate in all lesions but proceed independently in individual warts (Table).

CLINICAL OBSERVATIONS ON INVOLUTING FLAT WARTS

Clinical findings that suggest the onset of involutionary changes in flat warts include the following:

1. Sudden onset of itching of the warts; two patients referred to "tenderness" of the lesions.

2. Development of erythema and edema at the base of the warts so that the lesions suddenly appear larger and more prominent than previously.

3. An effluorescence of tiny new warts preceded the disappearance of all warts by several weeks in three patients.

4. Instability of the lesions. The warts may appear more prominent at one visit and less at the next. In one patient, the surface of the warts became white and edematous shortly before regression occurred.

5. Regression of one or more of the warts is a late but dependable indicator that involution is in progress.

6. Depigmented halos marked the onset of involution in two patients. Though a number of patients have since been followed up through the period of involution and regression of their warts, depigmented halos have not been seen in any other cases.

The clinical features that suggest the onset of the process of involution need more precise delineation. Studies at an institution with a controlled population that would permit frequent observation during the critical period of involution might more precisely define the clinical characteristics of the period of involution.

COMMENT

Involution evolves over a period of several weeks: two weeks was the shortest period observed, ten weeks the longest. The histopathologic changes in the early phase are primarily in the upper dermis and consist of accumulations of mononuclear cells around the subpapillary blood vessels. Exocytosis and injury to the epidermis are minimal, and the typical histopathologic features of flat warts are present. As the process evolves, mononuclear cell infiltration of the epidermis increases, and epidermal injury becomes apparent. The earliest epidermal change appears to be intercellular edema separating the epithelial cells. In the later "epidermal" phase, exocytosis of mononuclear cells and epidermal degeneration and necrosis dominate the histopathological picture. At this stage, the usual histopathologic features of flat warts may not be present, and the lesion may not be recognizable histologically as a flat wart. Associated histopathologic findings at this stage include the following: edema in the upper dermis, dilation of the papillary and subpapillary blood vessels, focal hemorrhage in the dermal papillae, individually keratinized epithelial cells, focal parakeratosis, and focal crust formation.

The mononuclear cell-associated injury to the epidermis resembles that seen in delayed cutaneous hypersensitivity responses and suggests that regression of flat warts may be due to a cell-mediated rejection reaction.

The mononuclear cell infiltration can be utilized as a histologic "marker" of involution in physiologic studies of the process of involution of flat warts.

CONCLUSIONS

Involuting flat warts are characterized histopathologically by a perivascular infiltration of mononuclear cells in the upper dermis, exocytosis of mononuclear cells into the epidermis, and a spectrum of degenerative changes within the epidermis that result in focal areas of epidermal necrosis.

Involution evolves over a period of several weeks. The intensity of the mononuclear cell infiltration and the degree of degenerative epidermal changes will depend on the stage of development of the process at the time a biopsy is done. When mononuclear cell infiltration and epidermal degeneration are advanced, the lesions may not show the characteristic histopathologic features ordinarily seen in flat warts and, in fact, may not be recognizable histologically as flat warts.

Mononuclear cell infiltration of lesions in patients with multiple flat warts can be utilized as a histologic "marker" in physiologic studies of involution of flat warts.

The onset of involution of flat warts can occasionally be recognized on clinical grounds.

The mononuclear cell-associated injury to the epidermis resembles that seen in delayed cutaneous hypersensitivity responses and suggests that regression of flat warts may be due to a cell-mediated rejection reaction.

Solar Urticaria Treatment by Inducing Tolerance to Artificial Radiation and Natural Light

Colin A. Ramsay, MD, MRCP

• **Solar urticaria was treated by means of repeated exposures of the skin to fluorescent lamps or natural sunlight. Repeated exposures over a period of hours induce a state of tolerance in the skin so that urticaria fails to develop. The state of tolerance can be maintained with regular daily exposures, and treatment can lead to complete symptomatic relief. Determination of the action spectrum for urticaria is advisable in order to choose the correct fluorescent lamp for treatment.**

(*Arch Dermatol* 113:1222-1225, 1977)

Solar urticaria is an uncommon but distinctive photodermatosis, and its effect on the patient can vary from mild discomfort to a life-threatening situation should urticaria develop on large areas of skin, producing hypotension and loss of consciousness. In the great majority of patients with this disease the cause is unknown. However, erythropoietic protoporphyria should always be excluded as the sunlight-induced eruption may be urticarial in persons with this inborn error of porphyrin metabolism.[1]

The treatment of idiopathic solar urticaria is difficult and unsatisfactory, usually consisting of orally administered antihistamines and advising the patient to avoid sunshine. This article, however, presents a completely different approach to the therapy of this condition. It has been recognized for some years that in physical urticaria due to heat, cold, and solar radiation, repeated stimulation of the same skin site with the causative agent results in that area of skin becoming unresponsive to further exposures and that this lack of response may persist for hours or days.

Nine patients with solar urticaria have been treated by repeated exposure with natural sunlight or artificial ultraviolet or visible radiation, and this would seem to be a worthwhile method of treatment that can offer complete symptomatic relief. In order not to presuppose the mechanism, which is unknown, the term "induction of tolerance" will be used to describe the process.

PATIENTS AND METHODS

The patients are detailed in Table 1.

Systemic effects after exposure to sunlight had occurred in two men (patients 1 and 7), and the effects were potentially serious for both of them. The usual sequence of events was for the patient to undress on the beach and then walk toward the sea. Exposure of a large area of skin to sunlight produced massive urticaria with hypotension. This frequently occurred just as he entered the water. Both patients had been rescued from the sea semiconscious after such a reaction.

Action Spectra for Urticaria

In each patient the action spectrum was determined using a water-filled quartz prism monochromator with 2-kW xenon lamp as the radiation source.[2] Narrow wavebands were selected throughout the ultraviolet and visible spectra between 300 and 700 nm, and the back of the trunk, previously covered, was used as the test site. To minimize the effects of stray radiation from wavelengths below 320 nm, glass filters were used, Schott filters WG 345 at 340 and 360 nm and WG 360 at 380 to 700 nm. The transmission characteristics of these filters are detailed by Kobza et al.[3] The doses given at each wavelength are shown in Table 2. Multiple doses were given at wavelengths below 320 nm, and when urticaria developed at this part of the spectrum (all patients except patient 9), it was usually possible to determine the minimal urticarial dose (Table 3). At each wavelength between 340 and 700 nm, only single large doses were given, and attempts were not made to determine the minimal urticarial dose. There were several reasons for this decision. Our prime interest in this investigation was in determining the limits of the action spectrum, so that a suitable fluorescent lamp could be selected for treatment. We were especially anxious to avoid using lamps emitting in the range of 290 to 320 nm in treatment because of the problem of delayed erythema from this part of the spectrum. Thus information on whether or not patients reacted to long-wave ultraviolet radiation (320 to 400 nm) and/or visible light (400 to 700 nm) was needed to decide to use a lamp emitting in these parts of the spectrum. In addition there was usually insufficient time and not enough previously unexposed

9, 33, M	1967	380-500

skin on the back of the trunk to determine the minimal urticarial dose at each wavelength. In Table, 1, where the limits of the action spectra are given, the longest wavelength shown is that at which urticaria developed using the doses shown in Table 2. One patient (patient 9) developed urticaria only between 380 and 500 nm, again using doses in Table 2.

The action spectra in patients 5 through 8 were very broad, but the relatively narrow band pass of the monochromator[2] and the filters used ensured that these action spectra were real and were not the result of stray radiation.

Passive transfer experiments were not carried out.

Induction of Tolerance

When the limits of the action spectrum for urticaria had been determined in each patient, one of the following fluorescent lamps was used for further treatment:

20-W White.—This has a broad emission between approximately 400 and 600 nm. The continuum is maximal at 540 to 600 nm, and mercury vapor lines are superimposed on the continuum.

20-W "Blacklamp".—The emission is approximately 320 to 400 nm, with superimposed mercury vapor lines.

20-W Actinic.—This lamp is similar to the blacklamp, but the colored filter is absent. Thus, the emission also contains mercury vapor lines in the visible light spectrum.

20-W Blue.—The continuum is approximately 330 to 500 nm with superimposed mercury vapor lines.

It can be seen from Table 1 that in one patient (patient 9), urticaria developed only between 380 and 500 nm, and the blue fluorescent lamp was therefore used. In all other patients urticaria was induced by long-wave ultraviolet radiation, 320 to 400 nm, and in some (patients 5 through 8) also by visible light. Thus the majority of these patients (patients 1, 3, 4, 5, 6, and 8) were treated with the actinic lamp, the blacklamp being used in one patient (patient 2) and the white lamp in one (patient 7).

Exposure to the lamps was carried out at a distance from the skin that was fixed for each patient but varied among patients. The number of lamps used, their distance from the skin, and the exposure time for the development of urticaria are shown in Table 4.

It was not possible to measure absolute intensity of the lamps, and so the dose used cannot be given in absolute units. However, in any one person the number of lamps used and their distance from the skin was constant throughout the period of treatment, and the same exposure time can be assumed to deliver the same dose in that patient. The lamps were always alight for 20 minutes before exposures were given, and it is reasonable to assume that the intensity of the lamps would be constant with the short exposure times used. To avoid systemic effects, a small area of skin was chosen on which to start treatment, usually one arm. The skin was exposed to the fluorescent lamps for sufficient time for urticaria to develop (Table 4), and exposures at the same site were repeated at hourly intervals until urticaria no longer occurred. This state developed in all patients but one after two to five exposures. In one patient (patient 6), it was only possible to expose the skin at two- to three-hour intervals, and it took 16 hours for tolerance to develop. In all persons the area of skin that no longer reacted by wealing was then exposed to the same amount of radiation at increasingly longer intervals of time, namely 3, 6, and then 12 hours. As soon as tolerance was achieved in one area, it was maintained by exposures every 24 hours. Coincidentally, tolerance was induced in other areas of skin in exactly the same way so that after about one week, the whole skin was refractory and this state could be maintained by exposures every 12 or 24 hours. The refractory state persisted for 48 to 72 hours unless regular exposures at 24-hour intervals were maintained. Although these regular exposures were necessary to maintain tolerance, they did not induce urticaria once the skin was in a nonreactive state. Patients were advised to purchase the appropriate fluorescent lamp and continue the treatment at home.

RESULTS

All patients were followed up for up to two years to determine whether this form of treatment offered any practical advantage. Obviously, a patient must have a high degree of motivation for this treatment to be successful. One patient (patient 2) was unable to devote the necessary time to carry out the treatment at home, mainly because he worked irregular hours, and he must be regarded as a failure.

Table 2.—Doses Given at Different Wavelengths

Wavelength, nm	Dose Given, Joules/sq cm
300	Multiple doses between 5 and 900 millijoules/sq cm*
307.5	
320	
340	10
360	12.5
380	15
400	25
500	35
600	50
700	50

*The lowest dose given at each of these wavelengths was 5, 7.5, or 10 millijoules/sq cm.

Of the remaining eight patients, three (patients 1, 4, and 7) used the lamps regularly, the remainder found that they had to spend too much time on the treatment when only four or six lamps were available at home. Ideally, a box containing sufficient lamps to irradiate the whole body at the same time should be used, but cost limits implementation of such extensive treatment. Production of tolerance with artificial radiation effectively prevented urticaria from natural sunlight in two patients (patients 1 and 4). In another (patient 7), the protection was only partial in that when the skin failed to react to fluorescent light, he still developed some urticaria from natural sunlight. Patient 7 and the remaining five patients (3, 5, 6, 8, and 9) then turned to natural sunlight for the induction of tolerance, tailoring the treatment to their own particular needs. They usually found that the urticaria produced most trouble in the summer months or at the time of a sunny winter vacation, when they exposed large areas of skin not normally exposed. These patients would then spend the first day or two of the vacation inducing tolerance with the sun, in the same way that we had demonstrated to them with the fluorescent lamps. Thus, the remainder of the holiday could be enjoyed without problems. At times these patients were content if only part of their skin was refractory, such as the upper limbs, and they would use sunlight to induce tolerance only on these areas.

None of the nine patients described here underwent spontaneous remission during the period of observation. Even in those who maintained complete tolerance with fluorescent lamps, if treatment was stopped for 48 to 72 hours, the urticaria returned.

COMMENT

The management of patients with

Table 3.—Minimal Urticarial Doses at 300 to 320 nm

Patient	Minimal Urticarial Dose, Millijoules/sq cm		
	300 nm	307.5 nm	320 nm

9	4	50	10

physical urticaria often presents problems. Treatment with repeated exposure to cold has been used in cold urticaria with varying degrees of success.[4,5] More recently one patient with severe cold urticaria[6] and another with localized heat urticaria[7] were treated by the induction of tolerance over the course of seven days with complete symptomatic relief.

The demonstration of tolerance in solar urticaria after repeated irradiation of the skin as described here is not original. It was observed by Duke in 1923[8] and has been reported on several occasions since that time.[9-11] My associates and I[12] quantitated this response in one patient at 300 nm. However, the induction of tolerance does not appear to have been used in any major way in the treatment of solar urticaria. In fact, Duke[8] stated that the tolerance gained in his patient was of no benefit. Rubin et al[9] reported one patient treated with orally administered antihistamines and repeated exposure with artificial ultraviolet radiation. Eventually the antihistamines could be discontinued, but tolerance to ultraviolet radiation could be maintained with daily exposures. These authors considered that pigmentation and/or thickening of the stratum corneum was responsible for the success of their treatment and that "densensitization" in the immunologic sense was not involved. Illig and Born[10] observed the phenomenon of what they termed "local desensitization" in two patients, but they did not apply the process in a therapeutic sense. The present report describes the use of repeated exposure to ultraviolet radiation and visible light as a form of treatment for solar urticaria in nine patients. The results varied from complete failure in one patient to partial success in six to complete success in two.

There is some evidence to support the view that at times solar urticaria is mediated by an immunologic mechanism. Harber et al[13] proposed a classification of the disease, dividing it into six types. There was evidence from passive transfer tests for an allergic mechanism in two of the types, the evidence being strong for one and less strong for the other. Sera from two patients with solar urticaria were studied by Sams[14]; in both patients there was a circulating serum factor that could be passively transferred and that behaved like a globulin although specific characterization was not possible. As Sams[14] pointed out, there are similarities and dissimilarities between IgE and the circulating factor in solar urticaria. In another type of physical urticaria—cold urticaria—it has recently been shown that a passively transferable serum factor was associated with IgE.[15] However, it should be stressed that in most persons with solar urticaria, no allergic mechanism can be demonstrated, and the cause is quite unknown.

Also unknown is the mechanism by which tolerance is induced in physical urticaria. One explanation is that specific IgE is blocked and cannot react with tissue cell receptors, thus leading to a failure of release of the mediators. No evidence exists to confirm or refute this hypothesis. True immunologic tolerance is unlikely to have occurred in these patients as the nonreactivity of the skin to the specific stimulus develops within a few hours. Another possibility is that repeated exposure produces degranulation of mast cells, so that the source of the mediators—whatever they may be—is exhausted.

Strong evidence to support this view in cold urticaria has recently been presented.[16] However, depletion of mast cells may not be the complete answer in all patients with physical urticaria in whom tolerance can be demonstrated. In one patient with localized heat urticaria,[7] an area of skin was injected at intervals with the histamine-liberator compound 48/80 until the last injection gave no response. This skin area then reacted with urticaria after exposure to heat. Conversely, in this patient an area of skin completely tolerant to heat reacted with a weal and flare to the injection of 48/80. Similar results have been obtained with ultraviolet radiation and 48/80 in patients with solar urticaria[11] (unpublished observations of the author). A patient with cold urticaria whose skin was refractory to cold reacted in a normal manner to the injection of 48/80.[6] It is possible, of course, that in these patients the cutaneous mast cells were not fully depleted by exposure to the physical agent causing the urticaria or by 48/80, and that further degranulation was produced by the other stimulus. On the other hand, there may be different receptors for the two processes.

A further possible explanation for the mechanism of action of induced tolerance is that true tachyphylaxis has occurred and that there is a lack of response of the end organ, the cutaneous blood vessels, to the mediator. Published reports do not enable any firm conclusions to be made on this point with solar urticaria, but in localized heat urticaria[7] and cold urticaria,[16] tachyphylaxis to histamine does not occur.

There are, of course, other methods of treatment of solar urticaria. If a patient reacts only to ultraviolet radiation below 320 nm, then conventional topical sunscreens might help. Many patients with solar urticaria, as in the group described here, react to long-wave ultraviolet radiation and to visible light, and topical sunscreens have limited benefit. Orally administered beta carotene was tried and failed.[17] Other systemically administered drugs have been used with apparent success, ie, chloroquine[11,18-20] and psoralen.[12] However, it is possible that in some cases the improvement that occurred while these drugs were being taken may have been due to coincidental tolerance induced by sunlight.

The results described in this article indicate that the induction of tolerance with artificial radiation or natural sunlight offers a useful treatment for solar urticaria. Highly motivated patients are able to use this form of treatment to keep themselves completely symptom-free. Others are able to maintain a level of tolerance that they themselves choose; eg, they can use the treatment just prior to a holiday in the sunshine. This variation in the degree of tolerance induced by an individual patient probably reflects the degree of interference with normal life produced by the disease. The induction of tolerance to natural sunlight probably explains the well-known clinical observation that patients with solar urticaria rarely develop problems on chronically exposed skin such as the hands and face.

CORRECTION

Missing Introductory Paragraphs.—In the article "Acne Fulminans," which appeared in the April issue of the ARCHIVES (113:444-449, 1977), the synopsis-abstract was printed twice rather than the following introductory paragraphs:

There are several severe forms of acne. An unusual acute variant with severe scarring was recognized recently. Burns and Colville[1] presented a case associated with an acute febrile reaction as "acne conglobata with septicemia (?)" in 1958. Windon (1961)[2] emphasized the combination of arthritis and severe acne in one patient as did Thyresson (1963)[3] and Moschella (1964).[4]

The most comprehensive report was published by Kelly and Burns (1971).[5] They reported three cases and described as distinctive features sudden onset with severe ulcerative lesions, fever and polyarthralgia, resistance to antibiotic therapy, and favorable response to debridement in combination with systemic therapy with corticosteroids. Ström et al[6] recently described two new cases of a similar syndrome. In addition, they reviewed 23 cases of acne conglobata admitted to the Karolinska Sjukhuset between 1962 and 1971 and found five case reports of patients with similar symptoms. The authors confirmed the findings of Kelly and Burns, with the exception of polyarthralgia, which was not present in all their patients. They stressed the importance of elevated leukocyte counts and proposed the term "acute febrile ulcerative conglobate acne with leukemoid reaction."

Atopic Dermatitis and Tuberculin Reactivity

Masami Uehara, MD

• **Transient suppression of already established tuberculin reactivity by a widespread, allergic contact dermatitis as well as by primary irritant contact dermatitis has been recently reported. Similar transient suppression of tuberculin reactivity by the eczematous inflammation of atopic dermatitis is now shown to occur. Thus, when the dermatitis is active, atopic dermatitis patients show diminished tuberculin reactivity. While they are in remission, however, a significant increase of their tuberculin reactivity occurs. Before the onset of dermatitis, their tuberculin reactivity was normal. Healed patients showed normal tuberculin reactivity. The presence of dermatitis may play an important role in the diminished cell-mediated immunity in atopic dermatitis.**

(*Arch Dermatol* 113:1226-1228, 1977)

Patients with atopic dermatitis often show diminished cell-mediated immune skin reactivity to fungal, bacterial, viral, and inorganic substances.[1-5] From a review of the literature, however, it was not clear whether the hyporeactivity is primary or whether it is secondary to whatever is causing the dermatitis.

It is known that transient impairment of cell-mediated immunity is seen in individuals with various, infectious as well as non-infectious, inflammatory processes.[6-8] Recently, Ofuji and I have shown that a widespread, allergic contact dermatitis as well as primary irritant contact dermatitis temporarily suppresses already established cell-mediated immunity in experimental animals.[9] The present study was undertaken to explore the possibility that similar temporal suppression of cell-mediated immunity might occur in patients with atopic dermatitis.

SUBJECTS AND METHODS

Patient Selection

Seventy-four patients with atopic dermatitis, ranging in age from 14 to 43 years, were the source of this study. The diagnosis was established on the basis of morphologic characteristics and distribution of skin lesions and a positive family history of respiratory atopy or eczema. All patients, on the initial visit to our clinic, had lichenified patches that involved the antecubital and popliteal fossae and other predisposed areas. Thus, according to the degree of skin involvement, they belonged to the moderately affected group (localization of the disease at four anatomical regions or more, but not generalized involvement). They were then treated for a period of two to ten years. The treatment consisted of topical application of corticosteroids and orally administered antihistamines. Internal use of corticosteroids was avoided. Clinical controls included ten adult patients with allergic contact dermatitis. Severity and extent of the dermatitis of these patients matched grossly those observed in the atopic patients. They also received topical corticosteroid and oral antihistamine therapy. Normal controls consisted of 60 adults without evidence of inflammatory skin disease.

Skin Tests

Each subject was injected intradermally with 0.1 ml of a tuberculin solution (0.5 μg of purified protein derivative per milliliter). The test solution was freshly prepared each time. The test site was normal-appearing skin on the flexor surface of the forearm. The reaction was interpreted at 48 hours. The grading was registered as positive if the diameter of the induration was 10 mm or more.

To see if the eczematous inflammation in patients with atopic dermatitis and in those with allergic contact dermatitis influenced already established tuberculin reactivity, serial examinations of their tuberculin reactivity were performed.

Patients With Atopic Dermatitis.—Thirty-two patients were tested during the exacerbation of the dermatitis and while they were in remission for a period of three weeks or more. Reexamination of tuberculin reactivity was done in 17 patients who had been almost completely free from the dermatitis for a period of one to four

years. Tuberculin reactivity before the onset of dermatitis was obtained by questioning 50 patients who had begun having the dermatitis after the age of 12 years. (In Japan, tuberculin reactivity of all school children, 6 to 12 years old, is determined and recorded by a society of health and physical education; tuberculin-negative children are inoculated with BCG vaccine.)

Patients With Allergic Contact Dermatitis.—All ten patients were tested when the dermatitis was active and during a period of two to four weeks after the subsidence of the dermatitis.

RESULTS

Patients With Atopic Dermatitis

The scattergram (Figure) demonstrates the values of tuberculin reactions found at the time of exacerbation and remission of the dermatitis in 32 atopic patients. When they had exacerbating dermatitis, the mean value of their tuberculin reactions was 3.88 ± 4.50 mm SD. If tested during a period of remission, however, the mean tuberculin reaction strength was 10.56 ± 9.24 SD. Thus, a significant increase of tuberculin reactivity occurred during the remission of the dermatitis ($P < .01$).

Fourteen of the 17 (82%) "healed" atopic patients showed a positive tuberculin reaction (the mean value was 15.00 ± 7.79 mm SD) (Table). Fifty-two of 60 (87%) normal controls were tuberculin positive (the mean value was 16.23 ± 8.12 mm SD). The tuberculin reactivity of healed atopic patients was not different from that of normal controls.

Forty-three of the 50 (86%) atopic patients who had begun having the dermatitis after the age of 12 years were found to have been tuberculin positive before the onset of dermatitis (Table). This incidence of positive reactions before the onset of dermatitis also was not different from that of normal controls.

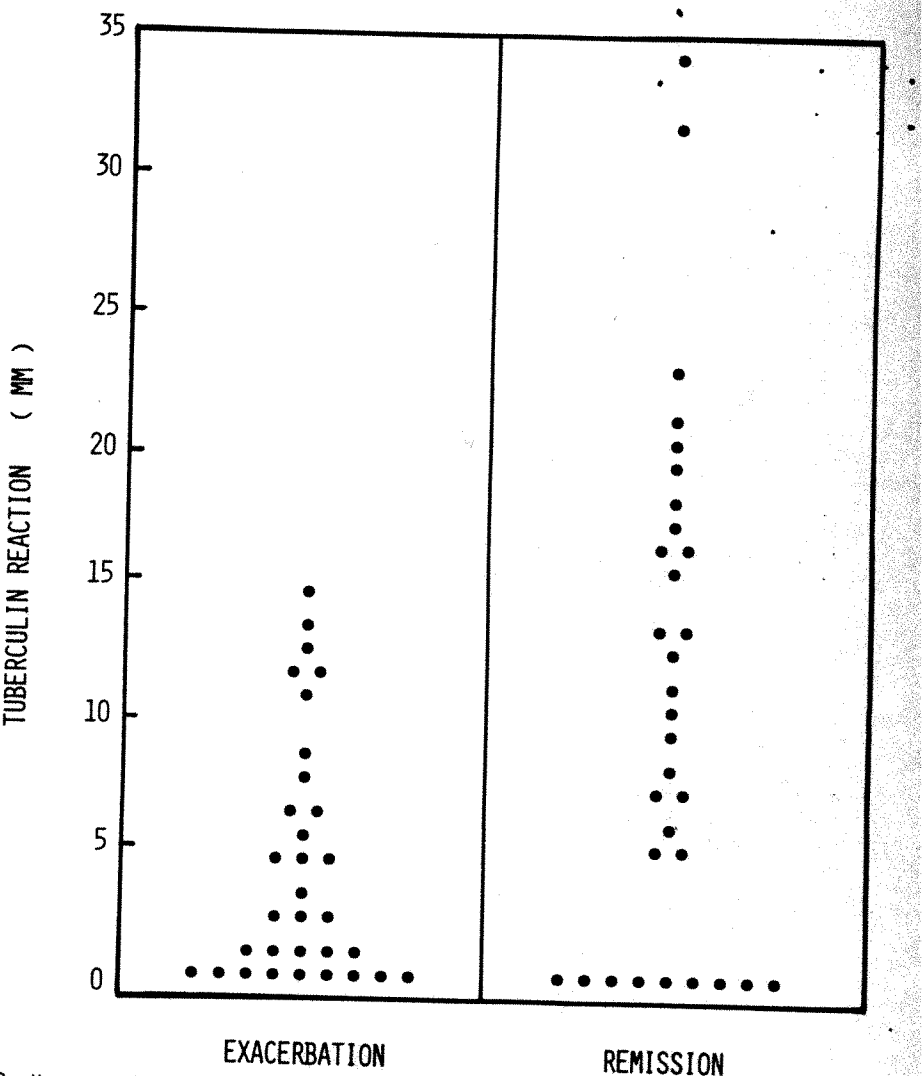
Patients With Allergic Contact Dermatitis

Two of the ten patients showed a positive tuberculin reaction when the dermatitis was active (the mean value was 6.41 ± 4.22 mm SD). Nine of the ten patients, however, were tuberculin positive at the time of reexamination after the subsidence of the dermatitis (the mean value was 15.80 ± 2.86 mm SD). Thus, allergic contact dermatitis brought about a significant suppression of tuberculin reactivity ($P < .01$).

COMMENT

The present study demonstrated that tuberculin reactivity in patients with atopic dermatitis fluctuated with the condition of the dermatitis. When there was exacerbating dermatitis, these patients exhibited diminished skin reactivity to tuberculin. If tested during a period of remission of the dermatitis, however, they showed a significant increase of tuberculin reactivity. "Healed" atopic dermatitis patients showed normal tuberculin reactivity. In those patients who had begun having the dermatitis after the age of 12 years, the incidence of positive tuberculin reactions before the onset of the dermatitis was not different from that in normal subjects. These findings suggest that, in the evaluation of cell-mediated immunity of patients with atopic dermatitis, it is necessary to investigate them not only at the time when the dermatitis is active, but also while they are in remission or free from the dermatitis.

The present study also demon-



Scattergram showing values of tuberculin reactions at the time of exacerbation and remission of atopic dermatitis (32 subjects).

Comparison of Tuberculin Reactions With Course of Atopic Dermatitis

Time of Test	No. of Cases	Tuberculin Reactions		% of Positive Reactions
		Positive	Negative

After healing of dermatitis	17	14	3	82

strated that transient suppression of tuberculin reactivity by eczematous inflammation occurred in patients with allergic contact dermatitis. Thus, it can be concluded that an eczematous inflammation of different cause suppresses already established tuberculin reactivity.

The mechanisms by which an eczematous inflammation leads to impaired tuberculin reactivity remain speculative. Inhibitory serum factors might be responsible for the diminished cell-mediated immunity in eczematous patients. Experimental animals sensitized with a contact allergen show increases in α-globulins that have immunosuppressive properties.[10] Macrophages of antigen-treated animals produce a low-molecular-weight substance that depresses the lymphocyte responses to phytohemagglutinin (PHA).[11,12] These serum factors may affect humans as well. Atopic serum with high IgE levels inhibits T-cell rosette formation of normal lymphocytes.[13] The IgE also decreases the lymphocyte proliferation with oxymercurisalicylic acid sodium (a T-cell mitogen).[14] Therefore, the IgE associated immunosuppression may play some role in the diminished cell-mediated immunity in patients with atopic dermatitis.

Several reports indicate that a subpopulation of immune lymphocytes (T lymphoblasts and their descendants) move nonspecifically to sites of eczematous inflammation.[15,16] It is therefore possible that a widespread eczematous lesion attracts a large number of immune cells in the circulating blood, so that these subjects fail to respond normally to skin test with tuberculin. All of these, as well as other possibilities require further study.

Lymphocytes from patients with atopic dermatitis are often less responsive to PHA compared with healthy subjects.[5,17] These patients show normal PHA reactivity, however, if tested during a period of remission of the dermatitis.[5,18] A recent report suggests that the leukocyte function defects in atopic dermatitis patients may normalize rapidly during remission of the dermatitis.[19]

On the basis of these data, it seems reasonable to consider that the presence of eczematous inflammation plays an important role in the diminished, in vivo and in vitro, cell-mediated immune reactivity in patients with atopic dermatitis.

Beta Carotene Therapy for Erythropoietic Protoporphyria and Other Photosensitivity Diseases

Micheline M. Mathews-Roth, MD; Madhu A. Pathak, MB, PhD; T. B. Fitzpatrick, MD, PhD; Leonard H. Harber, MD; Edward H. Kass, MD, PhD

• We treated with high doses of oral beta carotene (Solatene) (15 to 180 mg/day) 133 patients suffering from erythropoietic protoporphyria (EPP), 27 patients with polymorphous light eruption, six patients with solar urticaria, three patients with hydroa aestivale, one patient with porphyria cutanea tarda, and two patients with actinic reticuloid to relieve the photosensitivity associated with these diseases. Eighty-four percent of the patients with erythropoietic protoporphyria increased by a factor of 3 or more their ability to tolerate sunlight. On the other hand, only nine of the patients with polymorphous light eruption, and one fifth of the patients with all of the other forms of photosensitivity treated showed similar improvement.

We conclude that beta carotene is an effective treatment for EPP, but that other forms of photosensitivity will need empirical therapeutic study with beta carotene to determine the range of effectiveness, if any, of this compound in conditions other than EPP.

(Arch Dermatol **113:1229-1232, 1977**

In 1970 we reported that oral administration of beta carotene (Solatene) to three patients with erythropoietic protoporphyria (EPP) resulted in the amelioration of the photosensitivity associated with this disease.[1] In 1974, in collaboration with 16 other physicians, we reported the treatment of 50 additional patients.[2] Since that time, an additional 80 patients with EPP have been treated by us and our collaborating physicians. In addition, 39 patients with other forms of photosensitivity have been treated with high doses of beta carotene. We report herewith our data on the efficacy of beta carotene in the treatment of EPP, the lesser effectiveness of this treatment in other forms of photosensitivity, and the continued absence of evidence of toxic effects as a result of this treatment.

MATERIALS AND METHODS

Patients

The diagnostic criteria used for EPP in this study were those used previously.[2] All patients had elevated levels of protoporphyrin in blood and stool. Porphyria cutanea tarda (PCT) was defined as described by Tschudy et al,[3] including the presence of abnormal amounts of uroporphyrin and coproporphyrin in the urine. Polymorphous light eruption (PMLE), solar urticaria, and hydroa aestivale were diagnosed according to the criteria established by Pathak and Epstein.[4] Actinic reticuloid was diagnosed according to the criteria established by Ive et al.[5] The majority of the patients with these four conditions were accepted into the study because they had not obtained satisfactory photoprotection with the use of antimalarials, or the use of sunscreens had been unsatisfactory or, in the case of opaque sunscreens, cosmetically unacceptable. Porphyria was ruled out in all these patients by the finding of normal amounts of porphyrins in blood, urine, and stool.

A total of 133 patients had EPP (48 men, 36 women, 29 boys, 20 girls); 27 had PMLE (eight men, 13 women, three boys, and three girls); six patients had solar urticaria (five women and one girl); three patients had hydroa aestivale (one 7-year-old boy and two girls, 9 and 13 years old); one man had PCT, and two men had actinic reticuloid.

The patients with PMLE were classified according to lesion type as follows: 19 vesiculopapular, five erythema-edema, one eczematous, and two plaque-type. One of the six patients with solar urticaria was phototested, and was found to be sensitive to long-wavelength ultraviolet light. One of the five not phototested reported sensitivity to light through window glass. The patients with hydroa aestivale were not phototested, but all reported sensitivity to light through window glass.

Efficacy of Beta Carotene Treatment

To determine the efficacy of the beta carotene therapy, all patients visited the physician and answered detailed questionnaires.[2] All patients in all disease categories were studied two or three times over a two- to eight-week period before the beginning of therapy, to assess the variation in the patients' sensitivity to light, and at six-

†Patients showed little or no improvement despite blood carotene levels of at least 400 mg/100 ml after intake of highest dose appropriate for their ages.

to eight-week intervals during the course of therapy to assess the effect of beta carotene on the patients' tolerance to sunlight. The actual number of follow-up examinations of each patient depended on the length of time the patient was in the study. No patient had fewer than two visits, spread over a minimum of a two-month period. Fewer than 20% of the patients with EPP were seen only two times, and these were patients who did not respond to therapy or who were in the study for only six months. Eight of the patients with PMLE and half of the patients with the other photosensitivity disorders had only two visits; the remainder had three or more such visits. Similarly, 103 of the patients with EPP, 11 of the 27 patients with PMLE, and two of the 12 patients with the other forms of photosensitivity were in the study for two or more summers.

The present data from the questionnaires concern tolerance to exposure to light, and from these data we have calculated for each patient a protection index. This index is defined as the number of minutes of summer sunlight tolerated *without the development of symptoms* after therapy, divided by the number of minutes of summer sunlight tolerated without the development of symptoms before therapy. The criteria used as endpoints were itching and burning in the case of EPP and the development of characteristic skin lesions in the case of the other diseases. When patients reported a range of exposure that produced symptoms or signs of photosensitivity (the severity of photosensitivity may vary from time to time), the protection index for such patients was calculated, using appropriate statistical formulas to take these variations into account (Table 1). A protection index of 1 indicates those patients who said that beta carotene was of no benefit. To minimize the effect of small graded responses, we have considered that a protection index of less than 3 would not be held to represent appreciable improvement.

Administration of Beta Carotene

All patients underwent physical examination and a series of laboratory tests at each of their visits before and during treatment, as described previously.[2] Patients received beta carotene orally in starting doses ranging from 15 to 180 mg/day (children under 8 years, 15 to 90 mg/day; 8 to 12 years, 120 to 150 mg/day; 13 to 16 years, 150 to 180 mg/day; 16 years and above, 180 mg/day). They were instructed to increase their exposure to sunlight cautiously and gradually and to report immediately any untoward reactions (severe burning, swelling, desquamation, crusting, profuse eruptions, etc) that might occur. Dosage of the beta carotene was increased until the patient noted an amelioration of photosensitivity.[2] The serum carotene level was maintained above 400 μg/100 ml in 91% of patients. At the time therapy was begun, patients in all disease categories had few or no active skin lesions. In most cases, therapy was begun in spring or early summer before the patients experienced episodes of photosensitivity. When therapy was begun later, the patients had been avoiding exposure to sunlight.

Chemical Determinations

The hematologic and chemical analyses of blood, stool, and urine were performed as described previously.[2]

RESULTS

Table 2 shows the degree of tolerance to sunlight exposure that was achieved by the patients with EPP, as reported in the questionnaires. Eighty-four percent of the patients increased by a factor of 3 or more their stated ability to tolerate sunlight without the development of symptoms. When symptoms did develop, over three fourths of the patients reported that they were milder and of shorter duration than before treatment.

In 95% of the adult patients, the dosages of beta carotene used were those listed above. In 5% of the adults, the dose was increased to 240 mg/day before the patient experienced appreciable relief. A few children between 12 and 16 years old had to take the average adult dose (180 mg/day) to obtain relief. Those patients who did not respond to beta carotene therapy had all taken the medication for two to three months at the highest dose appropriate for their ages and had attained blood levels of beta carotene of at least 400 μg/100 ml.

Nine of the patients with PMLE and two of the patients with the other light-sensitive disorders increased their ability to tolerate exposure to sunlight by more than a factor of 3 (Table 3). Only two patients with PMLE reported marked improvement in their photosensitivity with the use of beta carotene alone. Seven patients with PMLE reported marked improvement with the use of a nonopaque topical sunscreen containing aminobenzoic acid (PreSun, Pabanol) or sulisobenzone (Uval) along with the oral beta carotene. The remaining 18 reported no improvement with the use of both oral beta carotene and the topical sunscreen. None of the 27 patients with PMLE had received any relief from the use of nonopaque sunscreens alone. One patient with solar urticaria and one patient with hydroa aestivale reported notable relief. Both stated that they obtained improvement without the use of a topical sunscreen.

In those patients who did not respond to beta carotene, therapy had been given for at least two months at the highest dose appropriate for the patient's age and blood carotene levels above 400 μg/100 ml had been attained. Of these patients who did obtain relief, two adults had to take more than 180 mg/day of beta carotene to obtain good results.

As in previous studies,[2,6-9] beta caro-

Table 3.—Effect of Beta Carotene on Tolerance to Sunlight of 39 Patients With Photosensitivity Other Than EPP

Diagnosis	Protection Index*						
	1	2	3-5	6-10	11-15	16-20	> 21
	No. of Patients						
PMLE	12	6	5†‡	2§‖	1§	0	1†‖
Solar urticaria	5	0	1‖#	0	0	0	0
Hydroa aestivale	1	1	0	0	0	0	1§
PCT	1	0	0	0	0	0	0
Actinic reticuloid	2	0	0	0	0	0	0

*Protection index is defined in Materials and Methods. Patients with protection indices of 1 and 2 showed little or no improvement despite blood carotene levels of at least 400 mg/100 ml following intake of highest dose of beta-carotene appropriate for their ages.

†One patient reporting a protection index of 4 and one patient reporting a protection index of 24 stated that they did not need to use a topical sunscreen in conjunction with beta-carotene ingestion. All other PMLE patients needed both beta-carotene and topical sunscreen to achieve the stated protection.

‡Three patients were in the study for one summer, two patients for two summers.

tene was well tolerated by all of the patients; no untoward side effects were noted other than a report by one patient who complained of an episode of loose stools, which cleared spontaneously and did not necessitate stopping treatment. The vast majority of the patients were not bothered by the carotenodermia, which developed after about four to six weeks of therapy. The hematologic and chemical determinations done while the patients were receiving beta carotene did not differ markedly from the values obtained before treatment. In the case of the EPP patients, blood and stool levels of porphyrin fluctuated, but in all cases remained above normal.

COMMENT

Two general groups of patients were treated with beta carotene: those with EPP and those with other forms of photosensitivity. In the 133 patients with EPP who reported on their tolerance to sunlight, 53 had taken beta carotene for three to five years (previously reported[2]), and the remaining 80 from six months to three years.

The data on tolerance to exposure to sunlight presented in Table 2, and also in Table 2 of our previous report,[2] are compiled from each patient's answers to the question in the standard questionnaire regarding the number of minutes (or hours) the patient could stay in the sun before symptoms developed. As mentioned above, the questionnaires were given before the start of therapy and repeated at six- to eight-week intervals after the serum level of beta carotene had reached 400 μg/100 ml. Patients were considered therapeutic failures who gave no evidence of relief to symptoms after at least two months, during which time the serum level of beta carotene was greater than 400 μg/100 ml.

Beta carotene increases the amount of time that the patient can spend in the sunlight and remain symptom-free (Table 2). It is a common experience for untreated patients to spend considerable time in the sun despite the development of unpleasant symptoms. Thus, after treatment, such patients may not actually increase the time they spend in the sun, but with treatment, they often report increases in the time spent in the sun while they remain symptom-free. The latter fact makes it necessary, in evaluating the efficacy of treatment of photosensitivity, to ask the patient, before and during treatment, about the amount of time in the sun that leads to symptoms. Otherwise, the determination of time spent in the sun may be misleading and may underestimate the effect of treatment on the appearance of symptoms. In the case of beta carotene, it is important to begin assessment of benefit only after blood levels over 400 μg/100 ml and carotenemia have developed; little or no improvement is likely to occur before attainment of such levels.

In our previous report,[2] the subjective responses of the patients were confirmed by phototesting with xenon arc light those patients treated in Boston and New York. Although the data we obtained did not allow the establishment of a linear relation between tolerance to a given amount of exposure to artificial light and tolerance to a given amount of exposure to sunlight, we found that all of the patients tested who reported increased tolerance to sunlight also demonstrated some increase to tolerance to xenon arc light. Phototesting was not routinely used during the last two years of the study reported here because of the increased number of patients. However, the testing of occasional patients confirmed the validity of the earlier observations that patients are able to verify improvement by response to standardized questionnaires. Our results have now been confirmed by several different groups of investigators.[6-9]

Two reports have been published concerning the use of beta carotene in the treatment of PMLE. Wennersten and Swanbeck treated eight patients with PMLE, and found improvements in the minimal erythema dose (tested with an appropriately filtered xenon arc lamp) of all the patients after treatment.[10] Jansen treated 66 patients, 55 of whom improved, as judged by patients' questionnaires and physicians' examinations.[11] In spite of high levels of serum beta carotene, only a third of the patients with PMLE studied by us obtained relief (Table 3). Jansen divided his patients into various clinical subtypes according to the morphologic appearance of the disease and suggested that there might be some difference in the reactions to beta carotene treatment of the various types. We have found no obvious relation between a given subtype of PMLE and likelihood of improvement after treatment with beta carotene, but our numbers are small, and larger patient numbers will be needed to elucidate a biologic basis for differences in responses of patients to the treatment.

Thune[12] administered beta carotene to 17 patients with PMLE and found "a significant increase in MED for unfiltered (xenon) light at the 5% level of probability." However, only five of the 17 patients had a protection index of more than 3 with respect to sunlight exposure, a much lower rate than the above two authors and more in line with our findings. He also could not show a direct correlation between the protection index obtained for artificial light and that obtained for sunlight exposure, as we had been unable to do for EPP.[2] He also found, as we have, that some patients benefited from the combined therapy of oral beta carotene and a topical sunscreen (5% para-aminobenzoic acid).

Porphyria cutanea tarda is success-

fully treated by phlebotomy,[13] but this treatment was contraindicated in our patient. Although acute phototoxic reactions similar to those noted in EPP are not usually seen, the cutaneous changes noted in PCT are due to porphyrin-induced photoinjury. Thus we decided to administer beta carotene in the hope of decreasing the frequency of appearance of new lesions. Examination of the patient's skin and the patient's own report after two months of beta carotene therapy showed no appreciable decrease in the number of new lesions formed. Urinary porphyrin levels and the patient's exposure to skin trauma had not changed considerably over the treatment period. Wiskemann has reported some success in the treatment of PCT with beta carotene.[14]

Our poor results with solar urticaria, hydroa aestivale, and actinic reticuloid confirm those of Kobza et al.[15]

Evaluation of therapeutic success is difficult in photosensitivity disorders in which the photosensitizer is unknown. For example, spontaneous remissions are known to occur in solar urticaria, and improvement during the course of the summer in the absence of therapy may take place in PMLE. There is the possibility that such spontaneous improvement may have occurred in some of the patients with PMLE, solar urticaria, or hydroa aestivale who stated that they improved with beta carotene therapy. The only way that the possibility of spontaneous improvement can be eliminated is to conduct a larger, controlled clinical trial, lasting more than two years. It is also possible that, in some patients, we did not give beta carotene treatment an extensive enough trial; a longer, larger trial would be needed to eliminate this possibility. In the case of the patients with EPP, the facts that make the finding of therapeutic success with beta carotene more secure are (1) porphyrin levels did not markedly decrease, (2) the majority of patients were observed for more than two years, and (3) phototesting with xenon arc light correlated qualitatively with the patients' reports of improvement.

The effectiveness of beta carotene in the amelioration in patients with EPP of photosensitivity reactions caused by long-wave ultraviolet and visible light has a scientific rationale. Excitation of protoporphyrin molecules (present either in the plasma or in the extracellular fluid that bathes the epithelial cells) by ultraviolet light can result in photo-oxidative reactions deleterious to skin cells, presumably through the formation of singlet oxygen or free radicals. Beta carotene has been shown to quench such photo-oxidative reactions.[16,17] It should be understood, however, that other types of cutaneous photosensitivity reactions (eg, the vesiculopapular eruptions, the plaque type, and the eczematous eruptions in PMLE) may not have the same cause as in EPP, and since the chromophore responsible for abnormal reactions other than in EPP is not known, the mechanism responsible for the induction of abnormal responses other than in EPP may not have the same molecular basis. Thus, beta carotene may not act as an effective blocker for the biochemical reactions that lead to the clinical symptoms in these other forms of photosensitivity. Indeed, some of the reactions in PMLE appear to have an allergic nature.[4] It should be realized, therefore, that oral beta carotene may not be an effective "sunscreen" for forms of photosensitivity disorders other than EPP. Each form of photosensitivity, both to ultraviolet and to visible light, will need empirical testing to determine the range of effectiveness of beta carotene in light-induced dermatoses.

The results we report here confirm and extend our previous findings that beta carotene therapy is usually effective in the treatment of the photosensitivity associated with EPP. At present it would appear that beta carotene may be useful in some conditions other than EPP along with a topical sunscreen, and that the use of beta carotene should be limited to those conditions (other than EPP) in which other treatments have been unsuccessful or contraindicated. In EPP, beta carotene alone seems to be an effective treatment.

This investigation was supported by research grants AM 14545-06 from the National Institute of Arthritis and Metabolic Diseases; CA 05003-17 from the National Cancer Institute; ES 00288-12 from the National Institute of Environmental Health Sciences; and HD 03693-08 from the National Institute of Child Health and Development. Hoffmann-La Roche supplied the β-carotene preparation (Solatene).

Clotrimazole vs Haloprogin Treatment of Tinea Cruris

Maj Jules V. VanDersarl, MC, USAF, Sgt Robert H. Sheppard

• A study to compare the efficacy of clotrimazole 1% solution with that of haloprogin 1% solution for the treatment of tinea cruris was conducted among military personnel on active duty in a hot, humid climate. Eighty patients with documented dermatophyte infections were treated with the topical antifungal agents. Analysis of the response to treatment for 14 days demonstrated that clotrimazole was significantly more effective clinically and mycologically than haloprogin. With no further treatment, significantly more patients treated with clotrimazole remained free of the disease four weeks later.

(*Arch Dermatol* 113:1233-1235, 1977)

Clotrimazole is an antimycotic agent effective against yeast and fungi.[1-6] To elucidate the potency of clotrimazole's antifungal capabilities in vivo, a double-blind study was designed to compare the therapeutic efficacy of clotrimazole 1% solution with that of haloprogin 1% solution, a widely used antifungal preparation. The study was conducted during the hot, humid, summer months on the Gulf Coast of Mississippi, and the population studied was limited to military personnel on active duty who had tinea cruris. The availability of large numbers of patients afflicted with dermatophytosis of the groin offered an excellent opportunity to compare the efficacy of these two antifungal agents.

SUBJECTS AND METHODS

Young men on active duty with the US Air Force who complained of a pruritic groin rash were examined by a dermatologist for clinical evidence of tinea cruris. The degree of erythema, edema, maceration, fissuring, and scale was rated by the dermatologist according to severity on a numerical scale of 1 indicating none; 2, mild; 3, moderate; and 4, severe. To verify the presence of fungi, scrapings from the areas of skin involved were examined microscopically after preparation of potassium hydroxide (KOH) mounts and were cultured on dermatophyte test medium (DTM).

Patients were accepted as study subjects who had clinical evidence of tinea cruris and a dermatophyte infection confirmed by the presence of fungal hyphae in the KOH mount and by the growth of a dermatophyte in culture, and who had not received any topical or systemic anti-infective or anti-inflammatory treatment for at least two weeks before the initial visit. Eighty men, who volunteered after the nature of the investigation had been fully explained, were admitted to the study.

The two test preparations, clotrimazole 1% solution and haloprogin 1% solution, were assigned to the patients by a third party at random according to a predetermined code. The medications were packaged in identical containers that were numbered consecutively, but labelled identically otherwise.

The patients were instructed to apply the medication with their fingertips twice a day for 14 days to the areas involved. No other topical or systemic anti-infective or anti-inflammatory agents were to be used during the 14-day study period. No specific instructions were given regarding dress or personal hygiene. A medical corpsman dispensed the coded test preparations to each volunteer, determined how much medication was used by each patient, and collected all unused medication at the end of the 14-day treatment period.

After the initial visit, the patients returned for examination at the end of one and two weeks of treatment. A follow-up examination was scheduled for four weeks after treatment ended. At each return visit, scrapings were taken from the treated areas and examined for the presence of fungi by microscopic examination of KOH mounts and by culturing on DTM. The mycologic response for each return visit was considered negative if no

fungal hyphae were seen in the KOH mount and the culture was negative for dermatophyte growth after two weeks. If either of these was positive, the mycologic response at that visit was considered positive. The clinical response was determined by the objective signs of disease and the patients' subjective evaluation of the therapy, both of which were recorded numerically according to severity and averaged for each treatment group at each follow-up period.

To evaluate the overall therapeutic efficacy of each drug at the two-week visit and at the follow-up visit, the clinical and mycologic responses were combined. Patients who had a clinical cure (ie, no signs or symptoms of dermatophytosis) and a mycologic cure (ie, negative KOH mount and negative culture) were considered to have an "excellent" response. Those who were mycologically cured but only improved clinically were considered to have a "good" response. A category of "fair" was assigned to patients who showed some clinical improvement but were mycologically positive. Those who did not respond clinically or mycologically were termed "no response."

Unless otherwise indicated, the Fisher's exact test was used for the statistical analysis.

RESULTS

The 80 men admitted to the study constituted two treatment groups which were compatible in that there were no statistically significant differences in age, race, weight, and total duration or severity of the disease when the study began.

Adverse Effects

All 80 patients who entered the trial were evaluated for tolerance to the medication. Side effects consisting of burning (12 patients), stinging (one patient), and complaints of an unpleasant odor (two patients) were reported by 15 of the 40 patients (37%) treated with haloprogin, whereas none was reported by the 40 patients treated with clotrimazole. Although the side effects were not severe enough in any patient to warrant discontinuation of treatment, the lack of side effects in the clotrimazole group was highly significant ($P < .001$).

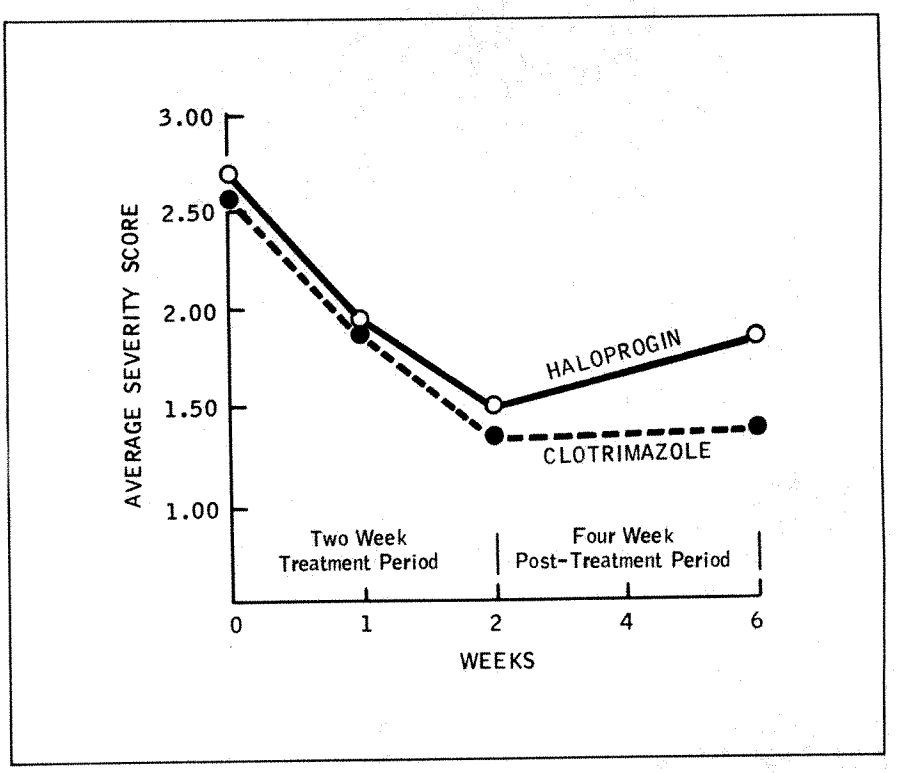
Therapeutic Efficacy

Although 80 patients entered the study, 14 were eventually omitted because of noncompliance with the protocol. Of the 66 from whom data were used for evaluation of therapeutic efficacy, 34 were treated with clotrimazole and 32 with haloprogin.

Mycologic Response.—After two weeks of treatment, the mycologic evaluation was negative (ie, conver-

Table 1.—Mycologic Response

		At End of Two-Week Treatment Period		Four Weeks After End of Treatment		
	N	Cure	Failure	Cure	Failure	No Follow-up
Clotrimazole	34	29 (85%)	5	17 (57%)	13	4
Haloprogin	32	20 (62%) ($P = .049$)	12	9 (31%) ($P = .067$)	20	3



Average severity of clinical signs and symptoms of tinea cruris during and after treatment.

Table 2.—Clinical Response

		At End of Two-Week Treatment Period			Four Weeks After End of Treatment			
	N	Cured	Improved	No Change	Cured	Improved	No Change	No Follow-up
Clotrimazole	34	22 (65%)	12	0	19 (63%)	8	3	4
Haloprogin	32	18 (56%) ($P > .05$)	12	2	10 (34%) ($P = .02$)	11	8	3

Table 3.—Overall Therapeutic Response

		At End of Two-Week Treatment Period				At Four-Week Follow-up Visit			
	N	Excellent	Good	Fair	No Response	Excellent	Good	Fair	No Response
Clotrimazole	34	20 (59%)	9	5	0	16 (53%)	1	10	3
Haloprogin	32	13 (41%) ($P = .05$)	7	10	2	7 (24%) ($P = .018$)	2	12	8

sion to negative KOH mount and negative culture), and the fungal infection was considered cured in 85% (29 of 34 patients) of the group treated with clotrimazole and in 62% (20 of 32 patients) of the haloprogin-treated group (Table 1). Analysis of the mycologic response demonstrated that clotrimazole was significantly more effective ($P = .049$) than haloprogin.

Four weeks after treatment ended, mycologic evaluation was negative in 57% (17 of 30 patients) of the group treated with clotrimazole and in 31% (nine of 29 patients) of the haloprogin group. The mycologic effectiveness of clotrimazole remained greater ($P = .067$) than that of haloprogin.

The dermatophytes isolated from the 66 patients before treatment were *Trichophyton rubrum* (in 24 subjects), *T mentagrophytes* (in ten), and *Epidermophyton floccosum* (in 32). After two weeks of treatment, *T rubrum* was no longer present in 83% (ten of 12) of the infections treated with clotrimazole and in 75% (nine of 12) of those treated with haloprogin. The infection with *T mentagrophytes* was eliminated in three of four patients treated with clotrimazole and in three of six treated with haloprogin. The mycologic evaluation became negative in 88% (16 of 18) of the infections with *E floccosum* treated with clotrimazole and in 75% (eight of 14) of those treated with haloprogin.

Clinical Response.—The clinical signs and symptoms of disease were recorded numerically according to severity, and average values were calculated for each treatment group at each follow-up period. As shown in the graph (Figure), the curves of the average severity scores indicated that the rate and degree of clinical improvement were similar in each treatment group until treatment stopped. At that time, clinical evidence of dermatophytosis began to recur rapidly in the group treated with haloprogin. By four weeks after treatment ended, the average score for severity of clinical signs and symptoms was greater in the haloprogin-treated group than in the group treated with clotrimazole; this difference was shown by the Wilcoxon two-sample test on ranked data to be statistically significant ($P = .036$).

Although there was no statistically significant difference between the two groups in the number of patients clinically cured at the end of the two-week treatment period, 65% (22 of 34) of those treated with clotrimazole had no clinical signs of dermatophytosis, compared with 56% (18 of 32) of those treated with haloprogin (Table 2). Four weeks later, however, 63% (19 of 30) treated with clotrimazole remained free of the disease, whereas only 34% (ten of 29) treated with haloprogin had no clinical signs of the disease. The numerical superiority of the clotrimazole group was statistically significant ($P = .02$).

Combined Therapeutic Assessment.—Analysis of the overall therapeutic response, as determined from the combination of clinical and mycologic data, demonstrated that clotrimazole was more effective than haloprogin at the end of the two-week treatment period ($P = .05$) and at the follow-up visit four weeks later ($P = .018$). In the group treated with clotrimazole, 59% (20 of 34) of the patients were cured after two weeks of therapy, whereas 41% (13 of 32) of those treated with haloprogin were cured (Table 3). Four weeks after treatment ended, the difference between the groups in overall therapeutic response was even greater. Only 24% (seven of 29) of the patients treated with haloprogin were cured, but 53% (16 of 30) of those treated with clotrimazole had no clinical or mycologic evidence of dermatophytosis.

COMMENT

The search continues for topical antifungal agents that are more effective yet clinically acceptable. The large number of patients treated for tinea cruris at Keesler Air Force Base during the past two years who failed to respond to treatment, or who improved initially only to have the disease recur as soon as treatment stopped, prompted us to study a new topical antifungal preparation in the hope that better remission rates might be obtained. We chose to compare its effectiveness with an antifungal agent frequently prescribed by physicians in the Gulf Coast area.

A 14-day treatment period was chosen because patients with fungal disease desire a rapid response to treatment and a prolonged cure without having to use medication any longer than necessary. Perhaps more "cures" would have been effected had the treatment been continued for a longer time; however, 14 days was long enough to compare the therapeutic efficacy of the two drugs.

Clotrimazole was not only effective, but it was significantly more effective than haloprogin in both the clinical and mycologic phases of the study. In addition, clotrimazole was preferred by the patients because it had fewer side effects.

The statistical analysis was designed and interpreted by C.M. Ordille, PhD, Delbay Pharmaceuticals, Inc, Bloomfield, NJ.

Sgt Marguerite Davis provided technical assistance.

The test materials were provided by Paul Spiekermann, MD, and Roy Battye, MD, of Delbay Pharmaceuticals, Inc.

Immunosuppressants and Prednisone in Pemphigus Vulgaris

Therapeutic Results Obtained in 63 Patients Between 1961 and 1975

Walter F. Lever, MD, Gundula Schaumburg-Lever, MD

• **Evaluation of the treatment in 63 patients with pemphigus vulgaris showed that six patients (9.5%) died of the consequences of high-dosage prednisone treatment, while 24 patients (38.1%) were free of lesions and not receiving treatment. Immunosuppressants (methotrexate, cyclophosphamide, and azathioprine) are of value in patients with severe pemphigus vulgaris since they often reduce the maintenance dose of prednisone required after high-dosage prednisone treatment. Immunosuppressants are of even greater value in patients in the early, stable stage of pemphigus vulgaris. Of 16 such patients initially treated with a combination of an immunosuppressant and maintenance doses of prednisone not exceeding 40 mg on alternate days, 13 at no time required treatment with higher doses of prednisone. The good results obtained with this method emphasize the importance of diagnosing and treating pemphigus vulgaris in its early stage.**

(*Arch Dermatol* 113:1236-1241, 1977)

In the report from the Tufts Department of Dermatology on the treatment of pemphigus vulgaris published in 1972,[1] the role of methotrexate as a therapeutic agent was discussed. Since then two other immunosuppressants, cyclophosphamide and azathioprine, have been studied.

The purpose of the present article is (1) to record the effect of treatment on the course of pemphigus vulgaris in all 63 patients first seen between 1961 and September 1975; (2) to assess the value of the immunosuppressants in the treatment; and (3) to point out the advantage of the availability of more than one immunosuppressant.

In the previous report[1] we expressed the belief that prednisone given in maintenance doses enhanced the effectiveness of methotrexate in pemphigus vulgaris. This was confirmed in the present study, particularly in regard to the treatment of pemphigus vulgaris in its early, stable stage in which the combined use of alternate-day maintenance doses of prednisone with an immunosuppressant appears to be the treatment of choice. This treatment can be carried out usually without the need for large doses of prednisone, making the therapy of pemphigus vulgaris much safer than it was when large doses of prednisone were administered routinely.[2]

PATIENTS AND METHODS

Patients

In 63 patients with pemphigus vulgaris who were first seen between 1961 and September 1975 the diagnosis was established by multiple biopsy specimens showing suprabasal acantholysis. Furthermore, the titer for antiepithelial antibodies in the serum was determined in all patients (except in patient 7, whose death preceded the use of this test) and was positive at least once at a dilution of 1:20 or higher.

The 63 patients had the following ethnic origin: 31 were Jewish, 12 Italian, five Irish, three Anglo-Saxon, three Arab, and three French. Furthermore, one patient each was Greek, Hungarian, Iranian, Negro, Scandinavian, and South American. The age of the patients at the onset of their disease varied from 20 to 79 years, and the average was 51 years. Thirty-two were women, and 31 men.

The 63 patients comprise patients 1 through 36 who were reported in the previous paper[1] with the same numbers, and patients 37 through 63 who have been seen since. For the purpose of the present report the patients were divided into five groups.

Group A comprises patients 1 through 12 in whom treatment was started routinely with daily doses of prednisone that usually were large (at least 120 mg) and rarely were intermediate (40 to 80 mg). The patients were subsequently given daily maintenance doses of prednisone and never received immunosuppressants.

Group B comprises patients 13 through 27 who, like the patients of group A, were routinely started on usually large doses of prednisone but subsequently received methotrexate in addition to maintenance doses of prednisone.

Group C comprises patients 28 through 33 and 35 through 38 with early, stable disease who initially were treated with only an immunosuppressant.

Group D comprises patients 34 and 39 through 53 with early stable disease in whom treatment was begun with the combined treatment combining alternate-day maintenance doses of prednisone not exceeding 40 mg per dose with an immunosuppressant.

Group E comprises patients 54 through 63 with advancing or advanced pemphigus vulgaris in whom treatment was begun with large daily doses of prednisone.

Monitoring the Immunosuppressants

A great advantage of treatment with immunosuppressants is that, in contrast with high-dosage administration of prednisone, serious side reactions are generally preventable by monitoring the treatment with blood cell counts, differential counts, platelet counts, and, in the case of methotrexate, liver function tests. Methotrexate frequently causes an elevation of the transaminases, SGPT and SGOT. It therefore can be given only to patients with normal liver function tests (SGOT, SGPT, alkaline phosphatase, and lactic dehydrogenase). Bone marrow depression, however, is induced rarely by methotrexate in the doses used. In general, liver function tests and blood cell, differential, and platelet counts were carried out every month initially, and, if the values remained normal, every two months later on. No liver biopsies were performed.

In contrast with methotrexate, cyclophosphamide and azathioprine in the doses used frequently cause a slight lowering of the WBC and occasionally a fairly pronounced lowering of either the total WBC or of the lymphocyte count, neutrophil count, RBC or platelet count. Usually, blood cell, differential, and platelet counts were carried out at first every two weeks, and later, if the values remained normal, once a month. Whenever the WBC count fell to values between 3,500 and 3,000/cu mm, the dose of cyclophosphamide or azathioprine was decreased, and when the values fell to below 3,000/cu mm, the drug was discontinued, at least temporarily.

RESULTS OF TREATMENT

Overall Results

The status of the 63 patients with pemphigus vulgaris first seen between 1961 and September 1975 was evaluated on Sept 1, 1976. Thus, all patients had been under observation for at least one year. Of the 36 patients who were included in the previous report,[1] none has been lost in the follow-up. On Sept 1, 1976, the status of the 63 patients was as follows: Six patients (9.5%) had died of the consequences of high-dosage prednisone treatment (see Causes of Death); five patients (7.9%) had died of causes unrelated to their disease or its treatment (see Causes of Death); 17 patients (27%) had a few lesions and were receiving treatment, one of them only with an immunosuppressant; 11 patients (17.5%) were free of lesions but were still being treated, three of them only with an immunosuppressant; and 24 patients (38.1%) were free of lesions and not receiving treatment.

Group A Results

Of patients 1 through 12 listed in the Table of the previous paper,[1] as of Sept 1, 1976, three (patients 7, 8, and 9) had died of the consequences of high-dosage prednisone treatment (see Causes of Death); patients 1 and 3 had died of unrelated causes (see Causes of Death); patient 4 had a few cutaneous lesions and was receiving treatment; and patients (2, 5, 6, 10, 11, and 12) were free of lesions and had received no treatment for periods of from 2 to 14 years, on the average for seven years.

Group B Results

Of patients 13 through 27 listed in the Table of the previous paper,[1] none had died of the consequences of high-dosage prednisone treatment; three (patients 13, 18, and 19) had died of unrelated causes (see Causes of Death); seven (patients 15, 20, 21, 22, 24, 25, and 26) had a few lesions and were receiving treatment; patient 27 had no lesions but was still receiving treatment; and four patients (14, 16, 17, and 23) were free of lesions and had received no treatment from two to eight years, an average of five years.

Group C Results

Of patients 28 through 33 and 35 through 38 (Figure), nine were treated initially with methotrexate alone and one patient (patient 38) with cyclophosphamide as the only drug. It soon became apparent, however, that even in patients with early, stable pemphigus vulgaris, treatment with only an immunosuppressant often was not effective; even in patients in whom it was effective, it was rather slow in taking effect. Immunosuppressant treatment alone, was abandoned, therefore, in favor of the combined treatment. Still, it is notable that four of the ten patients (patients 29, 30, 36, and 38) who initially were treated with only an immunosuppressant never had to be given any corticosteroids. They showed no worsening at any time, and even though improvement was slow, they ultimately cleared and treatment was discontinued. Patient 29 later on had a mild recurrence that responded to immunosuppressant therapy. These four patients have been without treatment for from four months to five years, on the average for two years.

The remaining six of the ten patients who had been started on immunosuppressants alone had flare-ups of their disease requiring high-dosage prednisone in patients 28, 31, 32, 33, and 37 and the addition of maintenance doses of prednisone in patient 35. Of the six patients requiring prednisone treatment, as of Sept 1, 1976, patient 28 had died of the consequences of high-dosage prednisone therapy (see Causes of Death); patients 32 and 35 had a few lesions and were receiving treatment; patients 31 and 33 had no lesions but were still being treated; and patient 37 had no lesions and had received no treatment for one year.

Group D Results

This group consisted of patients 34 and 39 through 53 in the early, stable stage of their disease. Only patient 34 described in the previous paper,[1] had received the combined treatment, but soon thereafter it became apparent that adding small doses of prednisone, initially 40 mg on alternate days, to the immunosuppressant was superior to the treatment with only an immunosuppressant. Whereas of the ten patients initially treated only with an immunosuppressant, five (50%) had a flare-up requiring high-dosage prednisone, only three of the 16 patients (18.7%) started on the combined treatment had a flare-up requiring high-dosage prednisone. Of these three patients, patient 41 required two high-dosage courses, and patients 44 and 50 required one high-dosage course. The other 13 patients at no time required prednisone doses exceeding 40 mg on alternate days. The state of the 16 patients on Sept 1, 1976, was as follows: Five patients (patients 34, 41, 43, 50, and 53) had a few lesions and were being treated; six patients (patients 40, 42, 44, 47, 48, and 52) had no lesions but were still receiving treatment; and five patients (patients 39, 45, 46, 49, and 51) were free of lesions and had been without treatment from three months to four years, for an average of one year. In the 11 patients who were still receiving treatment it consisted of maintenance doses of prednisone and methotrexate in four patients; of maintenance doses of prednisone and cyclophosphamide in four patients; of maintenance doses of prednisone only in two patients; and of cyclophosphamide only in one patient. Hospitalization was required by only patient 41 once for a week. This was for the purpose of studying her hyperglycemia.

Group E Results

Patients 54 through 63 were initially treated with large doses of prednisone because their pemphigus vulgaris was advancing or advanced. After their initial course of high-dosage prednisone, they were treated with alternate-day maintenance doses

Results of treatment. Present and pres. refer to Sept 1, 1976. + indicates slight involvement; + +, moderate involvement; + + +, extensive involvement; + + + +, very extensive involvement; •, oral involvement exclusively; o, oral involvement in addition to cutaneous involvement; hP, high doses of prednisone (120 mg daily or higher); mP, maintenance doses of prednisone (40 mg or less) on alternate days; M, methotrexate orally once a week; Cyc, cyclophosphamide orally every day; and Aza, azathioprine orally every day.

of prednisone and an immunosuppressant. Seven of the ten patients received only one course of high-dosage prednisone; patients 54 and 55 received two high-dosage courses; and patient 56 received four high-dosage courses. Of the ten patients in group E, as of Sept 1, 1976, patients 56 and 61 had died of the consequences of high-dosage prednisone treatment (see Causes of Death); patients 55 and 59 had a few oral lesions and were receiving treatment; patients 62 and 63 were free of lesions but were still being treated; and patients 54, 57, 58, and 60 were free of lesions and had not received any treatment for from five months to three years, for an average of 1½ years. In the four patients who were still being treated, the treatment consisted of maintenance doses of prednisone and azathioprine in two patients; of maintenance doses of prednisone and methotrexate in one patient; and of maintenance doses of prednisone and cyclophosphamide in one patient.

Recurrences

Among the 63 patients seven had recurrences of their pemphigus vulgaris after a full remission (ie, no lesions and no treatment). Patients 4, 14, 21, 23, 29, and 56 had one recurrence each, and patient 13 had two recurrences. The shortest interval between a full remission and the recurrence was nine months (patient 23), and the longest interval was ten years (patient 14), with the average duration of the interval being 3½ years. Five recurrences were mild: three of them cleared (patients 14, 23, and 29) and two persisted (patients 4 and 13, second recurrence). Two recurrences were moderately severe: one of them cleared (patient 13, first recurrence) and one persisted mildly (pa-

tient 21). In one instance (patient 56), the recurrence setting in after an interval of 20 months was very severe and resulted in death from corticosteroid-induced sepsis.

Causes of Death

In six of the 63 patients with pemphigus vulgaris high-dosage treatment with prednisone was responsible for their death. The causes of death of the first three patients have already been discussed in the previous report.[1] They died of acute myocardial infarction (patient 7), of peritonitis associated with mesentary artery thrombosis (patient 8), and of a retroperitoneal abscess (patient 9). The three patients who have died since 1972 died of staphylococcal sepsis (patient 28), of *Escherichia coli* sepsis (patient 56), and of systemic coccidioidomycosis (patient 61) (Figure).

Five patients of the previously reported series have died of causes unrelated to their disease or its treatment. Patient 3 died of a myocardial infarction while having a few lesions and receiving 7.5 mg of prednisone daily. Of the other four patients (patients 1, 13, 18, and 19) who have died since 1972, patient 1 died of bronchopneumonia and the other three of cardiac failure. Patients 1 and 18 had a few lesions and were receiving maintenance doses of prednisone but no immunosuppressants, ie, 7.5 mg of prednisone daily and 10 mg of prednisone every other day, respectively; patient 13 had no lesions and was receiving 20 mg of prednisone on alternate days but no immunosuppressant; and patient 19 was free of lesions and off treatment. These five patients had not received any high-dosage prednisone treatment for from 5 to 17 years.

Comment

Two reports of large series of patients with pemphigus vulgaris, or pemphigus vegetans, have been published recently. Rosenberg et al[3] described 90 patients with pemphigus vulgaris or pemphigus vegetans treated between 1949 and 1970. The treatment consisted almost entirely of corticosteroids; methotrexate was used in only three patients in an attempt to reduce the steroid maintenance dosage. In the 90 patients the disease- or drug-related mortality was 33%. When last seen, 20% of the 90 patients had discontinued steroid therapy. A study by Krain[4] included 49 patients with pemphigus vulgaris treated between 1955 and 1973. Only 8.2% of the patients had died of the disease or its treatment; 10.2% had died of unrelated causes; 6.1% had been lost to follow-up; 63.3% were still receiving treatment; and 12.2% were free of lesions and not receiving treatment. Thus, the mortality is similar to that of our series. However, the percentage of patients who were free of lesions and not receiving treatment is less than one third of this series (12.2% vs 38.1%). Krain indicated that the use of the Lever-White regimen (high corticosteroid dosage) and adjuvant immunosuppressive therapy (where needed for recalcitrant cases of disease) dramatically decreased mortality for pemphigus vulgaris. The immunosuppressant used was cyclophosphamide.

Evaluation of Immunosuppressants in Pemphigus Vulgaris

Three immunosuppressants have been used in the treatment of pemphigus vulgaris: methotrexate, cyclophosphamide, and azathioprine. They were given either (1) after high-dosage treatment with corticosteroids in conjunction with maintenance doses of corticosteroids, in the hope of achieving a more rapid reduction in the maintenance dose of corticosteroids amounting to a "steroid-saving" effect; (2) initially with various doses of corticosteroids; or (3) initially alone. In all reports except that by Wolff in 1976,[5] the number of patients was small and usually the length of treatment was limited. No appreciable difference in the effects of the three immunosuppressive drugs is evident from previous reports, so they will be discussed together.

Immunosuppressants Given With Maintenance Doses of Corticosteroids After High-Dosage Treatment With Corticosteroids.—A steroid-saving effect, even to the point of discontinuance of the corticosteroids, was observed in some patients with methotrexate,[6,7] cyclophosphamide,[4,8-10] and azathioprine.[11-14]

Evaluation of our own results in this category of patients can be based on 12 patients in group B (patients 15 through 21 and 23 through 27), four patients in group C (patients 31, 32, 33, and 37), and eight patients in group E (patients 54 and 55, 57 through 60, and 62 and 63). Of these 24 patients, as of Sept 1, 1976, two had died of unrelated causes (patients 18 and 19); ten patients still had a few lesions and were receiving treatment; four were free of lesions but were still under treatment; and eight were free of lesions and off treatment. With half of the patients being free of lesions, the impression is gained that immunosuppressants often are steroid-saving and, in some instances, lead to an earlier discontinuance of prednisone and even of the immunosuppressant.

Immunosuppressants Initially With Various Doses of Corticosteroids.—The initial treatment of pemphigus vulgaris with 25 mg of methotrexate weekly and, in addition, with daily high doses of prednisone seems to carry some risk because the combined action of two powerful immunosuppressants may lower the patient's resistance to microorganisms to such an extent that fatal sepsis may occur within a relatively short time. Ryan[15] observed in three of four patients receiving this type of treatment the sudden onset of a fatal bacteremia within a few weeks. Similarly, Jablonska et al[16] observed nine instances of bacterial infections, four of them fatal, among 19 patients with pemphigus; they had been given, generally for only a few weeks, methotrexate, 25 mg/week, and moderate daily doses of corticosteroids. In contrast with methotrexate, azathioprine, in daily doses of 100 to 200 mg daily, did not lower resistance to infection markedly, according to Wolff,[5] even when given initially with 150 to 200 mg of prednisone daily. He treated 24 patients with pemphigus vulgaris for from two to seven years. Two patients had died of unrelated causes; four patients still had a few lesions and were receiving treatment; 17 patients were free of lesions but were still being treated, five of them only with azathioprine; and one patient was free of lesions and off therapy. Wolff pointed out that the high initial doses of prednisone could be reduced considerably faster than when corticosteroids had been given alone.

The method of initially treating early, stable pemphigus vulgaris with an immunosuppressant and, in addition, with maintenance doses of prednisone not exceeding 40 mg on alternate days, as carried out on the 16 patients of group D, has not been used so far by other investigators. All 16 patients have done well, and only three of them needed high-dosage therapy with prednisone for short periods of time.

Immunosuppressants Alone Initially.—This treatment has proved effective only occasionally in early, stable pemphigus vulgaris. Thus, Roenigk and Deodhar,[17] in treating five patients with pemphigus vulgaris with azathio-

prine alone, achieved clearing of the lesions in two patients, but both patients were still receiving treatment with azathioprine at the time of reporting; one patient experienced a breakthrough, requiring high-dosage treatment with corticosteroids; and two patients failed to respond to azathioprine. Van Dijk and van Velde[14] described one patient with pemphigus vulgaris in whom all lesions cleared on azathioprine alone.

We obtained results similar to those of Roenigk and Deodhar[17] in ten patients with early stable pemphigus vulgaris in group C; four of the ten patients not only cleared of lesions but also discontinued the immunosuppressant. However, five of the ten patients worsened to such a degree that high-dosage prednisone became necessary. Thus, the treatment with immunosuppressants alone has shown itself to be inferior to the combined treatment with an immunosuppressant plus maintenance doses of prednisone on alternate days.

Gold Compounds.—Although this treatment has not been used in the present series of patients, it deserves mentioning as an alternative treatment. In two reports Penneys et al[18,19] described treatment with gold compounds in 18 patients with pemphigus (not all patients had pemphigus vulgaris). Gold therapy was discontinued in two patients because of toxic reactions, and one patient was unavailable for follow-up. Good results were obtained in 14 of the 15 remaining patients, and eight patients (44% of the total of 18 patients) had remissions requiring no therapy. With the exception of three patients in whom involvement was limited, all had received large doses of prednisone prior to their treatment with gold compounds. Two of the three patients who had received only chrysotherapy have been in remission without therapy for 8 and 13 months. According to Penneys et al,[19] the mode of action of gold is unknown. However, certain similarities seem to exist in the effects of gold and the immunosuppressants since in both there is a lag time of six to eight weeks or longer, and also gold therapy is suitable only for mild cases or cases partially controlled by prior therapy with corticosteroids. Like the immunosuppressants, gold can produce side reactions. Whether or not the gold compounds are equal or even superior to the immunosuppressants in effectiveness can be decided only by long-range comparison studies.

Conclusion.—In assessing the results obtained with immunosuppressants in the treatment of pemphigus vulgaris, we conclude that the immunosuppressants, when given in conjunction with maintenance doses of prednisone, are of value in two respects. First, in patients with severe or advancing pemphigus vulgaris, they are of value because, after high-dosage treatment with prednisone has been given, the administration of an immunosuppressant together with maintenance doses of prednisone has made it possible in many instances to reduce the maintenance dose of prednisone more rapidly than if prednisone had been given alone. Even more important is the role of the immunosuppressants in patients with early, stable pemphigus vulgaris, as shown in the 16 patients of group D whose initial treatment consisted of an immunosuppressant plus maintenance doses of prednisone. All 16 patients have done very well, and only three of them ever needed high-dosage therapy with prednisone. Since this treatment is suitable only for patients with early, stable disease, it is of the utmost importance that pemphigus vulgaris be diagnosed early. With few exceptions, patients with pemphigus vulgaris pass through an initial stable stage during which, for several months, only a few localized lesions are present, most commonly in the mouth.

Suggested Treatment for Severe or Advancing Pemphigus Vulgaris

High-dosage treatment with prednisone is given initially. Depending on the severity of the disease, the initial daily dose should be between 180 and 360 mg. If no improvement is noted within five days, the daily dose should be increased by at leat 60 mg. High doses of prednisone should be administered until all lesions have healed and, possibly, even beyond this time. A period of at least six weeks of high-dosage treatment is recommended, because relapses may be prevented or, if they occur, are usually mild. The prolonged treatment with high daily doses is usually well tolerated by patients receiving their first course of high-dosage prednisone, provided they did not receive prior prolonged intermediate-dose treatment. Patient 57, who died of coccidioidomycosis, was the first among the more than 100 patients with pemphigus in this series and the previous series reported by Lever and White[2] who died, without prior prolonged intermediate-dose treatment, during his first course of high-dosage prednisone. The danger of side reactions greatly increases with subsequent doses of high-dosage treatment.

After completion of the high-dosage treatment, the dose of prednisone is reduced to 40 mg daily for one week, to 30 mg daily for one week, to 25 mg daily for one week, and then to 40 mg on alternate days. At this point an immunosuppressant is added (see Suggested Treatment for Early, Stable Pemphigus Vulgaris). Further reduction of alternate-day dose of prednisone is carried out very gradually over many months, and it must be individualized. Generallly, the plan is first to eliminate the prednisone and then to reduce the immunosuppressant.

In case of an acute recurrence, high doses of prednisone should be given again, at least 120 mg daily. At the same time, the immunosuppressive drug shoud be temporarily discontinued. If high-dosage treatment is instituted soon enough, four to five weeks of treatment with high doses of prednisone may be sufficient. It seems inadvisable to give intermediate doses of prednisone, between 40 mg every other day and 120 mg daily. Intermediate doses rarely suppress an exacerbation adequately, and giving them for prolonged periods of time results in serious complications when the activity of the disease makes it unavoidable to give high-dosage treatment with prednisone.

Suggested Treatment for Early, Stable Pemphigus Vulgaris

In combining maintenance doses of prednisone with an immunosuppressant, the initial dose of prednisone is 40 mg on alternate days. Orally administered immunosuppressants may be either methotrexate, 20 mg once a week; cyclophosphamide, 100 mg daily; or azathioprine, 150 mg daily. In the stated doses they are equally effective in pemphigus vulgaris. (An occasional disadvantage of methotrexate is that oral lesions may respond poorly. Also, in rare instances a burning sensation is experienced in the oral lesions for several days after its administration.) Whereas it is inadvisable to raise the dosage of prednisone above 40 mg every other day, the dose of methotrexate may be increased to 30 mg once a week, cyclophosphamide to 150 mg daily, azathioprine to 200 mg daily. Since publication of the previous study[1] it has become apparent that no greater benefit is derived from methotrexate given in doses larger than 30 mg per week or from administering it paren-

terally rather than orally.

Usually several months, and sometimes more than a year, of this combined treatment are required before improvement occurs, but the mere fact that there is no worsening, which in most instances is the natural course of the disease, is a favorable sign. If, however, the patient's condition worsens, as it did in three of our 16 patients, high-dosage treatment is indicated. After clearing or nearly full clearing has been achieved by the combined treatment with an immunosuppressant and maintenance doses of prednisone, the amount of prednisone can be very gradually lowered from 40 mg on alternate days, at first by 5 mg per month and, after the dose has been reduced to 15 mg on alternate days, by 5 mg every two months. Thus, it requires nearly a year to phase out the alternate-day dose from 40 mg, provided there is no recurrence. Even in patients who have completely cleared, a more rapid decrease in the dose of prednisone than suggested may result in a recurrence. After elimination of the prednisone, the immunosuppressant is gradually reduced over a period of approximately six months.

In some patients reactivation occurs, even with the recommended slow decrease, necessitating either a holding of the prednisone dose at the same level for several months or a slight increase in the dose. It may be impossible for several years to eliminate the prednisone, but the alternate-day dose generally is so small that it does not pose a serious risk. In any case, none of the 13 patients who received only maintenance doses of prednisone had any complications from it. If elimination of prednisone seems unlikely in the foreseeable future, gradual reduction in the amount of the immunosuppressant can be considered to be about half the recommended initial dose.

As has been pointed out, methotrexate in several patients caused an elevation of the transaminases but did not produce any lowering of the blood cell, differential, or platelet count, whereas cyclophosphamide and azathioprine not infrequently caused a lowering of the blood cell, differential, or platelet count. Thus, in many patients a continuation of immunosuppressive therapy was possible by changing from methotrexate to cyclophosphamide or azathioprine, or vice versa (see Type of Treatment in Figure). All increases in the transaminases and decreases in the blood cell, differential, and platelet counts were temporary. In several instances, side reactions, such as nausea, lassitude, or drug fever, necessitated a change in the immunosuppressants; in patients 35 and 48 these side reactions prevented the administration of all three immunosuppressants in adequate doses.

Multiple Osteolytic Lesions in a Patient With Mycosis Fungoides

Kenneth E. Greer, MD; Larry L. Legum, MD; Charles E. Hess, MD

• **Skeletal lesions that were clinically significant and roentgenographically demonstrable developed in a patient with mycosis fungoides. Biopsy specimens from skin plaques and tumors and from a tibial tumor mass revealed an infiltrate of similar-appearing cells that were compatible with mycosis cells. Bone marrow involvement is not unusual in patients with mycosis fungoides with extracutaneous disease, but destruction of cortical bone in mycosis fungoides, as demonstrated by the patient in this report, is rare.**

(*Arch Dermatol* 113:1242-1244, 1977)

Mycosis fungoides is a cutaneous T cell lymphoma[1] that affects the skin primarily but that in its later stages may affect the lymph nodes and almost any visceral organ.[2] Involvement of the skeletal system is considered rare,[3] although in one recent report microscopic evidence of bone marrow involvement was demonstrated at autopsy in 12 of 31 patients with extracutaneous disease.[4] However, clinically significant or roentgenographically demonstrable bone lesions in patients with mycosis fungoides is very unusual.[5] We describe a patient with mycosis fungoides who had roentgenographic evidence of extensive bone involvement and pathological fractures.

REPORT OF A CASE

A 47-year-old man with known mycosis fungoides was admitted to the hospital in February 1975, for evaluation of polyarthralgia and a swollen right knee of three months' duration. Five years previously, annular erythematous patches developed on his chest and arms. The lesions were asymptomatic. In 1973, violaceous plaques and tumors developed in these same areas and were associated with mild burning but no pruritus. A diagnosis of mycosis fungoides was made on a biopsy specimen of an infiltrated lesion overlying the sternum, but no therapy was initiated at that time. The activity of these lesions would wax and wane without therapy. In November 1974, polyarthralgia of multiple joints developed, including the knees, ankles, wrists, and fingers. The patient was forced to quit his job, and he was begun on a regimen of oral prednisone, 15 mg/day, with only slight improvement of the joint symptoms but partial yet significant resolution of the cutaneous lesions. When the joint symptoms progressed, he was referred to the University of Virginia (Charlottesville) Hospital for admission.

Pertinent physical findings on admission were limited to the skin and the joints. Several tumors and infiltrated plaques characteristic of mycosis fungoides were noted on the chest and arms. There was erythema, swelling, and tenderness of the right knee, as well as slight swelling of several digits of the left hand. There was no lymphadenopathy and the liver and spleen were not enlarged as determined by palpation and percussion.

Laboratory investigations revealed hematocrit reading of 45%, a WBC count of 12,600/cu mm with a normal differential, an ESR of 119 mm/hr, and a platelet count of 377,000/cu mm. The lactic acid dehydrogenase level was 283 IU (normal, 120 to 230 IU); alkaline phosphatase level was 145 IU (normal, 30 to 85 IU), and protein electrophoresis revealed an albumin level of 2.2 gm/100 ml (normal, 4.2 to 5.2 gm/100 ml) with an increased alpha 2 fraction. Serum immunoelectrophoresis revealed an IgA level of 470/mg/100 ml (normal, 60 to 297/mg/100 ml). The tuberculin skin test was negative; skin tests with monilia and trichophytin were positive.

Roentgenograms of the bones revealed multiple osteolytic defects of the right tibia, with extensive destruction of the proximal tibia (Fig 1) and of the metacarpals and phalanges, with a pathological fracture of the fifth digit of the right hand (Fig 2). Similar defects were seen roentgenographically in numerous other bones, including the radius and ulna of both arms, both femurs, and the carpal bones of the right hand. In addition, pathological fractures were demonstrated in the proximal phalanx of the left third finger and the middle phalanx of the left second finger.

Aspiration of fluid from the right knee and bone marrow aspiration from the iliac crest revealed no abnormalities. Biopsy specimens from skin tumors and the right proximal tibial tumor mass revealed a dense infiltrate composed of large hyperchromic and anaplastic cells suggestive of mycosis fungoides (Fig 3). A biopsy specimen from an early and barely palpable skin plaque revealed exocytosis or penetration of the epidermis by these anaplastic cells with early Pautrier microabscess formation (Fig 4). Touch preps and electron micrographs revealed that the cells from the skin lesions and from the proximal tibia were remarkably similar and compatible with mycosis cells. The cells were mononuclear with large, hyperchromatic, and often irregularly shaped nuclei. Unfixed frozen sections of skin tumor were stained with hematoxylin-eosin and with fluorescein-labeled polyvalent goat anti-human immunoglobulins. The HE-stained sections revealed an intense infiltrate composed of mononuclear cells morphologically compatible with lymphocytes; no obvious immunofluorescence with anti-human globulins, indicative of B cells, was evident. This was consistent with the designation of these cells as T cells. Currently, no test is available for the positive identification of T cell markers in tissue.

On completion of the diagnostic workup, the patient was begun on a regimen of COP chemotherapy (oral cyclophospha-

mide, 750 mg/day for five days; oral prednisone, 200 mg/day for five days, and vincristine sulfate, 2 mg intravenously for one day) and radiotherapy with a cobalt teleroentgen therapy unit (4,000 rads divided in 20 doses to the right proximal tibia). The response of the tibial tumor mass to radiotherapy was excellent, with decreased pain and swelling, and in three months new bone formation was demonstrated roentgenographically. The tumors on the chest and forearm did not improve after two courses of COP chemotherapy and these lesions were subsequently treated with 2,400 rads in 12 treatments with complete regression. In September 1975, many new small infiltrated plaques developed on the trunk and extremities, as well as severe pain in the left lower tibia. Osteolytic lesions were demonstrated roentgenographically and local radiotherapy is now in progress to the left tibia.

COMMENT

Clinical or roentgenological evidence of bone involvement in malignant lymphoma varies significantly according to the type of disease, occurring commonly in Burkitt's lymphoma of African children,[6] not infrequently in Hodgkin's disease,[5] but rarely in mycosis fungoides.[7] Rappaport and Thomas[4] found microscopic evidence of bone marrow involvement in 39% of the autopsies done on patients who had had mycosis fungoides with extracutaneous disease. The lesions were grossly visible in only two. There have been few reports with roentgenographically demonstrable bone lesions in mycosis fungoides.[7] The patient reported here not only had roentgenographic evidence of extensive osteolytic lesions involving large and small bones (tibia and phalanges, respectively), but the bone lesions were clinically significant. Because of pain on ambulation from the right tibial lesion, as well as swelling and pain of the digits of both hands, he was unable to perform his duties as a heavy equipment operator.

The exact reason for the variable involvement of bone in the different types of malignant lymphoma is unknown. One plausible reason for the small number of reports of bone involvement in mycosis fungoides is the older idea of "evolution" of mycosis fungoides to Hodgkin's disease, lymphosarcoma, and histiocytic lymphoma (reticulum cell sarcoma), especially when there is extracutaneous involvement.[8] Rappaport and Thomas[4] have convincingly demonstrated in their review of the pathology of extracutaneous mycosis fungoides that the "neoplastic cellular proliferation in both cutaneous and extracutaneous tissue is distinct and different from those of other lymphoid and histiocytic neoplasms which usually arise in extracutaneous sites, but occasionally also in the skin." They base this statement on the similar appearance microscopically of the visceral and cutaneous lesions. In the early plaque stage of mycosis fungoides, the infiltrate is frequently pleomorphic with a small percentage of the so-called mycosis cells, which are characterized by their hyperchromatic and often deeply indented nuclei[9]; visceral lesions may show similar changes microscopically. Pautrier microabscesses are characteristic of the skin lesions of the plaque stage but are not seen in visceral organs. However, in the late-tumor stage, the mycosis cells are much more numerous and more anaplastic appearing, making it difficult to differentiate this disorder from other lymphomas. This may be true for both the cutaneous and extracutaneous lesions. Our patient demonstrated this difficulty in classification until the ninth biopsy specimen of his skin lesions was examined microscopically. This specimen was taken from an early and minimally infiltrated plaque and demonstrated more clearly the considerable exocytosis or penetration of the epidermis by mycosis cells producing the microabscesses. Earlier biopsy specimens had been taken from tumors or from older and heavily infiltrated plaques and they revealed a homogenous infiltration of anaplastic cells similar to the cells in the osteolytic lesion of the proximal tibia.

Another possible reason for the infrequent occurrence of gross involvement of bone in mycosis fungoides is the fact that the disorder results from the neoplastic proliferation of T cells[1] and not B cells (bursal equivalent or bone marrow-dependent lymphocytes) characteristic of most of the other malignant lymphomas and leukemias of lymphocytic origin. In addition, bone marrow involvement, when evident microscopically, is usually small and multifocal and rarely diffuse,[5] and it infrequently involves cortical bone. Also, the proliferation and infiltration of the neoplastic cells in visceral lesions of mycosis fungoides are not generally accompanied by the destructive effects characteristic of other malignant lymphomas and carcinomas.[4] The architecture of the tissue may be preserved despite the high degree of infiltration by these cells. The patient described here is unusual in that the tumor caused severe bone destruction with pathological fractures of the proximal tibia and of the phalanges.

The treatment of skeletal lesions of mycosis fungoides does not differ significantly from the treatment of other extranodal and extracutaneous forms of the disease.[10] The good response to radiation therapy in our patient was evident clinically and roentgenographically. The eventual prognosis, however, in a patient with evidence of extensive extracutaneous involvement is guarded.

Bony Lesions in Systemic Mastocytosis.

Scintigraphic Evaluation

Maj Samuel Sostre, MC, USAF, Maj Harvey L. Handler, MC, USAF

• **Bone, bone marrow, and gallium citrate Ga 67 scans were performed on a patient with systemic mastocytosis and bony involvement to evaluate their diagnostic value in such patients. The bone scan revealed increased tracer concentration in the involved areas. These abnormalities were less prominent than those on the roentgenograms, suggesting that only a part of the roentgenographic abnormalities were associated with reactive bone formation. Bone scanning may be less sensitive than roentgenograms to detect the full extent of the bony lesions of systemic mastocytosis. The bone marrow scan revealed a normal central marrow with peripheral marrow expansion. Possibly, the central marrow infiltration by mast cells was sufficient to interfere with its hemopoietic function to a degree that made it necessary to reactivate peripheral marrow tissue. There was no significant ^{67}Ga accumulation in the bony lesions of systemic mastocytosis.**

(*Arch Dermatol* 113:1245-1247, 1977)

Systemic mastocytosis is an uncommon disease characterized by the abnormal accumulation of increased numbers of mast cells in the skin, lymph nodes, viscera, and bone marrow. Bony abnormalities in this disease were first described by Sagher et al in 1952.[1] Since then, many cases with roentgenographically demonstrable bony lesions have been reported, and the roentgenographic findings in this disease are well established.[2,3] To our knowledge, the results of radionuclide scanning of such patients have not been reported.

We will describe the results of three different radionuclide imaging procedures (bone scan, marrow scan, and gallium citrate Ga 67 total body scan) performed in a patient with proven mastocytosis and roentgenographically detectable bony lesions.

REPORT OF A CASE

A 39-year-old woman came to the dermatology clinic at USAF Medical Center, Wright-Patterson AFB with a 20-year history of episodic facial flushing, nausea, tachypnea, blurred vision, dyspnea, and nasal congestion, as well as frequent headaches and skin lesions. These symptoms were exacerbated by a hot shower, exertion, swimming in cold water, or prolonged sun exposure. Headaches occurred daily, usually beginning in the late evening and lasting approximately one hour.

Results from physical examination were normal with the exception of the dermatologic examination that revealed hyperpigmented, brown macular lesions with surface telangiectases involving the entire body in a generalized fashion, but concentrated more on the extremities. Darier's sign was positive with the production of a wheal 30 to 45 seconds after scratching the lesions.

Skin biopsy specimen and toluidine blue stains revealed increased numbers of mast cells in the papillary dermis and surrounding the blood vessels. A chest roentgenogram was normal. Roentgenographic examination of the bones revealed diffuse

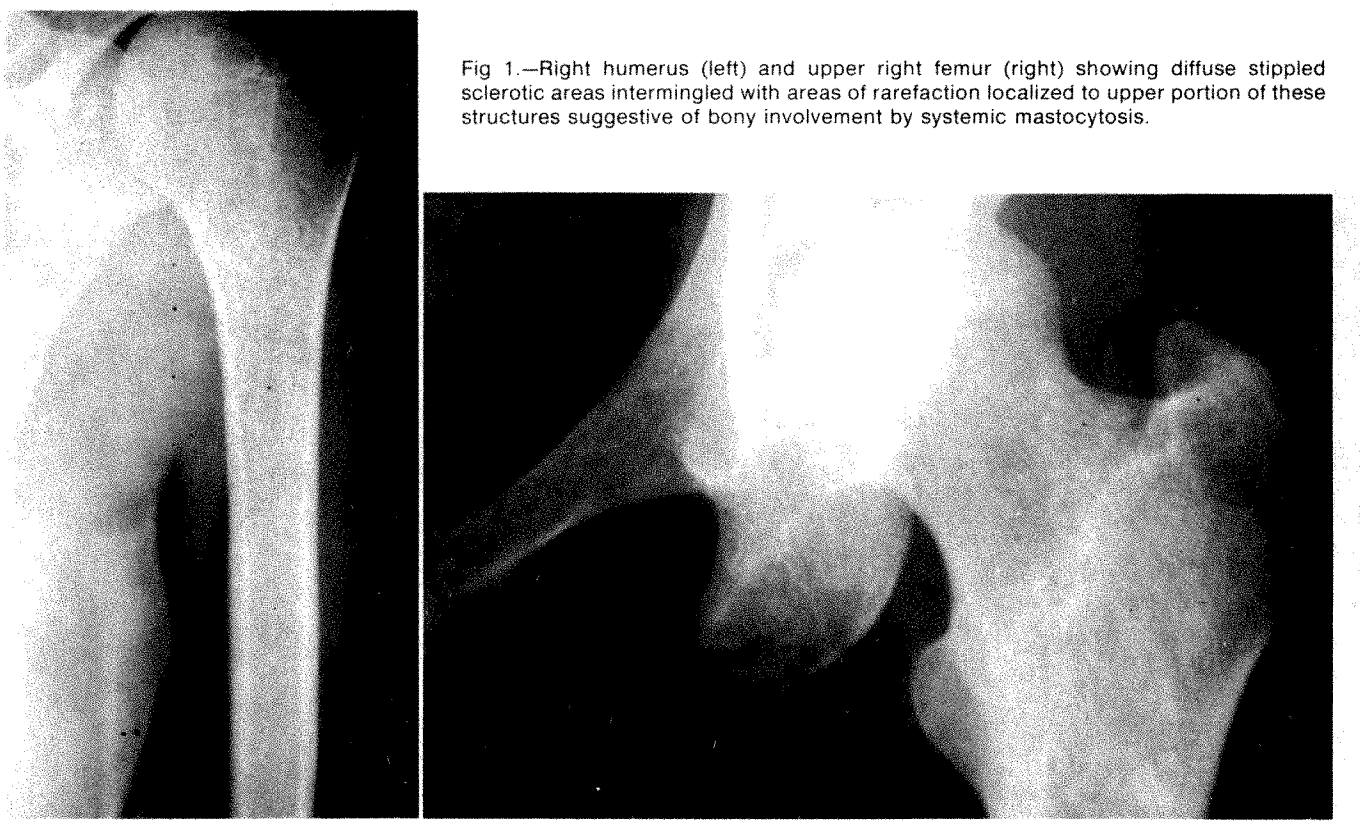

Fig 1.—Right humerus (left) and upper right femur (right) showing diffuse stippled sclerotic areas intermingled with areas of rarefaction localized to upper portion of these structures suggestive of bony involvement by systemic mastocytosis.

stippled sclerotic patches intermingled with small areas of rarefaction involving the pelvis, the proximal portion of the humeri, and the proximal portion of both femurs. No other areas were detectably involved (Fig 1).

Bone marrow aspirate from the right posterior iliac crest revealed normal myeloiderythroid ratio and orderly maturation. There was a marked increase in the number of mast cells present. Toluidine blue stains confirmed the metachromatic nature of the cytoplasmic granules. A biopsy done on bone marrow revealed impressive focal aggregates of mast cells. The complete blood cell, platelet, and reticulocyte counts were normal. Valves were within normal limits for alkaline phosphatase, SGOT, SGPT, lactic dehydrogenase, creatine phosphokinase, total protein, albumin, bilirubin, urinalysis, VDRL, sedimentation rate, and ECG.

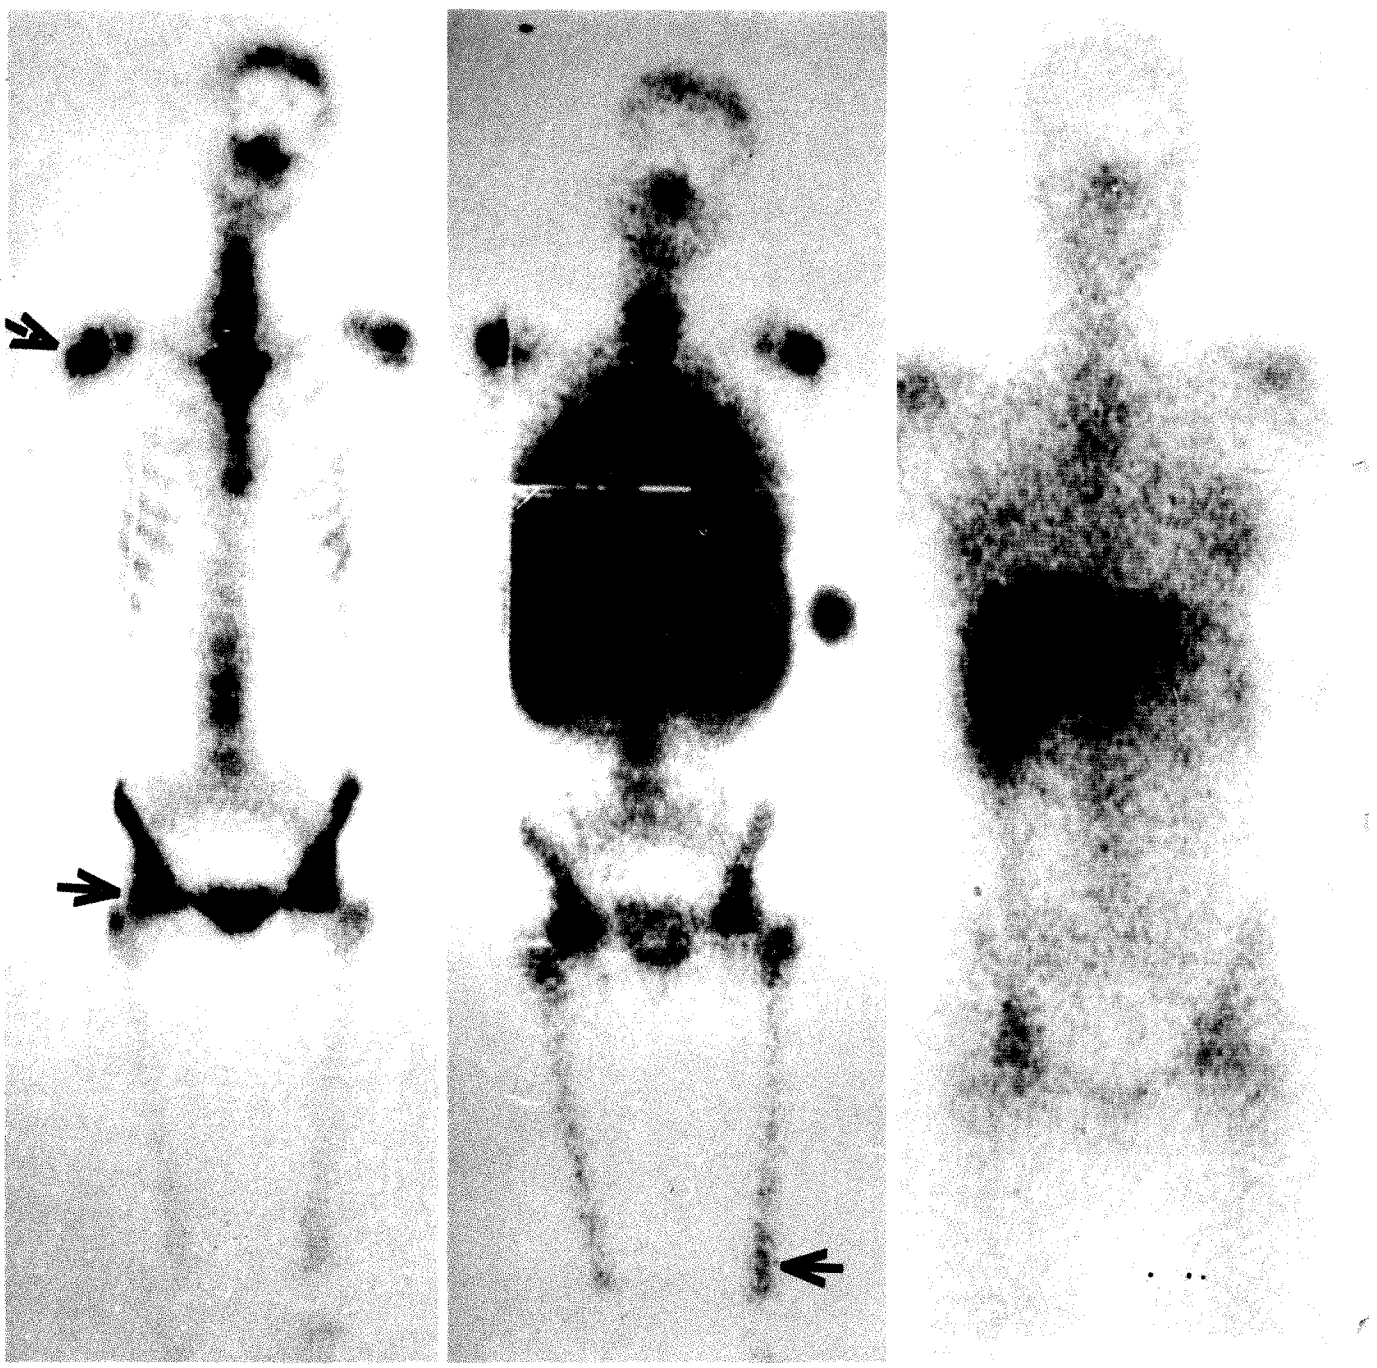
At this time, a bone scan, a bone marrow scan, and a gallium citrate Ga 67 total body scan were obtained for further evaluation of the bony lesions.

METHODS

The bone scan was obtained two hours after the intravenous administration of 15 mCi of technetium Tc 99m-pyrophosphate. A dual probe rectilinear scanner, employing a 5:1 minification mode, was used, with the window centered on the 140-kev photon of technetium Tc 99m. The bone marrow scan was performed after the intravenous administration of 12 mCi of technetium Tc 99m sulfur colloid.

For the gallium scan, the dual probe rectilinear scanner was also used, with 5:1 minification. The study was performed 48 hours after the intravenous administration of 3 mCi of gallium citrate Ga 67. Bowel preparation was performed prior to scanning.

Fig 2.—Left, Bone scan. Areas of increased activity in humeral heads and femoral heads (arrows). Center, Bone marrow scan shows expansion of peripheral marrow (arrow) with normal central marrow distribution. Right, Gallium citrate Ga 67 scan. Essentially normal findings.



RESULTS

The bone scan revealed increased activity in both humeral and femoral heads as well as in the greater trochanters of the femurs bilaterally. It was otherwise normal. These findings correspond in location to the abnormalities seen on the roentgenograms but are less extensive (Fig 2, left). The bone marrow scan revealed a normal central marrow with no focal defects, although there was significant peripheral expansion of marrow elements into the long bones (Fig 2, center). The liver was normal in size but the tracer uptake was nonuniform. The spleen was enlarged. The gallium scan was essentially normal except for a very slight increased activity in the heads of the humeri and femurs corresponding to the abnormality seen in the bone scan. There was some tracer uptake in the breast. Notice that there is no splenic uptake in spite of the splenomegaly and possible splenic involvement (Fig 2, right).

COMMENT

Urticaria pigmentosa was first described by Nettleship in 1869.[4] Although at first believed to be a disease limited to the skin, it was later learned that multiple organs could be involved with this abnormal accumulation of mast cells.[5] Lymphadenopathy and hepatosplenomegaly are determined by the hyperplasia of tissue mast cells in these organs. Various series report an incidence of 20% to 50% in systemic mastocytosia with urticaria pigmentosa that first appears after the age of 10 to 12 years. Symtoms in these patients are believed to be due to the release of histamine and possibly other substances, eg, kinins, from the mast cells into the peripheral circulation.

Stark and co-workers[6] were the first to perform a bone biopsy in a case of urticaria pigmentosa with roentgenologically demonstrable bone lesions. They found large aggregates of tissue mast cells in the bone marrow spaces that they designated "mast cell granulomas of bone." The larger lesions showed resorption of the adjacent bony spicules. Around some of these lesions there was also evidence of new bone formation. They believed that these histologic changes consisting of bone resorption and bone production correlated with the roentgenologic findings of increased lucency and increased density of bone.

Further evidence to suggest that the bony changes observed roentgenographically are secondary to the proliferation of mast cells in the bone marrow came with the autopsy studies of Sagher and co-workers.[7]

Because our patient had bone lesions, we inferred that she had mast cell involvement of her bone marrow, which was later confirmed by marrow aspiration and biopsy. To investigate the effect marrow invasion would have on a bone marrow scan, this study was performed. Intuitively, we had expected one of two changes: (1) A hypoplastic central marrow (pelvis and spine) due to replacement by tissue mast cells and/or (2) "focal defects" in the central marrow image in the areas of mast cell proliferation. Instead we found a normal central marrow with peripheral marrow expansion. Peripheral marrow expansion into the long bones can be thought of as a "compensatory phenomenon" and is seen in diseases in which blood cell production is markedly increased (ie, hemolytic anemias) or in diseases in which infiltration or "atrophy" of the central marrow occurs.[8] It is possible that the central marrow infiltration by mast cells in this patient was sufficient to interfere with its hemopoietic function to a degree that made it necessary to reactivate peripheral marrow tissue to "compensate" for the decreased blood cell production. Being microscopic, these mast cell collections are probably not large enough to be visualized by bone marrow scanning as focal defects, with the presently available techniques. Moreover, mast cell proliferation was not enough at this time to replace sufficient marrow tissue to give a "hypoplastic central marrow" appearance on the scintigram.

Generally, areas of increased activity in a bone scan represent increased blood flow or mineral turnover such as in new bone formation.[9] Mast cell aggregates in the bone marrow give rise to local bone resorption and reactive bone formation. These active areas of reactive bone formation are visualized in the bone scan.

The roentgenographic abnormalities were more striking and extensive than the scintigraphic changes present in our patient. This is unusual as bone scanning is usually more sensitive than roentgenograms in the detection of some bony lesions.[9] It may be that only a part of the roentgenographic abnormality is associated with active reactive bone formation at the time of the bone scan and, therefore, bone scanning may be less sensitive than roentgenograms to detect the full extent of bony lesions of systemic mastocytosis.

Gallium was first introduced as a bone scanning agent.[9] By serendipity, it was later found to accumulate in some malignant neoplasms, and at present it is frequently used for the detection of neoplasia. Considering mastocytosis to be a neoplastic disease, we performed a gallium scan in our patient to determine if there would be localized accumulation of tracer in the sites of bony involvement. There was a faint increased concentration of ^{67}Ga in the same areas that were abnormal by bone scanning, namely, both humeral and femoral heads. This abnormal tracer concentration is not near the extent of accumulation we usually see in malignant lesions. The faint increase in ^{67}Ga accumulation is probably a result of the tracer's function as a bone scanning agent (concentrated in the areas of increased bone formation) and not a result of its properties for visualizing a mass of cellular proliferation or infiltration.

These scintigraphic findings lend further support to the belief that mast cell marrow invasion is the cause for bony lesions in systemic mastocytosis. However, the findings themselves are nonspecific and maybe less sensitive than bone roentgenograms in the detection of bony lesions in this disease.

Obviously, it would be desirable to have more cases of systemic mastocytosis studied with these radionuclide scintigraphic techniques before judging their applicability. For the present, roentgenograms provide the best resolution and reliability for imaging bone lesions in patients with systemic mastocytosis.

Nodular Primary Localized Cutaneous Amyloidosis

Thomas A. Chapel, MD; Donald J. Birmingham, MD; Yolanta E. Malinowski, MD

• An 83-year-old woman had nodular primary localized cutaneous amyloidosis. Several anetodermic, bullous-appearing lesions were observed. Biopsy showed massive amyloid deposition with destruction of elastic and collagen fibers, but no bullous formation. It was concluded that the amyloid deposition induced anetodermic changes creating the clinical appearance of bullae.

(*Arch Dermatol* 113:1248-1249, 1977)

Nodular (tumefactive) primary localized cutaneous amyloidosis (NPLCA) is a rare condition. The skin-limited amyloid deposits appear as single or multiple pink to yellowish-brown nodules on the face, extremities, trunk, or genitals.

Recently we saw an elderly woman with NPLCA. Her nodular and bullous-appearing anetodermic lesions posed a perplexing diagnostic problem. The rarity of this condition and the unusual lesions noted in this patient prompted the following report.

REPORT OF A CASE

An 83-year-old woman was hospitalized because of a traumatic fracture of the right proximal humeral metaphysis, dehydration, and uremia. The patient's prior health had been good, and her medical history did not indicate chronic illnesses.

Examination showed a lethargic, dehydrated, somewhat senile woman. Her right arm was immobilized in a canvas splint. Large contusions were present on the right anterior section of her chest, and the deltoid and posterior scapular regions.

Abnormal physical findings included bronchial breath sounds and coarse rales over the left inframammary and left infra-axillary areas. Heart sounds were normal, and the cardiac point of maximal impulse was palpable 13 mm lateral to the midclavicular line in the fifth intercostal space.

Cutaneous examination revealed lesions of differing appearance. Shiny, wax-like, pinkish-tan to brownish-yellow, ovoid, firm nodules and plaques were present on the abdomen in the distribution of thoracic segmental nerves, T-9 to T-11. Purpura were noted in several lesions.

Six ovoid, brownish anetodermic plaques, ranging in size from 2 × 1.5 cm to 2 × 5 cm, were noted on the left side of the abdomen medial to the anterior superior iliac spine (Fig 1). The lesions suggested flaccid bullae, but fluid could not be aspirated. The overlying epithelium was easily lifted between the thumb and index finger. The elevated skin had a peculiar doughy feel and, upon release, was slow to return to normal contour. One of these lesions had a central ulceration covered with a hemorrhagic crust.

Determination of serum electrolytes, serum immunoglobulin electrophoresis, blood glucose level, VDRL, antinuclear antibody, rheumatoid arthritis latex fixation, creatine phosphokinase, and creatinine were within normal limits. Blood cultures were negative, and Bence-Jones protein levels were normal. Abnormal test results included a urine culture that grew appreciable numbers of *Escherichia coli*, an elevated lactic dehydrogenase level of 300 units/ml, uric acid 8.0 mg/100 ml, BUN 76 mg/100 ml, and alkaline phosphatase 22.5 units/ml. The hemoglobin level was 10.6 gm/100 ml, and WBC 11,900/cu mm.

An ECG showed evidence of a recent myocardial infarction. Roentgenographic examination of the chest showed slight cardiomegaly and a tortuous aorta with calcifications. A pneumonic infiltrate was present in the lingular segment of the left upper lobe.

Four-millimeter punch biopsies were obtained from both a nodular and a bullous-appearing anetodermic lesion. Sections of each were stained by the Congo red, hematoxylin-eosin, acid orcein-Giemsa, and crystal violet techniques. Both the tumefactive and anetodermic specimens had epidermal thinning with loss of the rete ridges (Fig 2). Bullae were not observed in either specimen. The papillary and subpapillary layers of both were disrupted by clumps of amorphous material that stained red with Congo red, light blue with orcein-Giemsa, and purple with crystal violet (Fig 3). Only remnants of elastic fibers remained and persisting collagen bundles stained purple in the crystal violet sections. The latter gave the impression that the collagen fibers were either impregnated with amyloid or transformed into amyloid without changing their morphologic characteristics. The walls of large vessels in the deep cutaneous plexus were thickened by metachromatically staining amorphous material.

The deeper dermis of the tumefactive specimen looked almost normal, although many collagen bundles appeared purple with the crystal violet stain. Most elastic fibers were preserved and sweat glands appeared normal.

Clumps of metachromatically staining material, together with metachromatically staining collagen bundles, filled the lower dermis of the anetodermic lesion. Elastic fibers were sparse, and those that remained were retracted and coiled. A few distorted sweat glands, surrounded by amorphous material, were observed in the upper half of the specimen. The diagnosis was cutaneous amyloidosis.

The patient became more alert with rehydration. The pneumonia cleared with aqueous penicillin G potassium, and her urinary infection was controlled with orally administered ampicillin sodium. She was ultimately discharged to a nursing home. A rectal biopsy for amyloid was not performed because of the patient's age and physical condition.

COMMENT

Cutaneous lesions of systemic amyloidosis and NPLCA are histologically indistinguishable. Both show amyloid infiltrating the deeper corium. Tumefactive lesions similar to NPLCA have

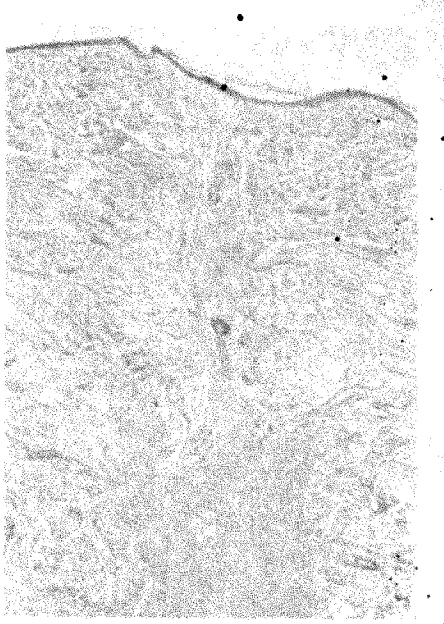

Fig 3.—Tumefactive lesion with Congo red stain (Congo red, ×20).

been described in systemic amyloidosis.[1,2] Therefore, NPLCA can be distinguished from certain types of systemic amyloidosis only after a thorough physical examination and laboratory evaluation has ruled out extracutaneous amyloid deposits. In our patient, physical and laboratory examinations showed no evidence of extracutaneous amyloid deposits or an underlying myeloma. Therefore, we believe the diagnosis is best considered NPLCA.

The case is morphologically interesting because of the prominent bullous-appearing anetodermic lesions. Blisters have been reported in association with primary systemic amyloidosis and amyloidosis associated with multiple myeloma.[3-6] Muller et al[6] removed a biopsy specimen from a frictionally produced hemorrhagic bulla in a patient with systemic amyloidosis and probable multiple myeloma. Bulla formation was due to fracture of the amyloid within the papillary dermis.

The epidermis overlying lesions of NPLCA may appear atrophic, anetodermic, or bullous. However, despite a bullous clinical appearance, histologic bullae have not been noted in patients with NPLCA.[7]

Chow and Burns[8] described a 55-year-old man with a nine-year history of flaccid bullae and waxy amyloid plaques. Neither multiple myeloma nor systemic amyloid deposits were found by extensive laboratory investigations. However, elevated gamma globulins, an elevated IgA, and a positive antinuclear factor led them to conclude that the patient had primary systemic amyloidosis. The histopathologic description reported massive amyloid deposition, but no bullous formation.

Reuter and Becker[9] reported a case of colloid degeneration of the skin in an otherwise healthy 75-year-old woman. The patient had a five-year history of pink papules and orange-colored nodules and plaques that began on the chest and spread over the trunk and onto the arms and thighs. Several anetodermic, bladder-like protuberances were observed on the arms and abdomen.

Brownstein and Helwig[7] found the clinical course and laboratory and histologic data in both these cases consistent with NPLCA. The bladder-like projections described by Reuter and Becker[9] and the flaccid bullae reported by Chow and Burns[8] are suggestive of the bullous-appearing lesions seen in our case.

The histologic sections from our patient's anetodermic lesion showed greater destruction of the deep dermal architecture than was observed in the tumefactive specimen. It appears that the severe anetodermic changes were produced by full dermal destruction of elastic and collagen fibers. This created the clinical appearance of bullae. However, the true nature of the process was suggested by the presence of purpura in adjacent plaque and nodular lesions. The association of spontaneous or traumatically induced hemorrhage in amyloid deposits is well known.

This investigation was supported by the Detroit General Hospital Research Corp. Amir H. Mehregan, MD, and Hermann Pinkus, MD, confirmed the diagnosis of cutaneous amyloidosis. Dr Mehregan also provided Fig 2.

Apocrine Cystadenoma of the Penile Shaft

Ralph F. Powell, MD; Charles H. Palmer, MD; Edgar B. Smith, MD

• What is to our knowledge the first apocrine cystadenoma reported on the penile shaft is described. Of 96 previously reported apocrine cystadenomas, more than 90% were located on the face, ears, or scalp; the remainder occurred on the chest, axilla, or prepuce. Apocrine cystadenoma should be considered in the differential diagnosis of solitary blue, gray, or flesh-colored cystic nodules in those areas.

(*Arch Dermatol* 113:1250-1251, 1977)

Apocrine cystadenoma (hidrocystoma) is a benign hamartoma derived from the secretory segment of apocrine sweat glands. It usually occurs singly as a smooth, dome-shaped translucent nodule that possesses a flesh colored or a gray or bluish black hue. Characteristic histologic[1] and ultrastructural features[2] have been described. This tumor is usually found on the face, and occasionally it is found on the ears or scalp, although uncommonly it is seen elsewhere. Because few of these lesions have been recorded on other parts of the skin, we are reporting an apocrine cystadenoma that occurred on the penile shaft.

REPORT OF A CASE

A 23-year-old uncircumsized man was referred to us for treatment of a penile "wart." On the ventral aspect of the penile shaft he had an asymptomatic cystic lesion that had been present for two years. The mass was flesh colored with a slight bluish hue and measured 4 × 5 mm (Fig 1). Preoperative diagnoses included apocrine cystadenoma, epidermoid inclusion cyst, and mucus retention cyst. The lesion was excised for histologic evaluation.

HISTOPATHOLOGY

The specimen consisted of a cystic soft tissue lesion measuring 1.3 × 0.3 × 0.2 cm. Examination of the microscopic section revealed a normal epidermis without follicles or other epidermal appendages. Within the dermis were several cystic spaces lined with simple to pseudostratified columnar epithelium and containing proteinaceous debris and homogeneous eosinophilic round bodies of varying size (Fig 2). Serial sectioning demonstrated that the spaces formed a single cyst. In some sections, the cyst wall consisted of a simple sheath of secretory epithelium; in other areas, papillary projections of the cyst wall were contained within the central cavity. The columnar epithelium contained focal areas of decapitation secretion, and a myoepithelial layer was seen peripheral to the secretory cells (Fig 3). With special stains, PAS-

positive, diastase-resistant granules were seen in the secretory cells.

COMMENT

In our review of the literature, we found that apocrine cystadenoma was rarely reported as occurring in areas other than the head. In one study of 17 apocrine cystadenomas, all of the lesions were on the face or scalp and most of them were on the cheeks.[1] Several case reports have additionally described one or several lesions on the face[3-5] or scalp,[6] some in association with nevus sebaceous.[7,8] In their large series of 50 apocrine cystadenomas in 42 patients, Smith and Chernosky[9] found only two lesions not located on the head. Both occurred on the anterior chest. Earlier, Holder et al[10] reported the first such tumor on the trunk, a giant apocrine cystadenoma, and also on the anterior chest. One such tumor has been reported in the axilla[11] and three apocrine cystadenomas have been reported on the prepuce.[12,13] Apocrine cystadenomas of the prepuce may be less rare than these two reports would suggest. A pathologist at our institution has seen several of these tumors, heretofore unreported, on routine examination of the products of circumcision (oral communication, William C. Black, MD, January 1975). Reluctance to have an asymptomatic penile lesion examined or to have a biopsy done also may account for the lack of reports of these lesions occurring there. Notwithstanding 96 previously reported cases, we found only seven apocrine cystadenomas (less than 7%) to occur below the neck, ie, on the anterior chest, axilla, or prepuce.

The tumor's bluish hue prompted consideration of apocrine cystadenoma in our differential diagnosis. About 50% of all reported cases of these tumors were various shades of blue, often being bluish black and occasionally grayish blue. The remainder were translucent or clear, pearly, skin color, or brown.

Apocrine glands are encountered on the face, scalp, axillae, around the nipples, the anogenital region, and as modified glands in the external ear canals, eyelids, and breast.[14] It is in these regions that apocrine cystadenomas should most commonly occur and must be considered in the clinical differential diagnosis of cystic lesions, particularly if they exhibit a bluish coloration.

Allergic Contact Dermatitis From Sunscreen Preparations Complicating Photodermatitis

Greg Thompson, MD; Howard Maibach, MD; John Epstein, MD

• **Two men with known histories of photosensitivity had apparent exacerbations of their dermatoses. Patch-testing showed the presence of allergic contact sensitivity to the sunscreens that they were using. The clinical distribution patterns of adverse reactions to sunscreens naturally simulate sun-induced reactions, thus providing clinical problems that require evaluation by both patch and photo-patch tests. These findings emphasize that allergic contact or photocontact dermatitis from sunscreens that are used for prophylaxis of photodermatitis can actually complicate or aggravate the preexisting state of photodermatitis for which the sunscreens are prescribed.**
(*Arch Dermatol* 113:1252-1253, 1977)

Of the several modalities available for control of photosensitivity dermatoses, protection from sunlight is the single most important. Few patients are able to spend their lives totally avoiding solar rays. Therefore, the use of sunscreen agents is often mandatory during daylight hours.

Accepted for publication July 23, 1976.

From the Department of Dermatology, University of California School of Medicine, San Francisco.

Reprint requests to University of California Hospital, San Francisco, CA 94143 (Dr Maibach).

Although there is no cosmetically acceptable sunscreen affording complete protection, some have gained considerable acceptance in the treatment of persons with photosensitivity. Among the more popular and widely used compounds are aminobenzoic acid and its esters, and the substituted benzophenones.

We describe a photosensitive patient who developed an allergic eczematous contact dermatitis to a sunscreen containing aminobenzoic acid esters and another patient who reacted to a benzophenone sunscreen.

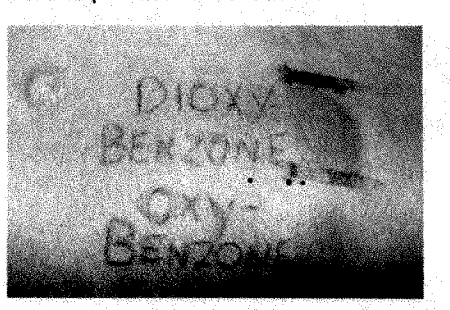
REPORT OF CASES

CASE 1.—A 62-year-old white man with psoriasis of ten years' duration was otherwise well until March 1974 when he developed an erythematous eruption involving the dorsa of his hands, face, and neck. He felt that sunlight was responsible for the eruption. His physician prescribed 0.1% triamcinolone acetonide cream, a lubricating lotion, and a sunscreen containing a benzophenone. The dermatitis gradually worsened during the ensuing five months. He was referred for patch, photo-patch, and photosensitivity testing. The patient was in excellent health except for his cutaneous problems and was taking no systemic medication. Pertinent physical findings at that time included an erythematous eczematous eruption of the face, V of the neck, and dorsa of the hands. In addition, he had classical psoriatic plaques on the elbows, knees, presacral area, and anterior portion of his thighs.

Laboratory examination yielded normal findings for CBC, urinalysis, and chemical analyses of the blood. An antinuclear antibody test was negative at less than 1:10 dilution.

The routine series of the International Contact Dermatitis Research Group (ICDRG), and patch tests for several sunscreens were applied to the upper back with A1 R test; phototesting was initiated. The grading of reactions was recorded according to the ICDRG system.[1] When seen for a 48-hour patch-test evaluation, a severe exacerbation of the dermatitis over the face and dorsa of the hands was noted. Forty-eight-hour patch-test examination showed a 2+ reaction with and without light exposure to the benzophenone sunscreen formulation. The active compounds,

Active compounds of benzophenone sunscreen, oxybenzone, and deoxybenzone gave 2+ reactions at 48 hours when used alone at product concentrations.



oxybenzone and deoxybenzone, at product use concentration, gave 2+ reactions (Figure). Patch-testing with these two benzophenones in ten adults produced negative results.

It was learned subsequently that the patient had applied the benzophenone-containing sunscreen to his face and hands on the same day that the initial patch tests were applied.

Final results of photosensitivity testing on normal skin by means of the repeated exposure technique to UVB radiation revealed a papular reaction at the test site that was histologically consistent with a polymorphous light eruption as described by Epstein.[2]

Case 2.—A 62-year-old white man with a history suggestive of a photosensitive dermatitis since 1960 was initially seen in 1968 when testing revealed positive patch-test reactions to Caine mix and positive photo-patch test reactions to tribromosalicylanilide (TBS) and tetrachlorosalicylanilde (TCSA). A positive photosensitivity test by means of the repeated exposure technique was consistent with polymorphous light eruption.[2] Over the ensuing six years he experienced several exacerbations of his photodermatitis that were successfully treated with topical and systemic corticosteroids; otherwise his eruption was well controlled with the use a benzophenone-containing sunscreen and topically applied corticosteroids. He was taking no other systemic medications.

In July 1974 he experienced another flare of his dermatitis after working in the sun and was given prednisone, 30 mg daily, to take orally. One week later he was changed from a benzophenone to an aminobenzoic acid ester sunscreen. Approximately ten days later, after working a full day in the bright sunlight, he developed a severe exacerbation of the dermatitis over his face and hands. At this time he was referred for further evaluation and treatment.

On examination, the patient exhibited an acute eczematous dermatitis of the face, V of the neck, and dorsa of the hands. He was treated with prednisone, 60 mg orally, daily; cool tap water compresses; and topical fluocinonide 0.05% cream. When the eruption subsided and the patient had discontinued systemic corticosteroids, therapy patch tests revealed positive reactions to Caine mix and to the aminobenzoic acid ester sunscreen. Photo patch-test and regular patch-test reactions were positive to TCSA and the octyl dimethyl and amyl dimethyl components of aminobenzoic acid sunscreen; photosensitivity testing with UVB rays produced a reaction clinically and histologically consistent with a polymorphous light eruption.

COMMENT

Although a few reports of allergic contact dermatitis from aminobenzoic acid have been published[3-6] and its potential as a sensitizing agent is well-recognized,[7] the same is not true for the benzophenones. Indeed, we could find only one report of a patient who developed contact dermatitis from a benzophenone.[8] In view of the widespread use of these agents, it is assumed that their sensitizing capacity is relatively small.

Predictive contact sensitization assays were not extensively employed when aminobenzoic acid was originally used. Kligman, using the maximization method, assayed 20% aminobenzoic acid in petrolatum and failed to sensitize any of 25 subjects[9]; however, we sensitized three of 200 men to 15% aminobenzoic acid in petrolatum, using the Draize human sensitization assay (unpublished observations). Our experience suggests that sensitization, at least in predictive assays, depends on concentration and vehicle.[10] The higher the concentration, the greater the likelihood of sensitization. Petrolatum, although an excellent vehicle for many diagnostic allergens, may not be so useful for predictive testing of aminobenzoic acid. We have no predictive assay data to demonstrate whether there is a difference in contact sensitization potential from aminobenzoic acid compared to its esters.

In the case of the first patient, we demonstrated positive patch-test responses to the finished product, and to oxybenzone and deoxybenzone. Patch-testing of the finished product in 100 control subjects revealed no positive reactions, suggesting that the formulation was appropriate for patch-testing (unpublished observations).

The second patient was tested with the final formulation and not with the aminobenzoic acid esters. It is assumed, but not documented in this patient, that sensitization was to the aminobenzoic ester and not to a vehicle ingredient. One hundred control subjects did not react to the final formulation, suggesting that it was in an appropriate concentration for patch-testing (unpublished data).

Patel et al noted that none of 50 men tested with a 10% concentration of 2-hydroxy-4-n-octoxybenzophenone developed evidence of either an irritant or allergic reaction.[11] Forbes et al found that only one in more than 1,000 individuals developed erythema after the use of a lotion containing 2-hydroxy-4-methoxybenzophenone-5-sulfonic acid.[12] Changing the patient's sunscreen to 10% benzophenone in isopropyl alcohol resulted in no recurrence of the erythema, thus suggesting that the vehicle in the initial preparation was possibly responsible.

The only documented evidence of allergic contact dermatitis to the benzophenones is that provided by Ramsey et al.[8] Their patient demonstrated both immediate urticarial and delayed contact allergic reactions.

Our first patient demonstrated only delayed contact hypersensitivity and was reactive to both of the active compounds (oxybenzone and deoxybenzone) present in the sunscreen he had been using.

Recently, in another patient clinically diagnosed as having a polymorphous light eruption, we encountered another sunscreen sensitizer, cinoxate. In this patient, testing demonstrated that photoallergic contact dermatitis only occurred (unpublished observations). Cinnamate contact dermatitis is not rare.

The clinical implication of the finding of contact dermatitis to sunscreens in these patients is obvious. Since such patients frequently experience flares of their photosensitive dermatoses, it is important that the clinician not assume automatically that any exacerbation of a light eruption is due to sun exposure. The possibility of a superimposed contact or photocontact dermatitis from the patient's sunscreen must be considered.

Localized Mycosis Fungoides With Prominent Epidermotropism

Woringer-Kolopp Disease

Walter F. Lever, MD

• **A patient had a single, large, sharply demarcated lesion on one leg. Under the mistaken diagnosis of malignant melanoma in situ, the lesion was excised and the area grafted in 1956. There has been no recurrence in the past 20 years. Histologic reevaluation led to a diagnosis of mycosis fungoides with pronounced epidermotropism of the cellular infiltrate. This case has close clinical and histologic resemblance with three cases published in Europe and regarded as a special form of reticulosis as first described by Woringer and Kolopp. Mycosis fungoides with marked epidermotropism is not always a benign localized disease but may be widespread and lead to death.**

(*Arch Dermatol* 113:1254-1256, 1977)

Infiltration of the epidermis by mycosis cells and formation of Pautrier microabscesses is a common histologic feature of mycosis fungoides. If the epidermal infiltrate is associated with a similar infiltrate in the dermis, the histologic diagnosis of mycosis fungoides generally can be made without difficulties. In some instances, however, there is such a marked affinity of the mycosis cells for the epidermis that they permeate the epidermis, whereas the dermis shows only a mild nonspecific inflammatory infiltrate. Often, the diagnosis of mycosis fungoides has not been made in such cases. Since Woringer and Kolopp[1] were the first authors to describe the predominantly epidermal distribution of mycosis cells, subsequent cases have been referred to either as reticulosis of Woringer and Kolopp,[2] pagetoid reticulosis of Woringer and Kolopp,[3] or as Woringer and Kolopp disease.[4] In this article, localized mycosis fungoides with marked epidermotropism of the cellular infiltrate is described. The patient was observed in 1956, but the proposed diagnosis was not made until after the above cited cases had been published.

Accepted for publication July 26, 1976.

REVIEW OF THE LITERATURE

In the original case, published in 1939 by Woringer and Kolopp,[1] a single asymptomatic, polycyclic, infiltrated plaque, 6 to 7 cm in diameter, was present on the left wrist of a 13-year-old boy. It had a red, scaling surface, a slightly raised margin, and areas of slight atrophy in the center. The lesion had been present for six years. After slowly increasing in size during the first four years, the lesion had remained unchanged during the fifth and sixth year.

In the second case, reported in 1970 by Gisiger,[2] a 66-year-old man had, for at least seven years on his left wrist, an asymptomatic, slightly indurated, sharply demarcated plaque, 3 by 4 cm in diameter. The lesion was bluish red and scaling, had an elevated margin, and showed central fading. It thus showed great clinical resemblance to the lesion in Woringer and Kolopp's case.

In the third case, described in 1973 by Braun-Falco et al,[3] a somewhat larger lesion than that in each of the first two cases was present. For ten years, the 58-year-old man had had a slowly enlarging lesion on his right foot. At the time of the report, the lesion occupied the dorsa of all five toes as well as the entire dorsum of the foot and extended to the inner aspect of the ankle and the instep. The lesion was dark red at its periphery and possessed a sharp, polycyclic border with considerable induration. In some areas, the center of the lesion showed hyperpigmentation with atrophy and slight redness as evidence of spontaneous healing. There was an area, 5 × 5 cm in diameter, on the dorsum of the foot where a portion of the lesion had been excised two years before and had been covered by a split-thickness graft. No recurrence had taken place within the graft.

The histologic picture was the same in all three cases. The epidermis was acanthotic and showed numerous clear spaces of varying size, which contained, depending on their size, one or several nonepidermal cells. The number of clear spaces was greatest in the lower layers of the epidermis. Both Gisiger[2] and Braun-Falco et al[3] thought that they resembled Pautrier microabscesses. The infiltrating cells in the epidermis, both within and outside the clear spaces, showed a rather scanty pale cytoplasm and fairly monomorphous nuclei that were quite large, irregularly shaped, and hyperchromatic. Many nuclei had an atypical appearance. Braun-Falco et al[3] observed numerous mitotic figures in the infiltrating cells. In all three cases, the dermis contained only a mild nonspecific cellular infiltrate. On electron microscopic examination, Baun-Falco et al[3] found that the cells infiltrating the epidermis, in contrast with the keratinocytes, possessed no desmosomes.

REPORT OF A CASE

In 1946, when he was 28 years old, a man first noticed an asymptomatic lesion, 2.5 cm in diameter, on the inner aspect of his right ankle. The lesion gradually increased in size.

Clinical Examination

When first seen in 1956, a large erythematous lesion was present on the right

Fig 1.—Left, Appearance of lesion prior to excision. Large, erythematous patch is present showing an irregular border that is slightly raised in several areas. Right, Appearance of area following skin grafting.

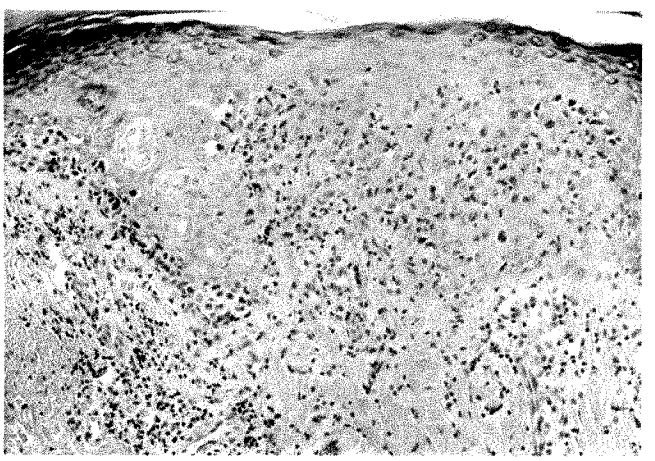

Fig 2.—Infiltrate of mononuclear cells is present in epidermis. It is densest in the lower portion of epidermis (hematoxylin-eosin, original magnification ×100).

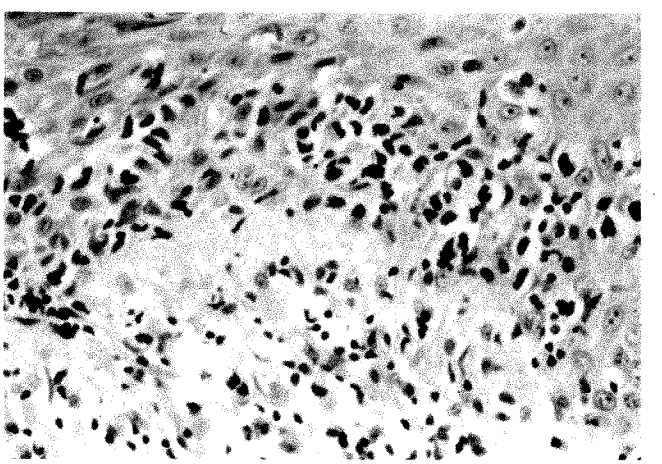

Fig 3.—Nuclei in epidermal infiltrate are deeply basophilic, irregular in shape, and variable in size and thus appear atypical. Many cells in epidermal infiltrate are surrounded by halo-like clear space. In several areas, one sees two or three nuclei lying closely together with a halo surrounding them (hematoxylin-eosin, original magnification ×200).

foot. It extended from the inner malleolus to the posterior aspect of the heel and along the medial side of the foot to the midportion of the sole. The entire lesion showed a sharp, irregular border that in several areas was slightly raised. In a few areas, especially on the medial aspect of the foot, the skin covering the lesion had an atrophic appearance. The appearance of the lesion is shown in Fig 1, left, and the appearance of the area following skin grafting is seen in Fig 1, right.

Histologic Examination

Four punch-biopsy specimens were taken. They all showed the same histologic picture. There was a moderate degree of acanthosis. An infiltrate of mononuclear cells was present in the epidermis. It was densest in the lower portion of the epidermis, especially in the basal cell layer (Fig 2). The nuclei of the infiltrating cells were deeply basophilic and irregular in shape and thus appeared atypical. Although variable in size, they were, in general, smaller than the nuclei of the keratinocytes of the epidermis (Fig 3). As a rule, the infiltrating cells had very little cytoplasm. Many of these cells were surrounded by a halo-like clear space; and, quite frequently, two or even three nuclei were arranged in nests and had a nonstaining halo at their periphery.

The dermis contained a mild to moderately severe chronic inflammatory infiltrate in which the nuclei did not show the deep basophilia and irregular shape seen in the epidermal infiltrate.

Course

After several conferences with members of the Department of Pathology at Massachusetts General Hospital, it was agreed that the histologic findings were consistent with a diagnosis of malignant melanoma in situ. The presence of halo-like clear spaces around individual cells and around nests of cells in the epidermis, and the atypical appearance of the nuclei in many of these cells seemed to support this diagnosis. It was thought advisable to excise the entire area.

The patient was referred to Bradford Cannon, MD, who on March 19, 1956, excised the entire lesion and covered the area with a split-thickness graft (Fig 1, right). The patient has been followed up at intervals until the present time. There has been no recurrence or any new lesions.

In 1973, when Braun-Falco et al[3] published their case in which there were atypical cells in the epidermis in pagetoid distribution, and also reviewed the two similar cases previously observed by Woringer and Kolopp[1] and by Gisiger,[2] it became evident that the case presented here belonged to the same category. It was thought most likely that the cells with atypical nuclei present throughout the epidermis in the three previous cases and in the present case represented mycosis cells.

COMMENT

The case just described and the cases reported by Woringer and Kolopp,[1] Gisiger,[2] and Braun-Falco et al[3] have a very similar appearance both clinically and histologically. Clinically, they were benign, showing a single cutaneous lesion that very slowly increased in size. Histologically, however, they did not appear benign but showed infiltration of the epidermis by atypical cells.

Not all cases that show the histologic picture first described by Woringer and Kolopp follow a benign course. Grosshans et al,[4] in their review of "Woringer-Kolopp disease," distinguished between a benign circumscribed form, as described by Woringer and Kolopp,[1] Gisiger,[2] and Braun-Falco et al,[3] and a disseminate form with lethal evolution, as described by Dupont et al[5,6] and by Mezzadra and Sapuppo.[7] Their own case seemed to lie between the circumscribed and the disseminate forms: their patient had had his eruption for ten years. Besides a large polycyclic, indurated plaque on his left thigh, the patient had disseminated plaques on his trunk with the same histologic appearance as the large lesion on his thigh. Grosshans et al[4] believed that the prognosis in their case was guarded.

It is of interest that the authors of the three circumscribed cases and of the three disseminate cases agreed that, histologically, the cells in the epidermis were atypical and that the disease represented a "reticulosis," ie, a lymphoma. However, none of the authors was willing to diagnose their case as mycosis fungoides. Gisiger,[2] although he found nests of infiltrating cells in the epidermis that in his opinion resembled Pautrier microabscesses, rejected the diagnosis of mycosis fungoides because of the pronounced permeation of the epidermis by the infiltrate and the absence of visceral lesions. Similarly, Braun-Falco et al,[3] in spite of the fact that he found the "pagetoid" permeation of the epidermis resembled Pautrier microabscesses, excluded the diagnosis of mycosis fungoides primarily because of the monomorphous appearance of the infiltrating cells in the epidermis, but also because of the disproportion between the severe epidermal and the very slight dermal infiltrate, and, furthermore, because of the presence of numerous mitoses in the epidermis. The term "epidermotropic reticulosis" was applied by Dupont et al[5,6] to their case.

The question arises as to why none of the above cited authors, even those describing the presence of Pautrier microabscesses, has been willing to consider mycosis fungoides as a diagnosis. The obvious reason is that in the past, the epidermotropic phenomenon, ie, diffuse epidermal invasion, has not been generally recognized as a manifestation of mycosis fungoides. This is somewhat surprising because the Pautrier microabscesses that generally are regarded as pathognomonic for mycosis fungoides are an epidermotropic phenomenon, and epidermotropic mycosis fungoides and mycosis fungoides with Pautrier microabscesses differ primarily in the degree to which epidermotropism is present. The other difference is that in epidermotropic mycosis fungoides, the dermal infiltrate is slight and nonspecific, and thus lacks the density and the presence of atypical nuclei seen in classical mycosis fungoides.

The existence of the epidermotropic phenomenon in mycosis fungoides has been emphasized recently by Ryan et al.[8] In biopsy specimens obtained from 36 patients with mycosis fungoides, they found a predominantly epidermal distribution of the mycosis cells in eight patients. They described the mycosis cell as having a large, dark-staining, irregular nucleus. Because of the relatively slight and nonspecific dermal infiltrate, Ryan et al[8] even considered the hypothesis that the mycosis cells might arise in the epidermis, possibly from Langerhans cells. This hypothesis, however, was weakened by the fact that on electron microscopic examination, they found no Langerhans granules in the mycosis cells.

In conclusion, affinity of the mycosis cells for the epidermis is a common phenomenon in mycosis fungoides. If the affinity is slight, Pautrier microabscesses are seen; but if the affinity is pronounced, epidermotropic mycosis fungoides results. Woringer-Kolopp disease either is identical with, or represents, a form of epidermotropic mycosis fungoides.

IN SKIN INFECTIONS, WHERE CLEANLINESS REQUIRES MORE THAN SOAP

BETADINE® Skin Cleanser

Degerms as it cleanses

'atients can use BETADINE Skin Cleanser to degerm and cleanse face, hands and body, gently and thoroughly—articularly when it is essential to prevent autoinoculation of new sites, as may be the case in infected acne pimples.

BETADINE Skin Cleanser, with its rich, golden lather, provides these advantages:

- Prompt, broad-spectrum microbicidal action—kills both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts.
- Maintains microbicidal activity in the presence of blood, pus and serum.
- Virtually nonirritating to skin and mucosa.*
- Nonstaining to skin and natural fabrics.

Supplied: 4 fl. oz. plastic bottles.

*In the rare instance of local irritation or sensitivity, discontinue use by the individual.

We kept the potency and got rid of the smell.

Exsel (selenium sulfide) 2.5% lotion:

DESCRIPTION Contains: selenium sulfide 2.5%
with edetate disodium, bentonite, sodium linear alkylate sulfonate, alphaolefin sulfonate, glyceryl monoricinoleate, silicone, titanium dioxide, citric acid monohydrate, sodium phosphate monobasic, monohydrate, perfume and purified water.

ACTIONS The mechanism of action of selenium sulfide in seborrheic dermatitis is unknown.

INDICATIONS Selenium sulfide is indicated in the treatment of seborrheic dermatitis of the scalp, including dandruff.

CONTRAINDICATIONS The product should not be used by patients allergic to any of its components.

WARNINGS Safety for use in infants has not been established.

PRECAUTIONS 1. Chemical conjunctivitis may result if this preparation enters the eyes.
2. The product should be used with caution when acute inflammation or exudation is present as an increase in absorption may occur.

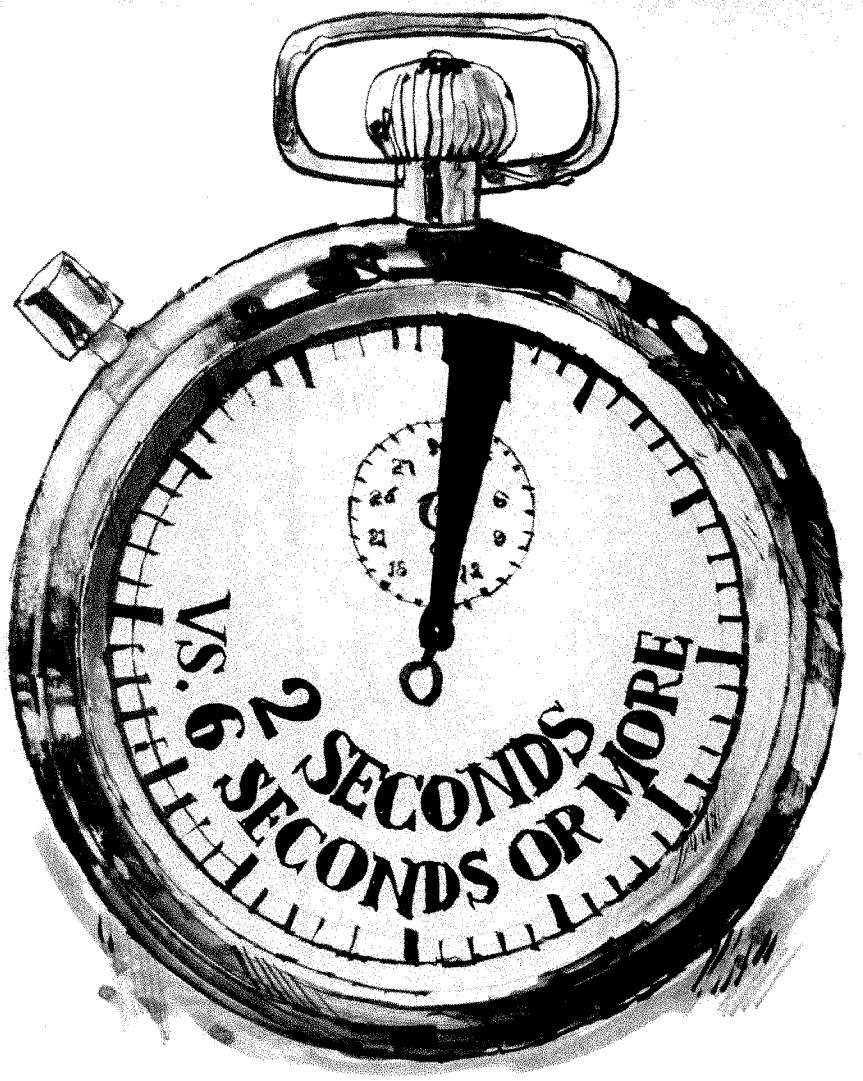
ADVERSE REACTIONS 1. Hair loss has been reported with the use of the product.
2. Discoloration of the hair may follow the use of selenium sulfide. This can be minimized by careful rinsing of the hair after treatment.
3. Oiliness of the hair and scalp may increase following the use of this product.

DOSAGE AND ADMINISTRATION Shake well before using.
1. Massage about 1 or 2 teaspoonfuls of the medicated shampoo into the wet scalp. Avoid contact with the eyes.
2. Allow product to remain on the scalp for 2 to 3 minutes.
3. Rinse the scalp thoroughly.
4. Repeat application and rinse thoroughly.
5. After treatment, wash hands well.
6. Repeat treatments as directed by physician.
The preparation should not be applied more frequently than required to maintain control of symptoms.

ACCIDENTAL ORAL INGESTION Selenium sulfide is highly toxic if ingested. Nausea and vomiting usually occur after oral ingestion. Treatment is to induce vomiting or if necessary perform gastric lavage, together with general supportive measures as required. Administer a purgative to hasten elimination.

HOW SUPPLIED In 4 fl. oz. plastic bottles. On prescription only.
Protect from heat. For external use only. Keep this and all medications out of the reach of children.

Herbert Laboratories/Dermatology Div. of Allergan Pharmaceuticals/Irvine, CA 92713



That's why CPT-4 can cut your claims reporting time at least 50%

Two seconds is all it takes to jot down a CPT five-digit numerical code for a medical, surgical, or diagnostic procedure.

Five seconds is the minimum time it takes to write out a description of the same procedure.

And that's the big reason **Physicians' CURRENT PROCEDURAL TERMINOLOGY** can dramatically reduce paperwork time for you or your administrative staff. Instead of having to write out descriptions of procedures on medical reports, you simply insert the CPT codes identifying the procedures. It's fast, simple, precise.

CPT provides a uniform coding system to accurately designate medical, surgical, and diagnostic services in terms that provide a uniform language among physicians, patients, and third parties. This new fourth edition of Physicians' CURRENT PROCEDURAL TERMINOLOGY is the most comprehensive and current system available and incorporates over 2,000 new and revised procedures. Each procedure is listed individually with a clear description and five-digit identifying code.

New CPT Updating Service is available at no additional cost. To insure your CPT stays up to date as new terminology is added, you can receive new and revised procedures on a regular basis. Updates are on self-adhering pages to be affixed to the pages they replace.

Metastatic Basal Cell Carcinoma

Review, Pathogenesis, and Report of Two Cases

George R. Mikhail, MD; Linda P. Nims, MD; Alexander P. Kelly, Jr, MD; Donald M. Ditmars, Jr, MD; William R. Eyler, MD

• In 93 reported cases of metastatic basal cell carcinoma (BCC), 76 had spread through lymphatics or blood vessels. Two more cases are presented, bringing the total to 78. Metastasis to regional lymph nodes was the most frequent, followed in frequency by lungs, bones, and other organs. The size of the primary tumor, its site, its resistance to x-ray therapy, and the effects of radiation appeared to contribute to the occurrence of metastasis. However, in an appreciable number of cases, tumor dissemination was related to incomplete excision followed by immediate wound closure, particularly by grafting. It is recommended that wound grafting be delayed for at least six months after excision of large or recurrent BCC in order to assure complete removal.

(*Arch Dermatol* 113:1261-1269, 1977)

Metastasis from basal cell carcinoma (BCC) of the skin is rare. The first case was reported by Beadles in 1894.[1] By 1974, there were 91 cases on record,[2] and two more cases appeared in the 1975 literature,[3,4] bringing the total to 93.

In 1951, Lattes and Kessler[5] established the criteria for the diagnosis of metastatic BCC. These are summarized as follows: The primary tumor must be in the skin and not in a mucosa. Metastases must be demonstrated at a site that is distant from the primary lesion and should not result by direct extension. The histologic picture should be the same in both primary site and metastases. It should conform to that of BCC with no squamous cell carcinoma component. Applying these criteria, we found only 76 true examples of BCC that had spread through lymphatics or blood vessels. We excluded cases where metastasis to the lungs had resulted or could have resulted by direct implantation of tumor by aspiration. The cases are summarized in Table 1. Two more cases are described in the present report, bringing the total to date to 78. The pathogenesis, pathological findings, prognosis, and diagnostic aspects of this entity are reviewed and discussed.

REPORT OF CASES

CASE 1.—We first saw this 57-year-old man in January 1969. He gave a history of radiotherapy for acne in 1932 (age 19) and a "nonmalignant growth" that was excised from the left cheek in 1962. On June 8, 1964, he consulted a dermatologist because an ulcerated lesion had appeared in the same area. A biopsy obtained at that time was reported by Hermann Pinkus, MD, as follows: "Sections show basal cell epithelioma in the form of solid masses and nests surrounded by mesodermal stroma in the corium. The corium shows marked scar tissue type fibrosis." The lesion was treated electrosurgically. A hypertrophic scar developed but responded well to intralesional injections of triamcinolone acetonide (20 mg/ml). The tumor recurred and was again treated by electrosurgery on Jan 24, 1966. Histological examination was again done by Hermann Pinkus, MD, and his report read: "Sections show solid masses and elongated cords of basophilic epitheliomatous cells embedded in a cellular mesodermal stroma in the dermis." Review of the material from both biopsies led to the decision that the lesion was a sclerotic BCC. On June 5, 1967, a firm subcutaneous mass was noted over the left angle of the mandible. The patient was then advised to consult a surgeon, but he did not. He was referred to us in January, 1969. Examination showed an ulcerated, indurated lesion about 3 cm in diameter on the left cheek near the buccal commissure. A hard, cord-like mass extended posteriorly from this lesion, connecting it to a nodular mass in the parotid region (Fig 1). When admitted to the hospital on Feb 16, 1969, he weighed 58 kg, the hemoglobin value was 15%, and the serum alkaline phosphatase level was normal. Biopsy material showed sclerotic BCC identical with that found in earlier studies (Fig 2). The tumor was excised by nine microscopically controlled stages of the Mohs chemosurgery technique. The extensive postexcisional defect is shown in Fig 3. The left buccal wall, the lower part of the ear pinna, and a significant portion of the left parotid gland, including part of the facial nerve, had to be removed. The middle third of the left mandible and the mastoid bone were exposed. Nine reconstructive surgery operations were undertaken between March 6, 1969 and May 23, 1970. The result is shown in Fig 4. When seen in July 1970, the patient complained of pain that had been present in the left hip since April 1970. No clinical signs could be elicited, but radiological examination showed destruction of portions of the left iliac bone. A biopsy obtained from the bone on July 23, 1970, showed infiltration with BCC. The tumor was composed of small groups of darkly staining epithelial cells arranged in cords and irregular strands. Peripheral palisading was well marked in the tumor masses that were embedded in a fibrous and mucinous stroma that had replaced the bone marrow (Fig 5). During this hospital admission, the patient weighed 55.5 kg, the hemoglobin value was 14%, and the serum alkaline phosphatase and lactate dehydrogenase levels were elevated. Radiotherapy with high-energy ^{60}Co during August 1970, failed to relieve the pain. Lytic changes were found in the second lumbar vertebra in October 1970. In March 1971, his weight had dropped to 50 kg, and the serum

alkaline phosphatase level was more elevated. Bleomycin sulfate was then administered intravenously in doses of 10 mg/sq m, twice a week, for a total of 420 mg during the period from March 12 to Sept 22, 1971. The treatment had to be discontinued because of chest pains and worsening of the bone pains. Radiographs on Aug 31, 1971, showed collapse of the second lumbar vertebra. The patient's last admission to the hospital was in November 1971, because of an ulcer in the left mastoid region. This proved to be another recurrence of the BCC. This time he weighed 39.5 kg, the hemoglobin value was 11.4%, and the serum alkaline phosphate level was unusually high. The patient died at home on Dec 19, 1971, about 20 months after the onset of symptoms of bone involvement. Permission for autopsy was denied.

CASE 2.—A 59-year-old woman was referred to us by a dermatologist whom the patient had consulted about a "sore on the face" that had never been treated. The lesion apparently originated near the outer canthus of the right eye and had been present for eight years. It was extensive, ulcerated, and involved the right temporal, frontal, and zygomatic regions. The eyelids were everted, and the eye was amblyopic (Fig 6). Histological examination showed a keratinizing basal cell carcinoma (Fig 7). On April 18, 1974, the lesion was excised en masse with the contents of the orbit and a 1-cm margin of clinically free skin. The zygomatic arch was also resected, and the wound was covered with a split-thickness skin graft obtained from the right thigh. The pathology report indicated complete

Fig 3.—Defect in case 1 after nine microscopically controlled excisions (Mohs chemosurgery technique).

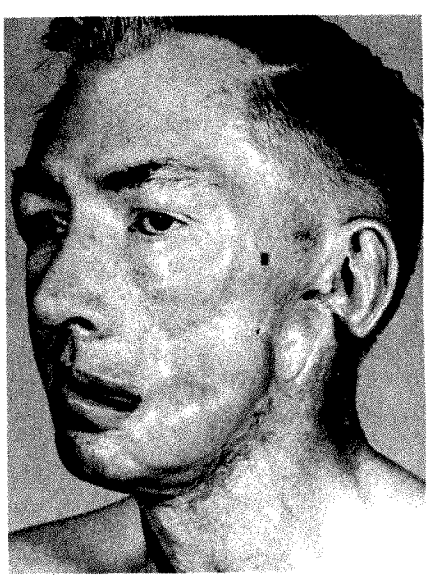

Fig 4.—Case 1 after nine reconstructive surgery operations.

removal of the tumor and absence of bone involvement. On Aug 28, 1974, two nodules were noted at the lateral margin of the orbit underneath the graft, one superiorly and the other inferiorly over the zygomatic bone. They proved to be recurrent BCC, and were excised in November 1974, by the Mohs chemosurgery technique. The lower lesion was found to extend into the maxillary bone and its antrum (Fig 8). During this hospital admission, the patient's serum alkaline phosphatase and lactate dehydrogenase levels were within normal limits. The wounds were left to heal by secondary intention, but the BCC had recurred again in the zygomatic region when the patient was seen on Jan 27, 1975. There was also another area of recurrence in the parietal scalp at the edge of the graft. Both lesions were excised by chemosurgery. In April 1975, an enlarged cervical node and a 2-cm ulcerated nodular mass of the left arm were excised. The histologic picture in both was identical with that of the primary cutaneous lesion. Subcutaneous nodular

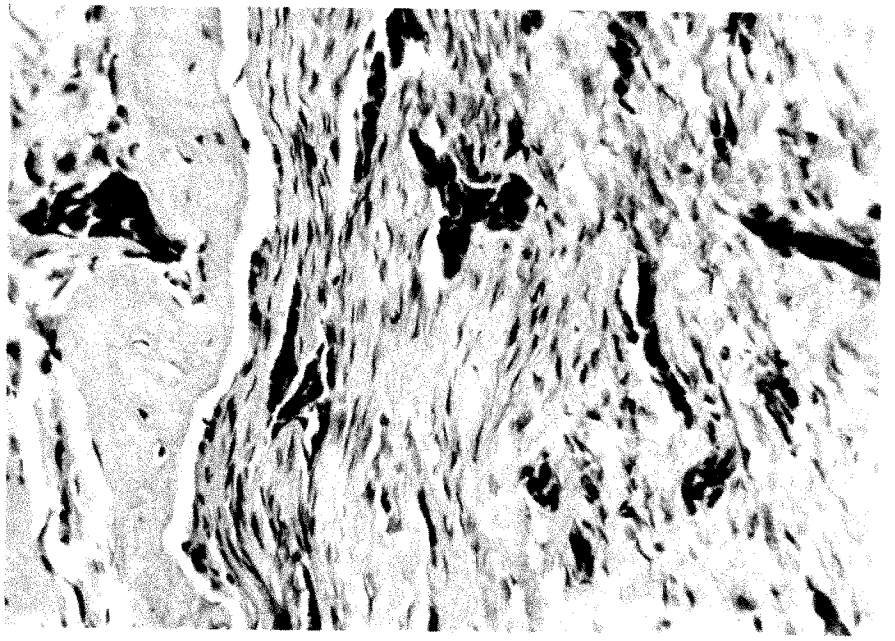

Fig 5.—Left iliac bone biopsy (case 1). Bone marrow has been replaced by mucinous, fibrous stroma that contains masses and strands of basal cell carcinoma (hematoxylin-eosin, original magnification ×420).

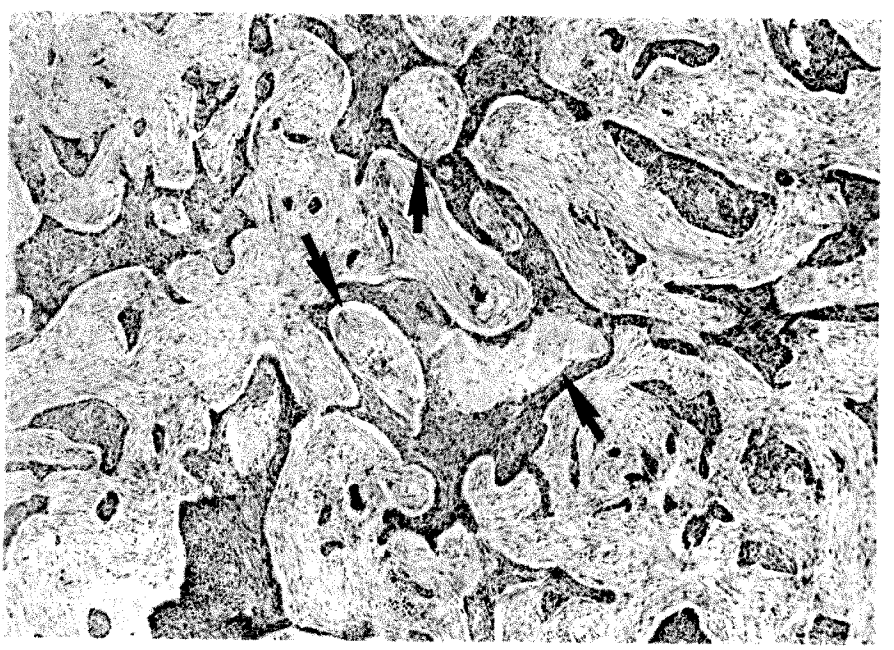

Fig 7.—Section from lesion shown in Fig 6. The histological findings were that of keratinizing basal cell carcinoma. Palisading well marked. The foci of keratinization are incompletely keratinized (arrows) (hematoxylin-eosin, original magnification ×90).

masses developed within the next month, several on the back. One on the right thigh about 2.5 cm in size (Fig 9) was excised and showed the same histological findings, but this tumor occupied the deeper dermis and the subcutis and was not connected with the epidermis. The wall of a deep subcutaneous arteriole was involved (Fig 10). By that time, the patient had lost about 8 kg, and the serum alkaline phosphatase and lactate dehydrogenase levels were markedly elevated. Because of these findings, and because of a complaint of bone pains, a radiographic bone survey was undertaken. This showed multiple compression fractures of several vertebral bodies and radiolucency of the ischium. Radionucleide examination, employing 15 mCi of technetium Tc 99m pyrophosphate, showed increased uptake of the radioactive material in the skull bones, the ribs, the sacrum, the left pubis, the left ischium, and the femurs (Fig 11). Biopsy material obtained from the right iliac bone demonstrated small masses of BCC embedded in a mucinous, fibrous tissue between the bony trabeculae (Fig 12). The cellular immune responses were found normal for the patient's age as measured by lymphocyte transformation using phytohemagglutinins and poke weed mitogens. The fluorescent antinuclear antibody test was negative, and the immunoglobulins were within normal values. Bleomycin therapy was

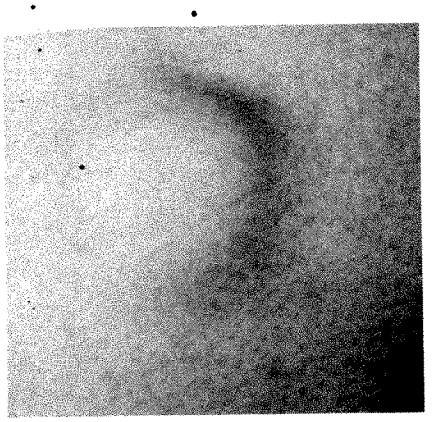

Fig 9.—Subcutaneous metastatic lesion on right thigh (case 2).

considered but was not administered because the patient failed to cooperate during the evaluation of pulmonary function. Methotrexate and leucovorin were then administered but had to be discontinued shortly afterwards because of thrombocytopenia. By June 19, 1975, there were 14 subcutaneous nodules on the back. The patient died one month later, four months after the first signs of metastasis. Autopsy was denied.

COMMENT

Cotran[21] has found nine examples of metastases among 9,050 cases of BCC seen during a 14-year period at Memorial Hospital in New York, an incidence of about 0.1%. This is probably much higher than the true incidence in the general population.[40] A survey conducted in Australia and New Zealand, where BCC is more common than elsewhere in the world, showed a metastasis rate of about 0.0028%.[51] The discrepancy between the two studies is probably due to the fact that Cotran's cases were from a hospital population while the Australian study was based on information obtained mainly from medical offices. Although metastasizing BCC is rare, it is possible that, due to the indolent nature of the disease, many cases are not seen by a physician at all or are overlooked. The diagnosis of secondary lesions has been made clinically in the majority of the reported cases, but several unsuspected metastases have been discovered at autopsy,[19,21,32,34,35,40] and one during surgery.[45]

The sites of metastases in the 78 cases are summarized in Table 2. Regional lymph node metastasis was the most frequent; metastases to the lungs and to bone were next in order of frequency. Metastases have also occurred in the liver, spleen, pancreas, peritoneum, diaphragm, pericardium, kidneys, adrenals, and skin. However, these areas were usually involved when at least one of the three major sites was also affected.[16,19,21,27,32,33,42] Metastasis to a single site occurred in 55 cases and to multiple sites in 23 patients. Metastasis to bone, possibly preceded by spread to a regional parotid lymph node, occurred in our case 1, while lymph node, bone, and skin metastases were found in case 2. Cutaneous metastasis is extremely rare with only one previously reported case.[33]

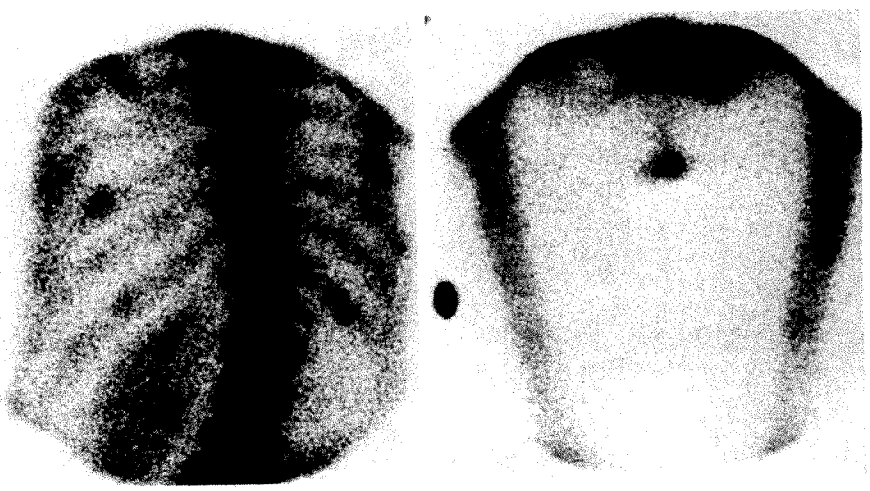

Fig 11.—Radionucleide bone scan shows increased uptake of radioactive material: left, in ribs; right, in sacrum, pubis, ischium, and femora (case 2).

In an attempt to better understand the conditions under which BCC may metastasize, certain factors have been considered, as follows: the site, size and histologic type of the primary tumor, the biologic behavior of BCC, the immune mechanism in the host, and the treatment that precedes the occurrence of metastases.

The great majority of the primary lesions (85%) have been located on the head and neck and the remainder on

Fig 12.—Section from biopsy material obtained from right iliac bone shows masses of basal cell carcinoma imbedded in mucinous fibrous tissue between bone trabeculae (case 2) (hematoxylin-eosin, original magnification ×390).

the extremities and back.[3,4,28,40] These tumors have been characteristically large, ulcerated, of long standing, locally invasive, and resistant to radiotherapy and surgery.[8,34,48] Metastases have been noted from 1 to 45 years (average 11 years) after the appearance of the primary lesion.[21,28]

The consensus is that there is no specific histologic type of BCC that is more capable of metastasizing.[31,40] Metastases have occurred from the solid or nodular type[2,40] and from sclerotic and adenoid BCC.[4,10,19,21,31,48] Montgomery,[52] Helwig,[53] and Graham[54] believe that of all types, the metatypical BCC is the one most likely to metastasize. This tumor has been described as composed of cells that are larger than those of typical BCC, tend to be polygonal, have a more eosinophilic cytoplasm, with peripheral palisading indistinct in some areas. Cellular pleomorphism, malignant dyskeratosis, and abnormal mitotic figures have also been described.[54] According to Montgomery,[52] this type accounts for 15% to 20% of all cases of BCC, and the presence of foci of incomplete keratinization is prerequisite for the diagnosis. Other workers[13,55-57] stress that keratinization can be found in typical BCC and that there is no need for a special terminology. The presence of foci of keratin has also been interpreted as evidence of maturation of the basal cells rather than an indication of malignancy.[58] Unlike that seen in squamous cell carcinoma, keratinization is parakeratotic and is usually incomplete.[52-58] Twelve cases of metastatic BCC are on record at the Armed Forces Institute of Pathology, all of which are "metatypical".[53] Discussing the types of BCC, Lever and Schaumberg-Lever[59] conclude that it can be assumed that the controversial basal squamous cell epithelioma represents a keratotic basal cell epithelioma, and that the intermediate type is a basal cell epithelioma with differentiation into two types of cells. Case 1 was of the sclerotic type while case 2 may be designated as keratinizing or metatypical BCC.

It has been postulated that, unlike squamous cell carcinoma, the epithelial component of BCC is specifically dependent on its stroma and cannot metastasize unless part of its stroma is also taken along, and that this would account for the rarity of metastasis in BCC.[57,60] In support of this theory is the demonstration that BCC could not be transplanted autologously unless some of its stroma had been included in the transplant.[61] On the other hand, since BCC has been grown in tissue culture,[62] the possible existence of stromal independence and the emergence of highly malignant cell clones under certain conditions, eg, therapy, have been proposed.[28,29,31,47]

That immune disorders or deficiencies may play a role in enhancing metastasis in BCC has been suggested but without corroborative evidence.[11,14,18,19,40] In case 2, the lymphocyte transformation using phytohemagglutinin and poke weed mitogens was normal, the antinuclear antibody test was negative, and the immunoglobulins were within normal range.

Review of the 76 previously reported cases and the two examples of metastatic BCC presented here shows that 70 patients (90%) had undergone surgical treatment or radiotherapy prior to the occurrence of metastasis (Table 3). It has been postulated that radiation energy may transform a low-grade BCC into a highly malignant one that is capable of metastasizing.[25] It is significant evidence in support of this view that 53 patients (68%) had radiotherapy (Table 3). However, the treatment could have been inadequate, or the tumors for some as yet unknown reason were radioresistant. This is especially true in the case of sclerotic BCC. A biologically acceptable thesis may be based on possible dissemination of tumor fragments, consisting of epithelial and stromal elements, through lymphatics and veins by direct erosion of the vessels by a deeply invasive BCC or by trauma during surgery.[28,31] Masses of BCC have been demonstrated within lymphatics[21,22,48] and veins[20,48] in the vicinity of the primary growth and near metastatic lesions.[48] Involvement of a subcutaneous arteriole was noted in a cutaneous metastatic lesion in case 2 (Fig 10).

In 1971, a group of German workers succeeded in measuring the collagenase content of tissues and found a significant relationship between collagen peptidases and tumor invasion.[63] Yamanishi and co-workers[64] found that malignant melanoma had a collagenolytic activity that was 20 times that in normal skin, junction nevus, and blue nevus. We have studied collagenolytic activity in tissue extracts of squamous cell carcinoma, Broders grade 3, nodular BCC, metatypical BCC (case 2), and normal skin by the Moore and Stein photometric technique[65] and standardized by *Clostridium histolyticum* collagenase and proteinase.[66] Normal skin contained 124 units of enzymatic activity per gram, while the values for the tumors were 294 for squamous cell carcinoma, 305 for nodular BCC, and 304 for metatypical BCC. The increased collagen-degrading enzymes in BCC may facilitate the spread of tumor cells and invasion of lymphatics or blood vessels. It is also possible that this collagenolytic activity may contribute to the formation of the mucin-filled spaces that surround epithelial nests that are seen in histological sections.

It is significant that 63 of the patients (81%) had undergone extensive and repeated surgical excisions and that tumor had recurred at the primary site by the time the metastases were discovered, indicating incomplete initial eradication.[26,31] Metastases occurred in 33 patients in whom there was immediate grafting of the wounds that resulted from excision of the primary lesions. This figure by no means represents the true number of cases that were grafted, for the history was silent on this point in reports on 26 patients who were subjected to extensive surgical procedures (Table 1). The scar that anchors a graft in its place is too tough to allow the residual tumor to grow through it toward the surface. The tumor is forced to expand in the direction of least resistance, the deeper tissues. In doing so, it is conceivable that larger lymphatics and veins may become involved, leading to metastasis. Therefore, it seems advisable to defer wound grafting, whenever possible, for at least six months after excision in order to allow the residual tumor to become manifest and be extirpated before reconstructive surgery is begun.[67] The wounds in both of our patients were grafted immediately following excision of the cutaneous tumors. Metastasis was detected in case 1 at 16 months after the first reconstructive surgery operation, and the patient died six months later. It took 12 months for the metastases to become manifest in case 2, and the patient survived for only four months.

The rarity of metastatic BCC can cause diagnostic difficulties in cases with clinical evidence of a metastatic malignancy. Because of the rare incidence and its biologic behavior, it is rational to assume that BCC metastasis may be a final stage in a series of changes these carcinomas undergo. Some authors believe that BCC does not metastasize and that previously published cases could have been basaloid squamous cell carcinomata or adenocarcinomata.[57] The metastases in BCC have occurred at an average of 11 years after the original lesion had become manifest.[21,28] This is unlike squamous cell carcinoma that metastasizes within three years.[26]

The average survival time after metastasis to the lungs, bone, and internal organs has been about 10 months.[21,40] Of the 40 cases in this group, only two cases have apparently been successfully treated, one by pulmonary lobectomy,[20] and the other by cobalt therapy to metastasis in the femur.[31] Chemotherapy with bleomycin and other cytotoxic drugs has been disappointing.[2,31,39,42] Our experience agrees. The prognosis was far better when only the regional lymph nodes were involved because of accessibility to surgical removal.[2,20,28,38,45]

Definitive ablation of a recurrent or invasive BCC can be best achieved by adequate excision and the demonstration of clearance of the margins. The microscopically controlled excision by the Mohs technique is ideal for this purpose.[62] Since large and recurrent BCC are more apt to metastasize, they should be aggressively treated because they are a possible threat to life. Wound grafting and reconstructive surgery should be delayed, whenever possible, for at least six months after excision to assure complete removal and to avoid burying a residual carcinoma. The follow-up examinations should be more frequent than in the usual cases, and careful search for involved regional lymph nodes is recommended at each visit. Since the nodes are the commonest sites of spread, early detection can be life saving. Chest and bone x-ray films and determination of serum alkaline phosphatase levels are indicated when there is history of weight loss, pulmonary symptoms, or pain in bones. The serum alkaline phosphatase level was markedly elevated in our patients and in the five reported cases of bone metastasis in which it was determined.[27,31,33,45,48] Although x-ray film evidence is not conclusive, it is helpful in detecting suspected lesions in lungs and bone. Radionucleitle radiography and bone biopsies were decisive in the detection of metastases in our cases.

Although the size of the primary

tumor, its site, and the effects of radiation or resistance to radiation appear to contribute to the occurrence of metastasis in BCC, it is possible that tumor antigenic factors, tumor angiogenic factors, hormonal influences, or immunologic defects may also have roles. However, one cannot ignore the appreciable incidence of metastases reported in patients where immediate grafting followed incomplete excision of primary tumors.

This work was supported in part by the National Institutes of Health Biomedical Research Support grant 5S07 PR 05490-14 and the Ford Foundation through the Henry Ford Hospital.

The lymphocyte transformation tests were done by Sam S Yanari, PhD, of the Allergy Research Laboratory, Henry Ford Hospital. The tissue collagenase activity was assayed by Rollin H. Heinzerling, PhD, Michael G. Mikhail, and Sally Szymanski of the Dermatology Research Laboratories, Henry Ford Hospital.

Occupational Hazards From Deep Mycoses

Jan Schwarz, MD, Carol A. Kauffman, MD

The increased recognition of fungi as an important cause of disease is translated into what appears as a high incidence of mycotic disease. The increase in deep mycoses associated with occupations may be due in part to better understanding of the pathogenesis of these infections.

The fact that inhalation of spore-containing dust is the mode of infection in histoplasmosis, coccidioidomycosis, paracoccidioidomycosis, blastomycosis, and probably cryptococcosis points to any major soil digging as a potential source of such infections. Spores of *Sporothrix schenckii* have been found on timber, on the leaves of certain bushes, and in sphagnum moss; traumatic transcutaneous inoculation leading to sporotrichosis is well established. A connection exists between pigeons and the occurrence of cryptococcosis, and between bats and birds and histoplasmosis.

LABORATORY INFECTIONS

A special chapter in occupational disease caused by "deep fungi" is that associated with laboratory exposure; inhalation of culture material and traumatic transcutaneous inoculations have been observed.

Blastomycosis

Eight cases of traumatic primary transcutaneous blastomycosis after puncture or cutting wounds in laboratories (including autopsy rooms) are on record. Slow healing chancres with or without regional lymphadenitis developed, and all eight cases became arrested, with a variety of therapeutic regimens, including surgical excision and no treatment.[1] One proven case of primary pulmonary (inhalation) disease was reported after exposure to cultures of *Blastomyces dermatitidis*.[2] Denton et al[3] assume that in a laboratory worker who had an osteolytic lesion in the head of the fibula, the primary pulmonary infection was acquired three months earlier when she was removing cellophane tape from Petri dishes containing cultures of *B dermatitidis*. However, a "natural" infection cannot be ruled out in this case. In view of the generally subclinical presentation of primary pulmonary blastomycosis, the possibility of more such laboratory-acquired inhalation infections should be considered.

Histoplasmosis

Laboratory infections with *Histoplasma capsulatum* acquired by way of inhalation of culture material and by local inoculation are on record. Inhalation of material from cultures on Petri dishes resulted in the conversion of histoplasmin skin tests to positive in 17 of 26 employees in the Mycoses Laboratory of the Public Health Service in Kansas City, Kansas, with an average conversion time of 4.2 months (one month to three years).[4] Since the laboratory was located in an endemic area of histoplasmosis, "natural" infection also has to be considered. However, the authors concluded that the risk for the laboratory worker was 26 times greater than among local school children. Forty-one percent of the converters had clinical illness. Comparative values of subclinical infection were amazingly similar in this group (59%), compared with laboratory personnel exposed to *Coccidioides immitis* (59.4%).[5]

A fatal infection in a mycologist was the result of infection either from positive soil samples or from the resulting soil cultures.[6] Almost identical sources were responsible for acute disease in two fellow workers in a laboratory in Michigan, but the outcome was favorable.[7] Cultures were responsible for six infections in a Swedish laboratory with considerable clinical illness in four of the infected persons.[8] The high infectivity of cultures of *H capsulatum* led to consideration of this organism as well as *C immitis* for biological warfare.[9]

Of 17 female medical technology students transferring four-week-old cultures in a laboratory in Madison, Wisconsin,[10] one developed grippe-like symptoms and erythema nodosum two months after exposure. All 17 had a positive skin test and eight had positive complement fixation (CF) tests for *H capsulatum*. One male student representing the 18th case of the group had radiologic and serologic (CF titer 1:512) evidence of histoplasmic infection. A comparable regional control group of students had 11.5% positivity with the histoplasmin skin test.

Loosli[11] observed ten laboratory infections at the University of Chicago, four with prolonged clinical illness. Spicknall et al[12] report conjunctival inoculation in a physician exposed twice to a spray of culture suspension. Six to ten days after exposure, soreness and edema of the palpebral conjunctiva developed and subsequently an ulcer appeared with associated tenderness of preauricular and upper cervical homolateral lymph nodes. A negative histoplasmin skin test changed to positive; cultures from the conjunctiva were negative as were CF tests for *H capsulatum*. The patient recovered uneventfully.

Coccidioidomycosis

Coccidioides immitis has a well earned renown for producing high infection rates in workers handling cultures.[13]

Inhalation infection with spores in the laboratory of Ophuls represents the first of a long chain of documented cases of pulmonary coccidioidomycosis acquired from culture material.[5] An even older case of laboratory infection is controversial.[14,15] Hanel and Kruse[16] give a detailed account of infection acquired in the laboratory in students, physicians and technicians. Of 63 fungus infections uncovered by a questionnaire sent to laboratories, 49 were attributed to *C immitis*.[17] Twenty-three of the group of 49 were clerk and maintenance workers who did not personally handle culture material.

A fatal case of laboratory infection developed in one of seven persons exposed to discarded culture materi-

al.[18] Other laboratory infections were reported by Nabarro[19] and by Bush.[20] An ulcer developed at the site of a thorn puncture in a technician who had been harvesting cultures of *C immitis* for four months prior to the accident.[21] Overholt and Hornick's[21] third case is quite similar in that a wrist ulcer developed in a laboratory worker with a poison ivy eruption, who was cleaning a laboratory known to be contaminated with *C immitis*. Both cases developed local lymphadenopathy strongly suggesting a primary complex. Overholt also reported an infection in a laboratory worker who had a positive coccidioidin skin test prior to the accident. Marked swelling surrounded the puncture site and the regional (axillary) lymph nodes suppurated, with *C immitis* demonstrated in the exudate. Local osteomyelitis developed, with permanent minor loss of mobility in the thumb. Another laboratory associated puncture wound in a man with a history of a positive coccidioidin skin test led to local induration, severe pruritus, and urticaria. No lymphangitis or lymphadenitis developed.[22] Accidental inoculation into the thumb of a graduate student resulted in a chancriform lesion at the point of trauma followed by a chain of nodules leading to the regional lymph nodes.[23] Injury at embalming was reported by Wilson and Smith,[24] and a traumatic infection in a physician performing an autopsy is on record.[25] Six cases of infection occurred in a German commercial microbiologic laboratory during attempts at growing *C immitis*.[26]

In 1964, Johnson et al[27] compiled 210 cases of laboratory acquired coccidioidomycosis from one institution and tabulated 96 cases from elsewhere. Of the 96 cases, the authors consider 59 proved, 28 probable, and 9 possible. Johnson's report is concerned with 2,013 workers potentially exposed to *C immitis* between 1944 and 1962 in a government installation located in Maryland far outside the endemic area. On initial coccidioidin skin testing, 118 workers were positive; they were not retested. Of the remaining 1,805 workers, 210 (10.4%) converted their skin test to positive. Only six showed significant clinical disease; three had cutaneous (primary) chancres—one after puncture of a finger with a briar thorn, one after a scratch in a hood containing *C immitis*, and the third after accidental injection of culture material into his wrist. The three other symptomatic patients had primary pulmonary coccidioidomycosis. All three had known exposure to cultures. Of the 210 converters, 76 were altogether asymptomatic, but 58 others had unexplained flu-like symptoms.

Hanel and Kruse[16] have reviewed many laboratory acquired infections up to 1967 and question the validity of the conversions reported by Johnson et al[27] because syringes used for coccidioidin skin tests had been used for other biologicals (skin test material). Disposable needles and syringes are undoubtedly preferable to avoid carryover of antigenic material.

Sporotrichosis

"Natural" sporotrichosis is, in most instances, the result of transcutaneous traumatic inoculation; small wonder that the same mechanism can be traced to handling of culture material. Fava[28] seems to have acquired the first laboratory infection when a culture suspension sprayed into his conjunctiva while injecting rabbits. Sporotrichosis after a rat bite (the animal had been inoculated with *S schenckii*) occurred in a French laboratory.[29] Aerosol from a broken capillary pipette produced conjunctival infection.[30] Meyer[31] had an inoculation ulcer on the third finger, Fielitz[32] on the forearm, and Norden[33] on a finger under a ring, after working with cultures of *S schenckii*. None of these authors were aware of trauma. Mikkelsen et al[34] reported an ulcer on the index finger of a mycologist after accidental inoculation. The ulcer took three weeks to develop and healed in three weeks under potassium iodide therapy. Carougeau[35] developed the classical picture with lymphangitis after accidentally scratching his skin after opening a subcutaneous abscess in a mule.

Cryptococcosis

Halde[36] cut her finger 5 mm deep with a knife used to open the abdominal cavity of a mouse injected intraperitoneally with a culture of *Cryptococcus neoformans;* the description of the peritoneal fluid as "viscous" suggests abundant development of cryptococci in the exudate. The wound was made to bleed and healed without further treatment. A 14-year follow-up of the patient was uneventful.

NATURAL INFECTION WITH DEEP FUNGI

Sporotrichosis

Sporothrix schenckii is a fungus of great importance in reference to occupation, since large numbers of persons have contact with and become infected by timber, sphagnum moss, marsh hay, barberry bushes, and other plant material. In fact, a person in any profession leading to contact with vegetable material is potentially at risk. An incomplete list ranges from berry pickers to bulb farmers, from miners (timber supporting the shafts) to chefs in restaurants, from pottery workers to packers in brickyards. A reasonably complete list of case reports can be found in Lurie's[37] chapter in Baker's Handbook.

Gardeners, florists and greenhouse workers, and farm hands are the most frequently affected persons. Skin tests to sporotrichin were positive in 58% of workers employed more than ten years in nurseries in Louisiana and in only 11.2% of controls from the same geographic area.[38] A glimpse into the complexities of sporotrichosis in a nursery is provided by the thorough study by McDonough et al.[39] Of 250 samples of sphagnum moss used for keeping roots of bushes covered and moist during winter in a nursery barn in Wisconsin, 15.6% were positive in culture for *S schenckii*. The sphagnum moss was the main source of subsistence for the fungus, and moisture around drainholes in the barn provided enough water for development and survival of the fungus. The authors concluded that the sphagnum moss became infected with *S schenckii* after reaching the barn since samples from only one of 34 bales of moss were positive for the fungus when received in shipping.

Clinical cases of sporotrichosis have been reported from nurseries throughout the country. In almost every instance, sphagnum moss shipped from Wisconsin has been implicated. D'Alessio et al[40] have reported 14 clinical cases that devel-

oped in a nursery in Vermont; all patients had documented contact with sphagnum moss obtained almost entirely from Wisconsin. Eight cases in two Florida nurseries were related to exposure to moss from Wisconsin.[41] Twenty-one cases in Minnesota originated from moss-packed trees.[42] A fisherman in Wisconsin developed sporotrichosis from moss used in his bait box. His three children developed CF antibody titers against *S schenckii*.[43] Recently, 13 forestry workers in Mississippi developed sporotrichosis following harvesting and packing of pine seedlings in sphagnum moss.[44]

Sphagnum moss is obviously a major reservoir of *S schenckii*, and attempts to decrease its fungal load by meticulous application of antiseptics in nursery barns would appear a reasonable prophylactic measure. A phenolic fungicide applied to the drainholes, floors, and walls has been shown to decrease the incidence of sporotrichosis dramatically.[39]

Other vocations besides those associated with gardening are at risk to develop sporotrichosis. The epidemic in gold miners in South Africa, that was traced to fungal contamination on the timbers in the mine, has been reviewed previously.[45]

Ahearn and Kaplan[46] repeatedly isolated strains of *S schenckii* from cold stored sausages (frankfurters). Although the strains differed from standard strains of *S schenckii* in their growth characteristics at 5 C and their proteolytic activity, they were pathogenic for mice. Studies such as this may have important implications for meat packers, cooks, and the general public.

Animals associated with transmission of *S schenckii* to humans include insects, fish, snakes, birds, rodents, bats, and dogs.[37] The usual type of infection is a chancre at the site of a bite.

Histoplasmosis

Numerous epidemics are on record[47] originating from spore-containing dust—how many are unpublished and remain unrecognized is anybody's guess. Bat infested caves have been associated with *H capsulatum* infection in spelunkers[48-52]; the oil bird, *Steatornis caripensis*, also has been incriminated in connection with cave disease.[53] Since bat guano is "harvested" from caves as fertilizer, the people involved in collecting, shipping, and actually mixing it into the soil are exposed to a rich source of *H capsulatum*.

Rural populations have higher skin test positivity than nearby city dwellers. Abandoned chicken houses endanger the farmer and his family especially when demolition of the chicken coop takes place.[54,55] Interestingly, only abandoned chicken houses give origin to group-infection; such buildings are often in poor repair, with broken windows, incomplete roofs, and missing doors. Bats have easy access to such places and can contaminate the floor of the buildings. Bat droppings may also be responsible for epidemics ascribed to a variety of birds, since the same shady trees invite birds and bats to roost.[56] Farmers are exposed to spore-containing dust in activities other than those connected with chicken coops—in silos,[57] when fertilizing with fecal material, and while plowing.

Scraping bridges prior to painting endangers small groups of people[58]; demolition of buildings and excavation for new construction have given origin to major outbreaks of acute (epidemic) histoplasmosis.[59,60] This and many other sources such as decaying trees, storm cellars, dust production during ballgames, spreading of topsoil,[61] and even peaceful visits to the parks create problems for those in the building trade,[62] gardeners, grave diggers, fishermen (digging for worms), and the population at large.[63]

How deceptive cultures from the environment may be was illustrated in a study of a group of bridge painters in Cincinnati; the most severely ill painter had positive CF and precipitating antibodies against *H capsulatum* and a sputum culture yielding *H capsulatum*. Several of his co-workers had elevated CF titers against *H capsulatum*. Scrapings from the bridge were injected into mice and yielded *Crypto neoformans*. Had the patient's illness not been documented beyond any doubt as being due to histoplasmosis, the incidental and additional presence of *Crypto neoformans* in scrapings from the bridge could have led to very wrong conclusions.

In view of the large number of clinically affected persons, and because these epidemics illustrate practically all aspects of the origin of "epidemic histoplasmosis," a review of the Mason City, Iowa epidemics follows.

Mason City, Iowa, Epidemics.—The epidemic outbreak of histoplasmosis in Mason City illustrates in rather unique form a gamut of coherent facts.[64-67] From July through mid-August 1962, a 200-yard long area along a creek was cleared of large trees and underbrush. Bulldozers were used to fell the trees and a power shovel dredged and widened the creek. Thousands of birds had roosted in the trees for the previous several years. Large clouds of dust were created when the trees were toppled. Twelve days after starting as a power shovel operator in this area, a 58-year-old man suddenly developed chills and fever; he died of bilateral pulmonary histoplasmosis seven weeks later. Three other men working in the area developed similar symptoms, and 24 more cases of acute histoplasmosis were recognized by a variety of diagnostic tools. Histoplasmin skin tests in 2,160 children living in the area of the earth clearing program revealed 77% positivity in subjects living within a block radius and only 20% positivity in children living one to two miles distant. Of ten soil samples taken from the undisturbed area adjacent to the "dug-up" site, nine were positive on culture for *H capsulatum*. Of 8,000 school children in Mason City, probably one third got infected during this first clearing operation, according to skin test data.[67]

Work was interrupted until January 1964, when city employees were ordered to saw up trees and underbrush accumulated in large piles from the clearing operation in 1962. The material was hauled to the city dump where it was burned. Cases of acute histoplasmosis were recognized about 12 days after work was started. Thirty persons developed erythema nodosum or erythema multiforme. School children showed skin test positivity varying from 21% to 100% depending on the distance between the area and the school site. Apparently 270 cases of clinical disease resulted from this

second epidemic in spite of attempts to limit the spread of the organism: winter had been chosen, the material was wetted down with water, and only workers with positive histoplasmin skin tests were allowed in the clearing process.[65]

1. The two epidemics show that within a city located in an area of low histoplasmosis endemicity, conditions can be created that are highly dangerous for large groups of exposed persons. Whether this condition is related to bird roosts or associated bat infestations cannot be decided,[56] but the presence of droppings from those winged animals (birds and bats) is too constant in similar epidemics to be fortuitous.

2. The closer to and the heavier the exposure, the more severe the disease and the higher the skin test conversion rate of the population in an area.

3. Clearing of trees and underbrush leads to soil-borne dust production, which is little influenced by weather conditions; simple procedures such as wetting down the spore-containing material are insufficient in preventing fungal fragments from becoming airborne.

4. Clinical disease can be severe, even lethal, in such epidemics. The large number of recognized cases, especially in women, permits correlation between erythema nodosum and erythema multiforme and primary infection with *H capsulatum*.

5. Prevention of such outbreaks by spraying the spore-containing soil with 3% formalin (in point sources)[65,66] or other methods of decontamination,[68,69] should be considered where and when practical.

As in the case of coccidioidomycosis, in individual cases of histoplasmosis within endemic areas, the decision as to whether an infection can be interpreted as "occupational" or simply represents the "natural" risk present in an endemic area is difficult. Even the fact that the infected person moved from a nonendemic area into the region of endemicity can obviously be interpreted for or against the acceptance of increased occupational hazard.

Coccidioidomycosis

A group such as archeologists may be threatened by coccidioidomycosis. Plunkett and Swatek[70,71] were the first to call attention to a small epidemic in four archeology students who became ill after a field trip near Inyokern, Calif; a fifth person cleaning the artifacts also developed coccidioidomycosis. Of 103 students excavating ruins near Chico, Calif in 1970, 61 contracted an illness consistent with the diagnosis of coccidioidomycosis.[72] Three smaller epidemics, involving a total of 79 students, occurred at archeological sites in northern California.[71,73,74] Since soil particles are brought to museums, workers in such institutions may become exposed to infection. Sterilization of the museum objects in an ethylene oxide, halogenated hydrocarbon mixture has been suggested to avoid infection.[75]

A 10-year-old boy dug up fossils 50 miles northwest of Los Angeles and subsequently cleaned them with an electric wire brush, a tool also used by his father. The boy developed severe clinical symptoms. He and the father were coccidioidin positive, three other family members were negative and so were two playmates who had been co-diggers, when searching for the shells. The difficulty of proving this case as fossil-born in persons living in the endemic area is self-evident.[76]

Since archeologists cannot be stopped from digging in the soil, it may be pertinent to emphasize that at least rodent burrows should be avoided, since they show particularly high positivity at culture.[72]

Bulldozing topsoil resulted in 34 cases of demonstrable infection at Edwards Air Force Base in 1960.[77] "Import" of topsoil for a residential garden led to a total of 24 cases of infection in San Diego.[78] Even after ten years, soil isolations were still positive at the garden site.

Coccidioidomycosis developed on the cheek and the scalp in two Filipino farm hands who scratched themselves on grapevines. The suspicion that the lesions represented primary inoculation foci was supported by the swelling of regional lymph nodes, absence of systemic disease, and in one case, by a positive precipitin reaction—suggesting recent infection.[79]

Coccidioidomycosis may be acquired from fomites.[80] Fruits, cotton, and vegetables are the most commonly postulated sources.[80,81] Dust from clothing has been implicated,[82] and cast material from a fracture site has been related to a hospital outbreak of coccidiodomycosis.[83] Two wool sorters, one from Massachusetts[84] and one from Canada[85] acquired fatal coccidioidomycosis. The first case had illness of one month duration. He supposedly had never traveled to the endemic area although the same patient described by a different author was said to have been in California many years earlier.[86] The second patient[85] also had not traveled to the area endemic for *C immitis*. An English businessman who was born in Ireland and had never left the British Isles unpacked pottery shipped from Arizona. The pottery was padded in finely shredded material, and unpacking produced a constant cloud of dust. The ensuing acute respiratory illness was diagnosed by biopsy and positive cultures as coccidioidomycosis.[87]

Although the two wool-sorters and the English businessman appear to be true fomite-transmitted infections, other cases occurring within the endemic area are much harder to prove.[80] Naturally, acquired infection is hard to rule out even if industrial exposure is demonstrated. In the endemic area, decisions are documented where infections in newcomers were accepted as pursuant to added risk (as compared with their previous habitat), and payment has been made to symptomatic members of a hospital staff, a porter traveling between Chicago and Los Angeles, a salesman, and a crane operator who came from nonendemic regions. Insurance companies do not necessarily follow the same pattern of empathy.[85]

The numerical importance and possible prevention of "occupational" coccidioidomycosis is discussed by Schmelzer and Tabershaw.[88] A point of particular importance is the need for "undusting" of earth moving equipment or any artifact that might be contaminated by fungus containing dust and would be moved from the endemic area to regions free of *C immitis*. Filtered air-conditioned cabs on earth moving equipment are likely to protect the driver as long as he stays within the cab and as long as he can do his job without opening the

windows. However, it seems rather utopic to expect major prevention of infection from the single procedure of air-conditioning cabs. Obviously, the dust accumulating on the equipment would have to be removed with utmost caution to prevent fragments of the fungus from becoming airborne. The employment of coccidioidin positive personnel in exposed occupations would seem a sensible precaution without completely eliminating the possibility of reinfection (breakthrough of the acquired immunity by heavy exposure is well documented).[89] From personal experience and statements by others, it can be accepted that wearing respirators in hot climates while performing physical work is less than pleasant and unbearable for any length of time. For a long time to come, we will have to accept any person involved in earth-digging procedures as a likely candidate for occupationally induced mycoses, especially histoplasmosis and coccidioidomycosis.

Cryptococcosis

Cryptococcus neoformans is not known as a cause of occupational disease, in spite of potential sources in infected domestic animals.[90] The well-documented cases of cryptococcosis with clinical symptoms in horses, dogs, cats, and pigs—to mention only domesticated animals—have not been associated with human infection.[91] Bovine mastitis due to *Crypto neoformans* occurs not infrequently in epidemic form,[92,93] apparently spread by contaminated milking machines or infected glucose-penicillin solutions used for injecting the breast tissue[94]; however, no infections in farm hands or veterinarians have been reported.

A high percentage of pigeon nests have been shown to contain *Crypto neoformans*.[95] Immunodiffusion antibody tests have shown positivity in the sera of pigeon fanciers: ten out of 50 asymptomatic pigeon breeders, five of six symptomatic breeders, and five of five cases of cryptococcosis showed precipitins.[96] Fink et al[96] doubt that pigeon breeders disease is caused by *Crypto neoformans*, but some exposure to *Crypto neoformans* present in pigeon excreta is apparently one source of sensitization.

In trying to explain the absence of major contagiosity in cryptococcosis, one is compelled to mention that a large number of clinical cases occur in immunosuppressed patients. Cryptococcosis is most commonly seen complicating Hodgkin disease and other lymphomas, terminal cancer, systemic lupus erythematosus, and following renal transplantation. *Cryptococcus neoformans* would therefore appear to be less invasive in the healthy population than *H capsulatum*, *C immitis*, or *B dermatitidis*. This may explain the absence of well-documented laboratory or industrial transmission of the disease even in persons handling the organism in the laboratory[36] or infected animals.[92,93]

COMMENT

A review of the literature reveals many cases of occupationally acquired mycotic infections. Prevention of those infections acquired in the laboratory should be feasible through education of laboratory workers and through the use of proper safety transfer hoods.

However, occupationally related fungal infections in persons exposed outside the laboratory may prove to be much more difficult to prevent. Soil is a large source of daily exposure to enormous numbers of workers in endemic areas. Although education of laboratory workers seems a realistic goal in preventive mycology, the education of those persons involved in digging and moving soil to practice techniques to decrease the exposure is a much more formidable task. Another approach to control of soil-borne mycotic infections is the vaccination of entire populations at risk. Although this approach may eventually prove feasible for coccidioidomycosis, no comparable vaccines have been developed for any other fungal diseases.

Soaking of soil with formalin solutions may help prevent epidemic outbreaks from point sources, but certainly the huge agricultural belts in which histoplasmosis is endemic cannot be expected to be sterilized by formalin.[65,66] Soaking with formalin those structures likely to be contaminated with *H capsulatum* such as bell towers, chicken coops, and old deserted buildings may decrease the risk of exposure during demolition.

Sporotrichosis presents a special problem since the mechanism of infection is generally traumatic-transcutaneous. Painting of timber with antiseptic material was successfully used in the South African mines to abort the ongoing epidemic.[45] In a similar fashion, it appears that soaking sphagnum moss in antiseptic solutions may also be useful in decreasing the content of *S schenkii*.[39]

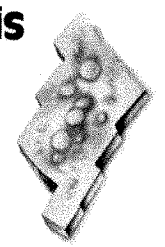
b.i.d.
Diprosone®
brand of
betamethasone dipropionate
Cream 0.05%
(Potency expressed as betamethasone)

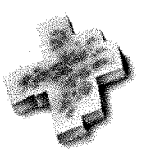
Twice a day for prompt relief of corticosteroid-responsive dermatoses

In contact dermatitis



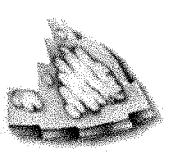
90% of patients showed marked or moderate improvement in seven days*
34 of 38 contact dermatitis patients responded to therapy.

In atopic dermatitis



86% of patients showed marked or moderate improvement in seven days*
133 of 155 atopic dermatitis patients responded to therapy.

In psoriasis



62% of patients showed marked or moderate improvement in only seven days*
116 of 188 psoriasis patients responded to therapy.

Additional benefits:

- Rapid onset of response.
- Economy and convenience of b.i.d. dosage.
- Occlusive dressings infrequently needed.
- Sensitivity is rare.
- Choice of convenient package sizes—in 15 Gm. and moneysaving 45 Gm. tubes.

Diprosone® brand of betamethasone dipropionate
Cream 0.05%/Ointment 0.05%

Clinical Considerations:

DESCRIPTION DIPROSONE is betamethasone dipropionate (9-fluoro-11β, 17,21-trihydroxy-16β-methylpregna-1,4-diene-3,20-dione 17,21-dipropionate). Each gram of DIPROSONE **Cream** 0.05% contains 0.64 mg. betamethasone dipropionate (equivalent to 0.5 mg. betamethasone) in a hydrophilic, emollient cream consisting of purified water, mineral oil, white petrolatum, polyethylene glycol 1000 monocetyl ether, cetostearyl alcohol, phosphoric acid, and monobasic sodium phosphate with 4-chloro-*m*-cresol as preservative. Each gram of DIPROSONE **Ointment** 0.05% contains 0.64 mg. betamethasone dipropionate (equivalent to 0.5 mg. betamethasone) in an ointment base of mineral oil and white petrolatum. **CONTRAINDICATIONS** DIPROSONE **Cream** and **Ointment** are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of such preparations. **PRECAUTIONS** If irritation develops with the use of DIPROSONE **Cream** or **Ointment,** treatment should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been absolutely established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time. DIPROSONE **Cream** and **Ointment** are not for ophthalmic use. **ADVERSE REACTIONS** The following local adverse reactions have been reported with topical corticosteroids: burning; itching; irritation; dryness; folliculitis; hypertrichosis; acneiform eruptions; hypopigmentation. The following may occur more frequently with occlusive dressings than without such therapy: maceration of the skin; secondary infection; skin atrophy; striae; miliaria. **DOSAGE AND ADMINISTRATION** Apply a thin film of DIPROSONE **Cream** to the affected skin areas twice daily, in the morning and at night. Clinical studies of DIPROSONE have indicated that applications twice a day are generally adequate. Apply a small quantity of DIPROSONE **Ointment** to the affected skin areas twice daily, in the morning and at night.

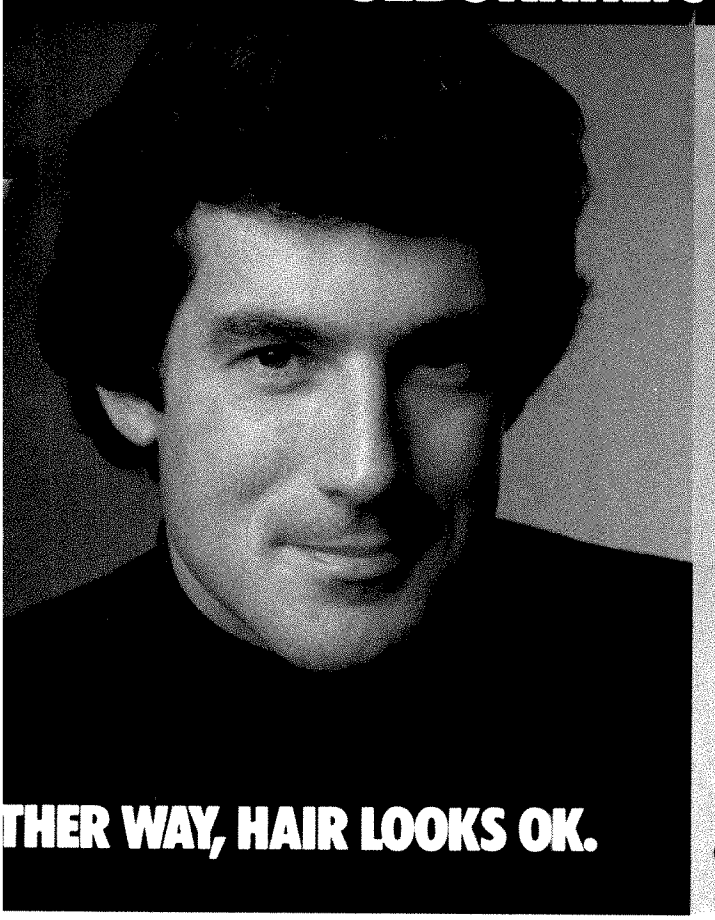
BARNES HIND OFFERS TWO Rx EXCLUSIVES FOR SEBORRHEIC DERMATITIS



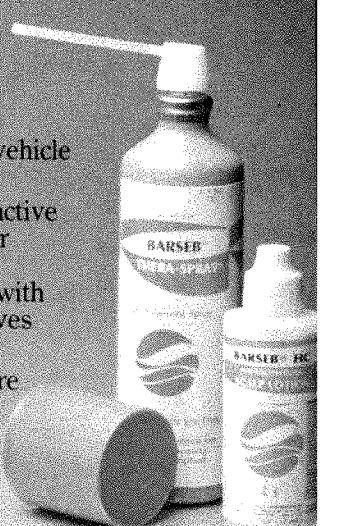
You can offer your seborrheic patients a choice of remedies that are effective yet cosmetically elegant—Barseb® Thera-Spray® and Barseb® HC Scalp Lotion.

Either way, you'll be prescribing Barnes Hind exclusive combinations of hydrocortisone and salicylic acid with their proven anti-inflammatory, antipruritic and keratolytic capabilities.

Without mussing the hair, the Thera-Spray snorkel directs the active ingredients onto the scalp in a vehicle that spreads and penetrates.

The Barseb HC base holds the active ingredients on the skin, not on the hair shafts. Barseb HC won't dry hair, or increase oiliness. And it's compatible with hair sprays, colorings, permanent waves and grooming agents.

Both Thera-Spray and Lotion are clear, non-staining, odorless.



BARSEB® THERA-SPRAY®
BARSEB® HC SCALP LOTION

(hydrocortisone and salicylic acid)

For complete prescribing information, please see package insert.

ONTRAINDICATIONS
ydrocortisone is contraindicated in tuberculosis, ngal, and most viral infections of the skin (espe- ally herpes simplex, vaccina and varicella, etc).

ARNING
hile topical steroids have not been reported to ve an adverse effect on pregnancy, the safety of eir use has not been absolutely established. herefore, they should not be used extensively on egnant patients in large amounts nor for long riods of time.
oid inhalation, ingestion or contact with eyes nose.
ARSEB® THERA-SPRAY
ntents under pressure. Do not puncture or burn

PRECAUTIONS
Transient discomfort may occur when first applied to an inflamed scalp. This normally disappears with repeated use. Discontinue use if condition does not improve or if sensitivity reactions occur. The anti-inflammatory action of hydrocortisone may mask the presence of infection. If bacterial or fungal infection exists or supervenes, concomitant antimicrobial or antifungal therapy should be considered. When topical steroids are used on large areas of skin for long periods of time, there is the possibility of systemic absorption. Should adrenal suppression, electrolyte imbalance, metabolic changes, or other symptoms of systemic absorption occur, suitable counter measures

when hydrocortisone is used in the treatment of skin diseases associated with impaired circulation, such as stasis dermatitis.
Avoid spray inhalation, ingestion, or contact with eyes or nose. If medication accidentally gets into eyes, immediately flush with copious amounts of water; if irritation persists, notify your physician.
Keep out of reach of children.

CAUTION
U. S. Federal law prohibits dispensing without prescription.

Barnes Hind Pharmaceuticals, Inc.

New Health Practitioners and Dermatology Manpower Planning

Melvin Krasner; David L. Ramsay, MD, MEd; Peyton E. Weary, MD; Marie-Louise T. Johnson, MD, PhD

• To assess the need for dermatologists in the United States, the potential role of new health practitioners in this specialty is considered. Available data on physician extenders in general and informed opinion on dermatologist extenders in particular suggest that specially trained, nonphysician personnel could substantially augment the supply of dermatological services. At present, however, widespread adoption of new staffing patterns appears unlikely. A long-run trend toward greater use of all categories of ancillary personnel in this specialty is expected, and the profession is urged to play an early and active role in this trend's development.

(*Arch Dermatol* 113:1280-1282, 1977)

A central consideration in estimating national dermatology manpower requirements is the quantity of patient care provided by a dermatologist. Many factors including the state of medical technology and the general organization of practice may affect productivity; however, a change in manpower staffing patterns, especially the introduction of new health practitioners (NHPs), eg, the physician's assistant, nurse practitioner, and MEDEX,[1] is viewed as a particularly important influence on the productivity of dermatologists.

As part of a study sponsored by the American Academy of Dermatology with the support of the Bureau of Health Manpower, Department of Health, Education, and Welfare, an effort has been made to analyze available information regarding NHPs, both in general medicine and in dermatology, to draw some broad conclusions about the potential impact of NHPs on manpower needs in the specialty.

Although using ancillary personnel in providing medical services is new neither in concept nor in practice, this subject has received considerable attention in recent years.[2,3] The substitution of auxiliary personnel for physicians whenever possible, and the development of NHPs have been proposed as methods for increasing the productivity of physicians, which would in turn alleviate the apparent problems in health care provision: (1) shortage of physicians, (2) rising cost of personal medical care, and (3) geographic inequality in the availability of such care.[4] The fact that auxiliary personnel, particularly NHPs, can have a corrective influence on these problems is generally recognized; however, the extent and magnitude of such influence remain largely unclear.

NHPs in General Medicine

Despite some reservations, patients have generally accepted NHPs.[5,6] Physicians have also expressed enthusiasm for such personnel,[7] but with important reservations and some dissent.[8-10] Both patients and physicians who have had some experience with NHPs are more likely to favor them than those who have not.[11,12] The quality of care, in terms of patients' outcomes, has been similar for traditional medical practices and those employing NHPs.[13,14] The greater personal attention, which an NHP can provide, and the additional physician time that is made available for difficult cases, are positive aspects of such care.[11,12]

A major consideration in manpower

planning is the productivity of NHPs. A wide range of productivity estimates is presented in the literature, but with the diversity of practice settings, training, experience, and other factors that are involved, this variation in productivity is to be expected.

Nelson et al report that ambulatory practices employing a MEDEX showed a 37% increase in patient visits, after three years of training and experience.[15] According to Schiff et al, the introduction of a nurse practitioner in a pediatrics practice can augment the productivity of a physician by more than one third.[16] The Burlington random trial of the nurse practitioner resulted in a 41% increase in the number of families under care.[13] In five Canadian family practices, additional training of employed personnel led to an average increase in productivity of 18%.[17] Lave et al report an instance where a physician's assistant saved 43% of a physician's time, which could have been used to expand patient care activities by 75%.[18] Steinwachs et al recently estimated that in routine adult ambulatory care, an NHP increased the productivity of a physician by 39%.[19]

Although wide variation in productivity is reported, the evidence seems to indicate that a reasonable expectation would be for an NHP to augment a physician's services by 30% to 40%. However, caution is necessary in generalizing these findings. Important determinants of the NHPs productivity include the following: (1) frequency of physician consultation, (2) time spent per patient, (3) type of care required,[20] and (4) physician and patient attitudes. These factors will necessarily differ among practices, and will undoubtedly be important considerations in extending findings in family practice and pediatrics to dermatology.

NHPs in Dermatology

Although there are formal physician's assistant training programs in many diverse specialties,[21] except for pilot or informal programs, there is no civilian program in dermatology. This fact is quite surprising, in light of the early interest shown in dermatologist extenders by the National Program for Dermatology.[22] In addition, a recent study of NHPs in general medicine revealed that diseases of the skin and subcutaneous tissue was a particularly suitable category for involvement by NHPs.[19]

Clear information upon which to assess the potential role of dermatologist extenders is rather sparse, despite a general feeling within the specialty that ancillary personnel can and often do contribute substantially to dermatological patient care. Dermatologists have been using support personnel in their practices for years, and many dermatologists delegate a large portion of their patient care to their assistants.[23-26]

Perhaps the most important consideration is the acceptance of NHPs among dermatologists. A survey of American dermatologists in 1968 found that about 60% of the respondents would be willing to delegate less than 10% of their professional office tasks to specially trained nurses or aides.[27] A more recent survey of the Chicago Dermatology Society "revealed a definite place for physician's assistants in dermatology."[26] However, the respondents felt that only about 15% of their work load could be handled by a trained assistant. A survey of the Louisiana Dermatology Society, reported by Welton,[24] seems to indicate a distinct reluctance among dermatologists to relinquish many tasks to assistants. A similar survey among California dermatologists found little interest in employing dermatologist's assistants in private practice.[22] In western New York, the recently established nurse practitioner program at the State University, Buffalo, appears not to have generated the expected enthusiasm among dermatologists in private practice, according to a letter from Richard L. Dobson, MD (March 3, 1976).

However, as experience with assistants grows and as the supply of adequately trained personnel increases, one can expect that more dermatological care will be handled by nonphysicians, particularly in institutional settings. A particularly effective experience in dermatology with a MEDEX who was the primary provider for about 40% of the patients in an institutional setting is described by Johnson.[28]

A recent survey of prepaid group practices conducted by the authors found extensive use of auxiliary personnel, although estimating their productivity was not possible. The most important group of support staff involved in direct patient care, was registered and vocational nurses; some nurses had special training and responsibility. One large group practice reported that a clinic assistant operated an acne clinic, which handled about two thirds as many patient visits annually, as ordinarily handled by one of its dermatologists.

The military has been a particularly encouraging environment for dermatologist extender training and utilization. The Dermatology Technician School of the US Navy, Philadelphia, is the only program in the country that trains large numbers of paramedical personnel in dermatology. Trainees are accepted into the program only after extensive general paramedical training and experience.[23] Hayen estimated that such personnel can augment the productivity of dermatologists by about one third,[23] which is consistent with the findings about NHPs in general, discussed earlier. Since the program's inception in 1957, more than 200 technicians were graduated; however, only 8% have been able to apply their experience and training in civilian careers, according to a letter from C. Robert Charles, MD (Feb 17, 1976). Thus, although the Navy program is a potential resource for the rest of the military and the civilian sector, there seem to be obstacles to the effective utilization of this resource.

Future Prospects

In the future, civilian academic medical centers may also play an important role in the development of NHPs in dermatology. The traditional response of medical centers to increasing demand, ie, expansion of residency positions, is largely precluded in the current austere economic environment. Compounding this situation is legislative and other pressure to expand primary care residencies at the expense of other specialty positions and to regulate the supply of residency positions to meet long-run national medical manpower requirements rather than the immediate

needs of individual health institutions. The increasing demand for care would encourage medical centers to consider implementing new staffing patterns for inpatient and outpatient services. As succeeding cohorts of physicians are trained in an environment where allied health personnel are extensively used, one would expect a corresponding increase in the acceptance and employment of such personnel in private practice.

Although this projected increase in the use of dermatologist extenders is expected to occur gradually, early planning and development of effective training programs are essential. Early experience with the use of dermatologist extenders showed great promise, but general interest was less than anticipated, perhaps because these efforts were premature or fragmented. Existing paramedical training programs, particularly the Navy Dermatology Technician School, should be considered as models for study and possible expansion or replication. A consortium of medical centers and dermatology associations should be established to provide the broad-based financial and professional support necessary to ensure the success of training programs and the effective integration of their trainees into the dermatology community.

The impact of nonphysician health care personnel on projections of national requirements for dermatologists appears limited in the near future. Dermatologist extenders have been shown to be acceptable and effective in a variety of settings, but many factors would limit the general applicability of their services at the present time.

In the long run, however, with the anticipated transformation in health services organization, the potential for change in manpower staffing patterns and physician productivity appears to be great. A farsighted, united effort by the specialty to prepare for such change can provide lasting social benefit.

This study was supported by grant 231-75-0021 from the Division of Medicine, Bureau of Health Manpower, Health Resources Administration, Department of Health, Education and Welfare.

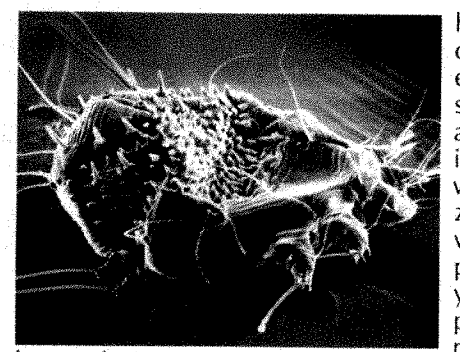
THE ONLY WAY TO END THE EPIDEMIC IS OVER HER DEAD BODY.

Kill the female itch mite (*sarcoptes scabiei*) and you've stopped the current scabies epidemic. Because when she burrows deep into the stratum corneum, she defies diagnosis and resists removal by surface-acting medications and cleansers. Her success has been making headlines around the country—with reports of scabies outbreaks in rural and suburban areas as well as in the cities.



A quick and simple diagnosis. Scabies can mimic a number of dermatological conditions,[1-3] such as urticaria, furunculosis and dermatitis—as well as syphilis with which it may coexist. But there's an almost foolproof way to recognize it. Even in the absence of the fierce nocturnal itching[3] and the lesion distribution characteristic of the disease (hands, wrists and elbows in 9 out of 10 cases),[1] a quick microscopic look can confirm your scabies diagnosis.

To demonstrate the itch mite, look for an unscratched, inhabited burrow (wherever the patient says he itches at that very moment is a likely spot). Use a strong light, a magnifying glass and a surgical blade to which a drop of mineral oil is added. Scrape several sites. Transfer the material to a slide, cover and examine under low power magnification.[1,3,4] (If you don't spot any parasites in egg, larvae or adult stages, look for their red fecal compactions. They can be just as diagnostic.)

Kwell: penetrating action to kill mites, their eggs and larvae. Once you've found scabies, there's a positive way to eradicate it. Kwell (1% gamma benzene hexachloride) Lotion or Cream. It penetrates to reach the scabietic burrows, kills the female mites and, of course, the less tenacious males, as well as their eggs and any larvae that may have hatched. In fact, Kwell works so consistently and well against scabies that it has been the most widely prescribed scabicide for three decades.

Nearly 100% effective. The clinical record of Kwell has never been surpassed by any other pediculicide. It is "nearly 100% effective,"[1] and often works with a single application (a second or third application may be made at weekly intervals, if needed). Your patients will appreciate the low risk of sensitization and irritation.[5,6] And you will appreciate that Kwell works so predictably that it serves to confirm your diagnosis of scabies. Not many pharmaceutical preparations can match *that* record of dependability.

Contraindications: Kwell is contraindicated in individuals who develop hypersensitivity to the product or to any of its components.

Precautions: If accidental ingestion occurs, prompt institution of gastric lavage will rid the body of large amounts of the toxicant. However, since oils favor absorption, saline cathartics for intestinal evacuation should be given rather than oil laxatives.

Central nervous system manifestations can be antagonized by the administration of pentobarbital or phenobarbital in sufficiently large doses to the limit of their therapeutic effectiveness. It is not desirable to depress the patient to the point of hypnosis. However, persons poisoned with stimulants may tolerate large doses of barbiturate without undue depression and with great benefit. Intravenous calcium gluconate may be used in conjunction with the barbiturates. Epinephrine should not be used because ventricular fibrillation may result.

If accidental contact with eyes occurs, flush with water. If irritation or sensitization occurs, discontinue the product and consult physician.

Adverse Reactions: Eczematous eruptions due to sensitization of this product have been reported.

Available on prescription as Kwell Lotion in 2 and 16 fl. oz. bottles, and as Kwell Cream in 2 oz. and 1 lb. jars. See package insert for complete prescribing information.

Cream/Lotion

KWELL® gamma benzene hexachloride

THE SCABICIDE OF CHOICE.

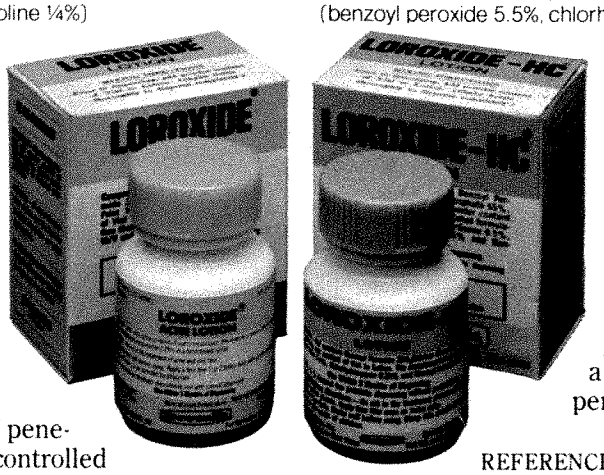
An unsurpassed standard of therapy

For effective and individualized control of acne....

Prescribe the only benzoyl peroxide acne medication available in cover-up lotions....

LOROXIDE® Acne Lotion and LOROXIDE-HC® Lotion

(benzoyl peroxide 5.5%, chlorhydroxyquinoline ¼%) (benzoyl peroxide 5.5%, chlorhydroxyquinoline ¼%, hydrocortisone ½%)



■ Contains the proved synergistic bactericidal combination of benzoyl peroxide and chlorhydroxyquinoline (300% greater antibacterial activity[1]) — which topically reduces C. Acnes *within* comedones[2]

■ LOROXIDE-HC® effectively treats papular, pustular and cystic acne[3] — a favorable response has been reported in 75% of patients in as short a period as two weeks[4]

■ Ideal therapy providing "all day," penetrating antimicrobial activity with controlled drying and desquamation — at school, work or play.

■ No sun-sensitizing properties — no need to restrict your patient's outdoor activities or eliminate the known benefits of natural UV exposure.

■ *The only* adjustable tint-intensity benzoyl peroxide lotions available.

■ Replaces and helps to prevent abuse with over-the-counter cosmetics.

■ For *day-long control* of all grades of acne vulgaris.

■ Lesion-masking base helps to eliminate the..."natural but distorted feelings that other people perceive him as 'acne with a person attached rather than as a person who happens to have acne.'"

Plus "Instant Social Confidence" Dermik Color Blender™

EXCLUSIVE!

Dermik

Dermik Laboratories, Inc.
Fort Washington, Pa. U.S.A. 19034

LOROXIDE® Acne Lotion and LOROXIDE-HC® Lotion

DESCRIPTION: Loroxide Acne Lotion contains (as dispensed) benzoyl peroxide 5.5%, and chlorhydroxyquinoline 0.25%, incorporated in a water washable lotion consisting of purified water, propylene glycol, hydroxyethylcellulose, caramel color, cholesterol-sterol, cetyl alcohol, propylene glycol stearate, polysorbate 20, lanolin alcohol, propylparaben, decyl oleate, purcelline oil syn., antioxidants, vegetable oil, methylparaben, tetrasodium EDTA, buffers, cyclohexanediamine tetraacetic acid, calcium phosphate, silicone emulsion, silica, kaolin, talc and titanium dioxide, with "Dermik Color Blender™" supplied separately.

Loroxide-HC Lotion contains (as dispensed) hydrocortisone 0.5%, benzoyl peroxide 5.5% and chlorhydroxyquinoline 0.25% incorporated in a lotion identical to Loroxide Lotion (see above).

Actions: Provides keratolytic, peeling and drying action.

Indications: An aid in the treatment of acne and oily skin.

Contraindications: This product is contraindicated for use by patients having known hypersensitivity to hydrocortisone, benzoyl peroxide, chlorhydroxyquinoline or any other component of this preparation. Topical steroids are contraindicated in viral diseases of the skin, such as varicella and vaccinia.

Warning — Usage in Pregnancy: Although topical steroids have not been reported to have an adverse effect on the fetus, the safety of their use during pregnancy has not been absolutely established. Therefore, they should not be used extensively, or in large amounts or for prolonged periods of time on pregnant patients.

Precautions: For external use only. Keep away from eyes. If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of appropriate antifungal or antibacterial agents should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated, or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken.

Do not add any other medicaments or substances to this lotion unless specifically directed by physician to do so. Patients should be observed carefully for possible local irritation or sensitization during long-term topical therapy. Apply with caution on neck and/or other sensitive areas. There may be a slight, transitory stinging or burning sensation on initial application which invariably disappears on continued use. Ultraviolet and cold quartz light should be employed in lesser amounts, as this lotion is keratolytic and drying. Harsh, abrasive cleansers should not be used simultaneously with this lotion. Colored or dyed garments may be bleached by the oxidizing action of benzoyl peroxide. Chlorhydroxyquinoline may cause temporary light-yellowish skin staining in rare cases. Keep out of the reach of children.

Adverse Reactions: The following local adverse reactions have been reported with topical corticosteroids: burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneiform eruptions, and hypopigmentation. The sensitizing potential of benzoyl peroxide and chlorhydroxyquinoline are low, but they can, on occasion, produce allergic reaction. Occurrence of excessive redness or peeling indicates that the amount and frequency of application should be reduced.

Directions: Shake well before using. Apply a small quantity to affected areas with light massaging 1 to 3 times daily, or in accordance with the physician's directions.

(Important information directed to the Pharmacist: At time of dispensing, add contents of vial* to the bottle. Shake well and/or stir with a glass rod to insure a uniform dispersion. Place expiration date of three (3) months on bottle label.)

*"Benzie-Pak" vials contain a mixture of benzoyl peroxide 35% and calcium phosphate 65%.

Net weight of each vial is 3.8 grams.

How Supplied: Bottles, 25 Gm.

Caution: Federal law prohibits dispensing without prescription.

Search for a Causal Agent of Psoriasis by Seroepidemiologic Methods

Joan J. Ratner, MS, Kendall O. Smith, PhD

The cause of psoriasis is unknown, although one current hypothesis is that it is an inherited disease. Identical twin studies and clinical observations suggest that environmental factors are involved. The idea that this disease might be due to an infectious agent has been reported in the literature at various times. Zech and Lagerholm[1] reported virus-like particles in electron photomicrographs of psoriatic scales that were not present in the unaffected epidermis of psoriatic or normal skin. In 1971 Pozdnyakov[2] reported the isolation of a cytopathogenic agent for human epithelial-2 cells from the blood of patients in the progressive stage of the disease. Varelzidis and Theodoridis[3] reported an increase in serum IgA levels in patients with psoriasis, which returned to normal when the lesions were resolved by ultraviolet light therapy. In 1974 Stankler[4] found that the sera of patients who recovered from active psoriasis contained a factor that inhibited the development of lesions in these same patients during the progressive stage of the disease.

The purpose of this study was to determine whether an infectious agent plays a role in the cause of the disease, and a seroepidemiological study of psoriatic patients, with the use of a highly sensitive radioimmunoassay (RIA) was the method of approach. The plan was to determine antibody levels in patients with psoriasis and matched control patients against a select group of viral agents known to be associated with skin diseases; thus, it could be determined whether a substantial difference between the two groups exists. Psoriatic scales were cultured for the presence of unusual bacteria that were used as test antigens in the RIA. Suspensions of psoriatic scales were also used as antigens in the test.

From the Department of Microbiology, University of Texas Health Science Center, San Antonio.

Reprint requests to Department of Microbiology, University of Texas Health Science Center, 7703 Floyd Curl Dr, San Antonio, TX 78284 (Mrs Ratner).

Materials and Methods

Varicella-zoster virus and cytomegalovirus antigens were prepared from human fetal lung fibroblast cultures as previously described by Smith et al[5] and Patterson and Smith.[6] Herpes simplex virus type 1 was similarly prepared from human amnion tissue culture cells, and measles virus antigen was prepared from Vero cells. Control antigens were prepared from uninoculated tissue cultures.

Molluscum contagiosum "pearls" were minced, ground in a tissue grinder, and clarified by centrifugation at 39 g for three minutes. Phosphate-buffered saline was added to the supernatant fluid to a volume of 8 ml—a 1% (v/v) suspension.

A 1% (v/v) suspension of psoriatic scales was tested either untreated or treated with 0.02M glycine hydrochloride buffer at pH 3.2 (to dissociate antigen-antibody complexes).

Psoriatic scales were placed in tubes with sterile saline and thoroughly mixed. Suspensions were inoculated into culture media and incubated aerobically and anaerobically.

A positive control serum was tested for each of the viral antigens. Negative controls consisted of uninoculated tissue culture antigens or negative control serum.

Sera from 24 psoriatic patients and 24 controls, matched for age and sex, were used. All came from within a 24-mile radius of San Antonio, Tex.

The RIA procedure previously described by Smith et al[5] and Patterson and Smith[6] was followed. Specific counts were determined by subtracting counts that were obtained from the corresponding uninfected tissue culture antigens incubated with serum from those of virus-infected cell culture antigens incubated with the same serum.

Results

Staphylococcus aureus, *S epidermidis*, *Escherichia coli*, and an unusually large group-D *Streptococcus* were isolated from the cultures of psoriatic scales. This *Streptococcus* was used as antigen in one of the tests.

Specific counts were calculated for each serum with each antigen. Mean values were calculated for psoriatic patients and matched controls, and P values were determined by the Student's t test.

No statistically significant differences (P range, .1 to .9) between the psoriatic and control groups for antibodies to herpes simplex virus type 1, varicella-zoster virus, measles virus, molluscum contagiosum virus, cytomegalovirus, group-D *Streptococcus*, and treated and untreated psoriatic

scales were found. There was no unusual distribution or lack of antibody in either of the two groups.

Comment

There is the possibility that direct antibody determination may not be a suitable method of detection or that the causal agent was not included in the battery of tests.

Darl VanderPloeg, MD; Bob Limmer, MD; J. Lewis Pipkin, MD; and Charles Reiter, Jr, MD, assisted in obtaining specimens for this study.

Basal Cell Carcinoma With Bony Metastases Producing Myelofibrosis

Rama M. Jager, MD; Leonard J. Weiner, MD; Robert S. Howell, MD

Basal cell carcinoma rarely metastasizes. In more than 60% of reported patients, only lymph nodal metastases were present; bony metastases occur in fewer than 17% of patients with metastatic basal cell carcinoma.[1] In this report, we describe a patient with myelofibrosis secondary to bone marrow metastases from basal cell carcinoma.

Report of a Case

A 55-year-old man was admitted to the hospital in June 1976 with anorexia, dyspnea, weakness, and weight loss of gradual onset. He underwent chemosurgical excision of a superficial skin cancer of unknown histologic type over his right lower eyelid in 1959 and was symptom-free until 1965 when the skin ulcer recurred. It was surgically excised (Fig 1), but during the next 11 years, it recurred several times and required multiple curettages, electrodesiccations, and surgical resections. In January 1976, radical exenteration of the right eye and right radical maxillectomy and resection of the ethmoid sinus were done because of the infiltration of the inferior rectus muscle with recurrent basal cell carcinoma. The patient remained free of symptoms until the present admission.

Results of physical examination on his current admission showed a single firm, but movable, 2-cm lymph node along the anterior border of the right sternomastoid muscle and an enlarged left lobe of the liver. A biopsy specimen from the lymph node showed follicular hyperplasia, but no lymph nodal metastases.

Results of laboratory studies on the present admission disclosed some unexpected values: hemoglobin, 10.3 gm/100 ml; WBC, 5,000/μl, with 25% polymorphonuclear leukocytes, 73% lymphocytes, and 2% eosinophils; platelet count, 24,000/μl. The peripheral blood smear showed anisocytosis, poikilocytosis, polychromasia, and moderate leukoerythroblastic reaction. Liver-spleen scintiscan showed enlargement of the left hepatic lobe and moderate enlargement of the spleen, but no evidence of metastases. A chest roentgenogram was negative for metastatic disease. Bone scintiscan (^{99m}Tc) showed increased uptake of the isotope by multiple marrow-containing bones (Fig 2). Bone marrow was aspirated and had notable hypocellularity (Fig 3) and infiltration with neoplastic cells resembling basal cells, as anastomosing cords, with severe desmoplastic response around these cords (Fig 3).

The patient was treated twice weekly with vincristine sulfate (1 mg intravenously), bleomycin sulfate (15 units over 24 hours), and prednisone (40 mg by mouth per day), for six weeks. After four weeks of therapy, the pancytopenia in the peripheral blood smear regressed, with a WBC count of 6,000/μl and platelet count of 150,000/μl. The patient remained in partial remission, as evidenced by the normal peripheral blood smear, until February 1977, when he showed recurrence of basal cell carcinoma in his right orbit, requiring electrocoagulation and continuation of systemic chemotherapy.

Comment

True basal cell carcinomas lack the ability to metastasize despite chronic and extensive growth and destruction of adjacent organs. This inability may be explained by the lack of autonomy of basal cell cancers evidenced by their failure to grow as autografts unless a connective tissue stromal component is present, in contrast to squamous cell cancers.[2] Basal cell cancer xenografts also fail to grow in immunologically privileged sites, such as the anterior chamber of the eye, unlike squamous cell cancer xenografts.[3]

Carcinomatous invasion of bone marrow leading to a clinical syndrome of myelofibrosis with myeloid metaplasia has been described with various malignant tumors.[4] Basal cell carcinoma metastatic to bone marrow producing "myelophthisic" anemia, to our knowledge, has been reported in only one patient.[5] Bone marrow failure complicated the therapy of this patient by reducing the number of

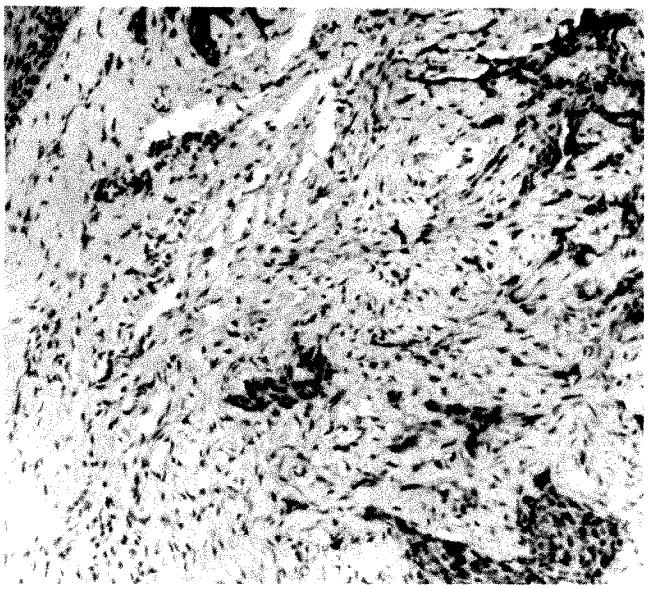

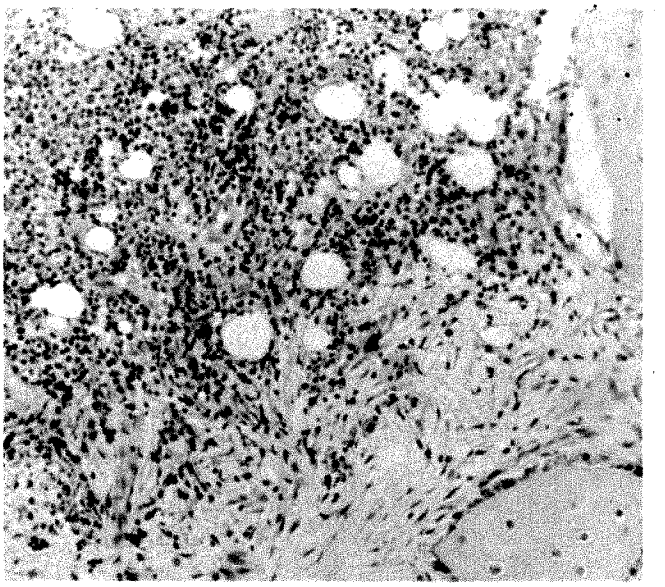

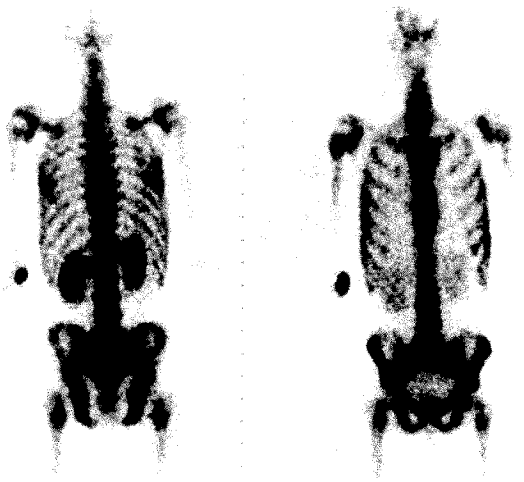

Fig 1.—Top left, Basal cell carcinoma showing characteristic uniform epithelioid cells arranged in masses.

Fig 2.—Bottom left, Bone scintiscan showing areas of increased uptake (suggestive of metastases) in multiple bones.

Fig 3.—Top right, Basal cell carcinoma metastatic to bone marrow, producing diffuse myelosclerosis. Note paucity of bone marrow cellularity and similarity between primary tumor and bone marrow metastases.

usable chemotherapeutic agents. The drugs selected should be nonmyelotoxic to avoid further suppression of bone marrow function in these patients. The choice of vincristine and bleomycin to treat this reported patient was based on the (1) selective concentration of bleomycin in epidermal cells, (2) relatively low myelotoxicity of the combination, and (3) synchronization of malignant cells in the mitotic phase by vincristine, in which phase cells are preferentially susceptible to bleomycin cytotoxicity.

The present case raises the question of the length of follow-up of patients with basal cell cancers. Patients with more than one basal cell cancer are estimated to have a 56% probability of developing a second skin cancer. Therefore, a more careful follow-up of patients with basal cell carcinoma is recommended. Basal cell carcinomas that have not recurred for six years are estimated to have less than 1% probability of recurrence.[6] This information, coupled with the observation that a majority of patients whose basal cell cancers metastasized had multiple previous recurrences, suggests that when a basal cell cancer recurs after a long latency and especially after multiple resections, chemotherapy, and radiation, the clinician should be alert to the possibility of lymph nodal or distant organ metastases.[1] Basal cell carcinomas may also become malignant during their long clinical course and acquire the ability to metastasize after multiple recurrences and multiple therapeutic maneuvers. Publication of information on use of newer chemotherapeutic agents with all the detected cases should aid in proper treatment of this rare disease.

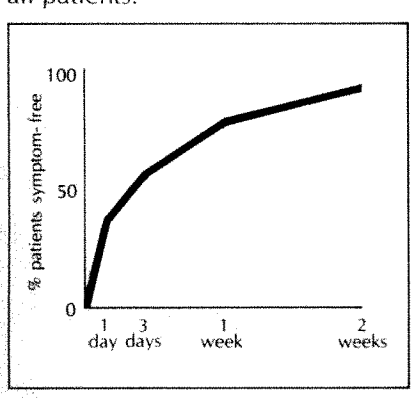
Th seven most important reasons to prescribe a topical antifungal. Right at your fingertips.

1 It is effective against the most prevalent fungal pathogens. MicaTin brand miconazole nitrate 2% offers exceptional effectiveness against the most difficult-to-treat pathogen—*Trichophyton rubrum*, and is equally effective against *Trichophyton mentagrophytes, Epidermophyton floccosum, Candida albicans* and *Malassezia furfur.*

2 It clears the most common fungal infections. MicaTin provides outstanding clinical and mycological efficacy in tinea pedis,* tinea corporis* and tinea cruris* as well as candidiasis and tinea versicolor.

3 It relieves symptoms quickly. Within 72 hours for the majority of patients. Within 1 to 2 weeks for virtually all patients.



4 It demonstrates effectiveness in extensive studies. Clinical studies† demonstrate the outstanding success rate of MicaTin in the treatment of tinea pedis, tinea corporis and tinea cruris, when used with the recommended dosage of twice daily for one month. At the end of therapy, 88—94% of the patients were clinically clear.

The clinical studies of patients with candidiasis and tinea versicolor are equally impressive. Nine out of ten patients with candidiasis or tinea versicolor were clinically and mycologically clear within two weeks—the recommended duration of treatment.

Pathogen	Infection	Conversion KOH	Culture	Clinical Clearance or Improvement
Trichophyton rubrum	Tinea pedis	82%	86%	88%
Trichophyton mentagrophytes / *Epidermophyton floccosum*	Tinea corporis / Tinea cruris	93%	90%	94%
Candida albicans	Candidiasis†	92%	86%	88%
Malassezia furfur	Tinea versicolor	89%	—	92%

5 Its low relapse rate promises an outstanding chance of cure. To prove how effective MicaTin really is in keeping fungal infections clear, we evaluated these same patients one month later (median).† Of the 121 patients who were clear of tinea pedis, tinea corporis and tinea cruris at the end of treatment *and* were available for follow-up, 92% showed no clinical or mycological recurrence of the original infection.

And of the 34 patients cleared of cutaneous candidiasis *and* available for follow-up, 91% were still clear two weeks later (median).

6 It has a low incidence of side effects. Reports of "burning" sensation, irritation and maceration with MicaTin have been few and isolated. Naturally, it should not be used in patients with known hypersensitivity to any of its ingredients.

7 It is economically priced. The retail price of MicaTin is usually lower than that of other prescription antifungals.

Introducing new
MicaTin Lotion
brand miconazole nitrate 2%
12 ml. and 30 ml. bottles
MicaTin cream
brand miconazole nitrate 2%
new 85 g. (3 oz.) tube
and familiar 1 oz. and 15 g. sizes

Description: MicaTin brand miconazole nitrate cream 2% and lotion 2% each contain miconazole nitrate‡ 2%, formulated into a water miscible base consisting of pegoxol 7 stearate, peglicol 5 oleate, mineral oil, benzoic acid, and butylated hydroxyanisole.

Actions: Miconazole nitrate is a synthetic antifungal agent which inhibits the growth of the common dermatophytes, *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum,* the yeast-like fungus, *Candida albicans,* and the organism responsible for tinea versicolor (*Malassezia furfur*).

Indications: For topical application in the treatment of tinea pedis (athlete's foot), tinea cruris, and tinea corporis caused by *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum,* in the treatment of cutaneous candidiasis (moniliasis), and in the treatment of tinea versicolor.

Contraindications: MicaTin has no known contraindications.

Precautions: If a reaction suggesting sensitivity or chemical irritation should occur, use of the medication should be discontinued.

For external use only. Avoid introduction of MicaTin brand miconazole nitrate cream 2% and lotion 2% into the eyes.

Adverse Reactions: There have been isolated reports of irritation, burning, and maceration associated with application of MicaTin.

Dosage and Administration: Sufficient MicaTin cream should be applied to cover affected areas twice daily (morning and evening) in patients with tinea pedis, tinea cruris, tinea corporis, and cutaneous candidiasis and once daily in patients with tinea versicolor. It is preferable to use MicaTin lotion in intertriginous areas; if the cream is used, it should be applied sparingly and smoothed in well to avoid maceration effects.

Early relief of pruritus (first week) and early clinical improvement (one to two weeks) have been seen in treatment of infections caused by common dermatophytes. Even though clinical improvement may be seen fairly soon after treatment is begun, *Candida* infections should be treated for two weeks and dermatophyte infections for one month in order to reduce the possibility of recurrence. If a patient shows no clinical improvement after a month of treatment, the diagnosis should be redetermined. Patients with tinea versicolor usually exhibit clinical and mycological clearing after two weeks of treatment.

How Supplied: MicaTin brand cream 2% containing miconazole nitrate at 2% strength is supplied in 1 oz., 15 g., and 3 oz. tubes. MicaTin brand lotion 2% containing miconazole nitrate at 2% strength is supplied in polyethylene squeeze bottles in quantities of 12 and 30 ml.

*When infecting organisms are *Trichophyton rubrum, Trichophyton mentagrophytes* and *Epidermophyton floccosum.*

†Data for tinea pedis is based on 4 weeks' therapy in 138 patients; for tinea cruris and tinea corporis—4 weeks' therapy in 50 patients; for tinea versicolor—2 weeks' therapy in 38 patients; for candidiasis—2 weeks' therapy in 23 patients and 4 weeks' therapy in 20 patients. (There was no significant difference in effectiveness between the two candidiasis groups.) Data on file, Dermatological Division, Johnson & Johnson.

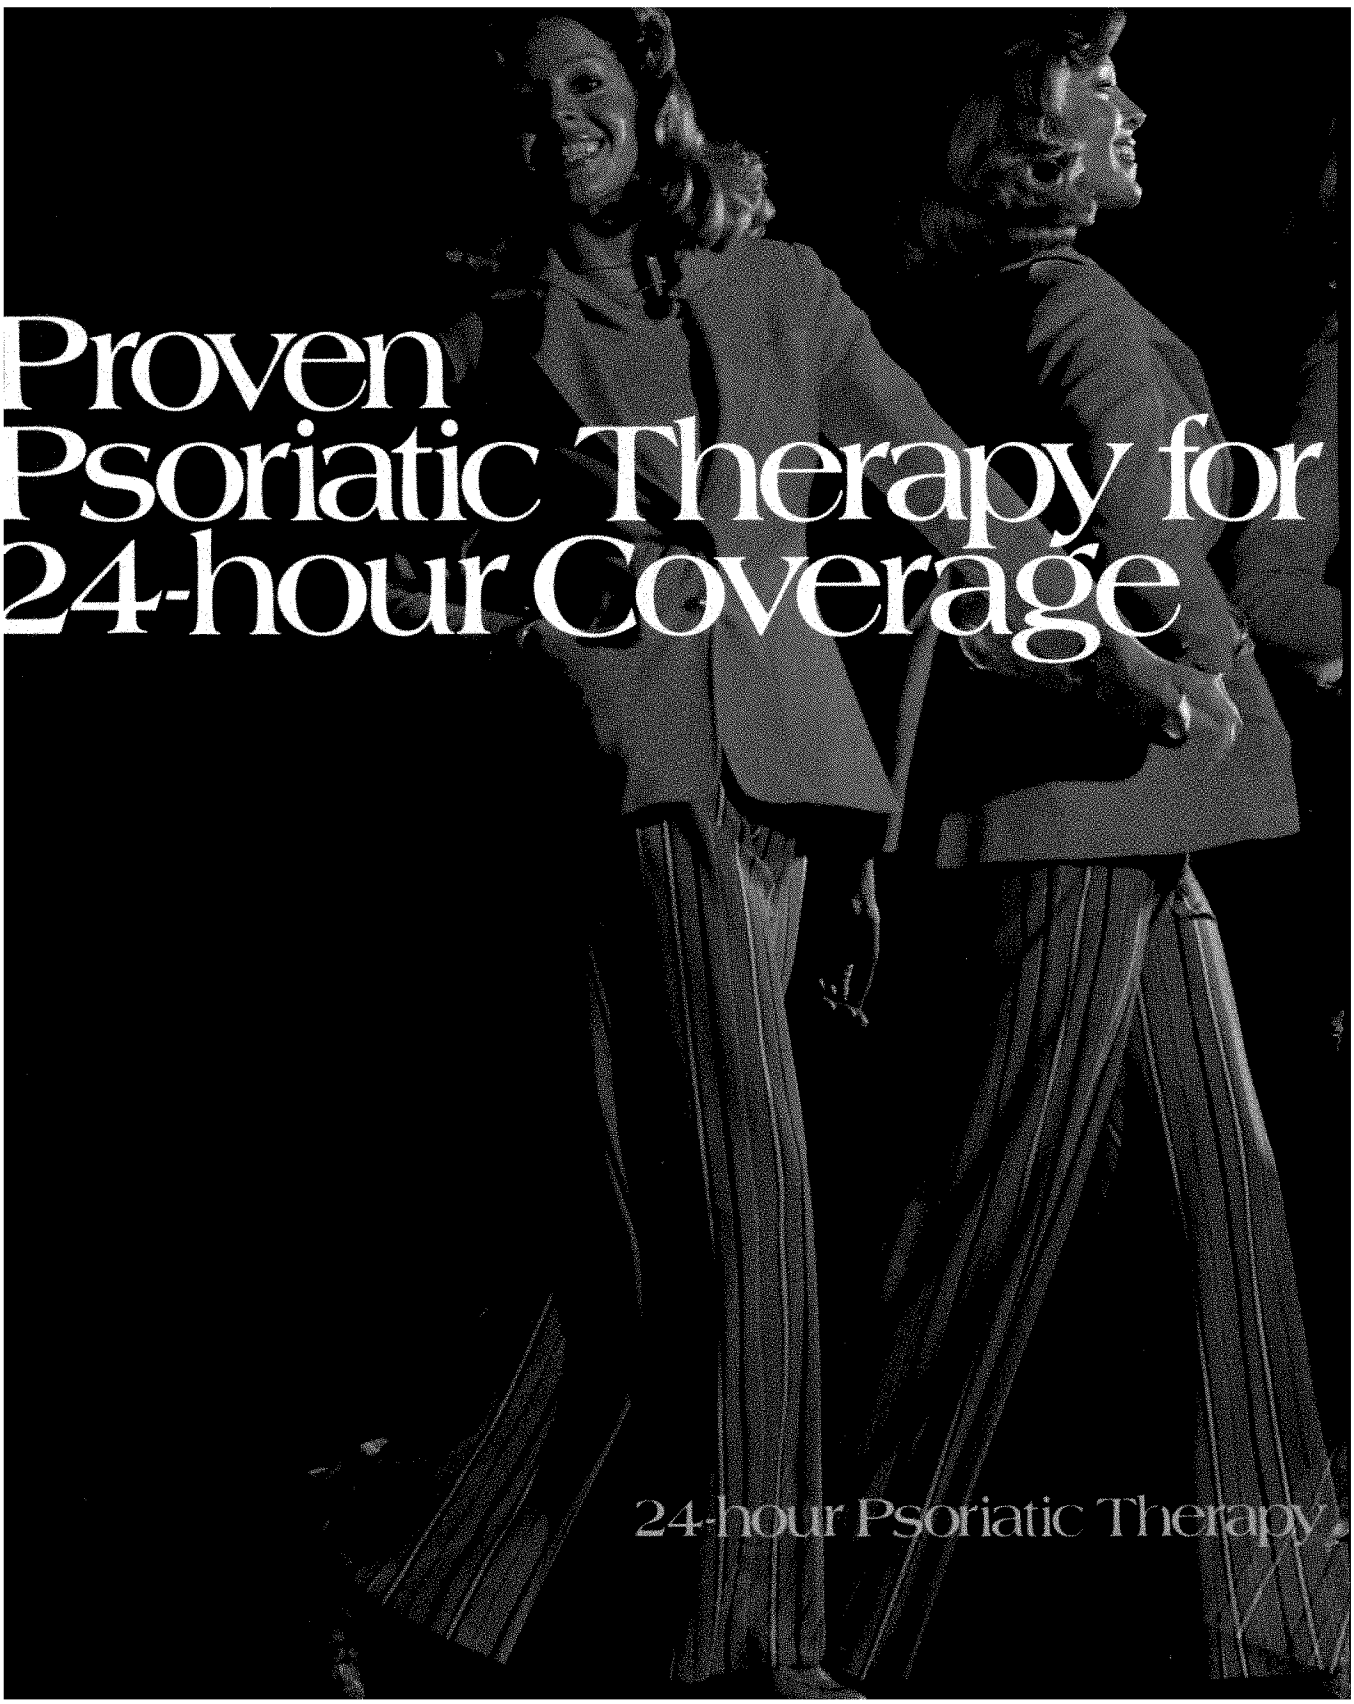
It all adds up to confidence.



Proven
Psoriatic Therapy for
24-hour Coverage
24-hour Psoriatic Therapy

estar™

Therapeutic Tar Gel

Tar odor won't betray **estar** therapy. Proven **estar** Therapeutic Tar Gel is equivalent to 5% crude coal tar in everything but odor. No sticky, greasy residue to remain on the skin . . . proven therapy to control the formation of psoriatic scales and reduce itching with antipruritic action so that scratching is less likely.

The gel base enables the patient to apply **estar** evenly and smoothly. Tar therapy that doesn't smell like it . . . **estar** Therapeutic Tar Gel.

Balnetar®

Water-dispersible Emollient Tar

Change ordinary water into a psoriatic treatment for patients who bathe before bedtime. **Balnetar** can work through the night to provide keratoplastic, antieczematous, and antipruritic action. It lubricates and moisturizes the skin to relieve and help prevent excessive dryness while it softens and aids in the removal of scales and crusts. One to three capfuls of **Balnetar** added to a tub of warm water can extend the effect of **estar** Therapeutic Tar Gel to twenty-four hour tar therapy. The active ingredient in **Balnetar** treats the skin without staining it or the porcelain of the tub.

Sebutone®

Therapeutic Tar Shampoo

When psoriasis finds its way to the scalp, **Sebutone** can penetrate, soften, and remove scales, crusts, and excess oil with its chemically and biologically standarized tar. Microfine particles of tar remain on the scalp for up to three days (as shown with Wood's light) providing prolonged residual action. The fresh, clean fragrance and excellent cleansing properties of **Sebutone** make no other shampoo necessary when treating scalp psoriasis or any stubborn case of seborrhea or dandruff.

estar™
Therapeutic Tar Gel

Composition: Westwood® Tar (biologically equivalent to 5% Coal Tar USP) in hydro-alcoholic gel (29% alcohol).

Actions and Uses: A therapeutic aid in the treatment of psoriasis and other tar responsive dermatoses such as eczema (atopic dermatitis, lichen simplex chronicus, nummular eczema) and seborrheic dermatitis. **estar** is suitable for use in a modified Goeckerman regimen, either in the hospital or on an outpatient basis; it also can be used in follow-up treatment to help maintain remissions.

Contraindications: estar should not be applied to acutely inflamed skin or used by individuals who are known to be sensitive to coal tar.

Dosage and Administration:

Psoriasis:
The patient should massage **estar** into affected areas, once or twice per day or as directed by physician. Rub in well, allow the gel to remain for five minutes, and then remove excess by patting with tissues.

Chronic atopic dermatitis, Lichen simplex chronicus, Nummular eczema, and Seborrheic dermatitis:

One or two applications per day, as described above, are suggested. If dryness occurs, an emollient may be applied one hour after **estar.**

Caution: AFTER USING, PROTECT TREATED AREAS FROM SUNLIGHT UNLESS DIRECTED BY PHYSICIAN. DO NOT USE ON HIGHLY INFLAMED OR BROKEN SKIN. If used on the scalp, temporary discoloration of blond, bleached, or tinted hair may occur. If undue irritation develops or increases, discontinue use and consult physician. AVOID CONTACT WITH EYES. In case of contact, flush eyes with water.

Slight staining of clothing may occur. Standard laundry procedures will usually remove stains.

For complete prescribing information, see PDR

SUPPLIED: 3 oz. plastic tube.

Balnetar®
Water-dispersible Emollient Tar

CONTAINS: WESTWOOD® TAR (Equivalent to 2.5% crude coal tar U.S.P.) mineral oil, and lanolin oil.

Balnetar is an important adjunct in the management of a wide range of dermatoses, including:

Atopic dermatitis
Psoriasis
Chronic eczematoid dermatitis
Eczematoid dermatitis
Seborrheic dermatitis

Suggested for use in modified Goeckerman regimen.

Directions:
Balnetar should always be used with water—either added to water or rubbed into wet skin.

Bath: Add 1 to 3 captuls to a tub of warm water. Do not use soap. Soak for 10 to 20 minutes. Pat dry. Frequency depends on nature and severity of condition.

Direct Application: Pat off excess with tissue or old towel to help minimize staining of clothing or linens.

Scalp Application: Mix 2 to 3 captuls with ¼ cup of water. Rub into scalp with fingertips. Apply once a day, preferably before bedtime. A therapeutic shampoo may be used the following morning.

Contraindication: Not indicated when acute inflammation is present.

CAUTION: If irritation persists, discontinue use and consult physician. In rare instances, temporary discoloration of blond, bleached, or tinted hair may occur. In rare cases, Balnetar may cause allergic irritations attributable to coal tar. Keep out of the reach of children. AVOID CONTACT WITH EYES.

PRECAUTION: After use of Balnetar, avoid exposure to sunlight unless otherwise directed by physician. GUARD AGAINST SLIPPING IN BATHTUB. TO AVOID STAINING, DO NOT USE IN FIBER GLASS BATHTUBS.

SUPPLIED: 8 fl. oz. plastic bottles.

Sebutone®
Therapeutic Tar Shampoo

CONTAINS: WESTWOOD® TAR (equivalent to 0.5% Coal Tar U.S.P.) sulfur 2% and salicylic acid 2% in SEBULYTIC® brand of unique penetrating surface-active combination of soapless cleaners and wetting agents.

CAUTION: If undue skin irritation develops or increases, discontinue use and consult physician. In rare instances, temporary discoloration of blond, bleached, or tinted hair may occur. For external use only. Keep out of the reach of children. AVOID CONTACT WITH EYES. IN CASE OF CONTACT, FLUSH EYES WITH WATER.

SUPPLIED: 4 and 8 oz. bottles and Sebutone Cream in 4 oz. tubes.

Letters to the Editor

Spread of Condyloma Acuminata to Infants and Children

To the Editor.—In their letter to the editor (ARCHIVES 112:1329, 1976), Goldman et al indicate that condyloma acuminata and digital or plantar warts may spread from family member to family member. We have had two occasions in the past year to suspect that young children with perianal condyloma acuminata had been sexually molested by family members who also had condyloma acuminata. Such an investigation might be worthwhile in the cases of Goldman and his associates.

Additionally, the work of Cook et al indicates that the mothers of children with laryngeal papillomas not uncommonly had condyloma acuminata at the time of delivery of their infected children.[1] Boyle and co-workers[2] were able to identify a papovavirus by electron microscopical examination of a laryngeal papilloma obtained from an adult and a papilloma obtained from a child. Boyle et al further commented on the transmissibility of the virus in condyloma acuminata and noted that the child in their study was born to a mother who had genital warts.

Laryngeal papillomas in children can be totally incapaciting and are associated with respiratory distress and frequent recurrences even after the lesions have been surgically removed. The treatment is surgical at the present time, although the immunotherapeutic approach to treatment with autogenous vaccine, as was first suggested by Powell et al[3] for condyloma acuminata, has been extended by Curtis and Ablin.[4] Condyloma acuminata in pregnant women should be treated with enthusiasm; possibly, some obstetricians and gynecologists may consider doing cesarean sections in the instances of women who have very extensive lesions. Perez-Figaredo and Baden[5] have recently mentioned that podophyllum probably should not be used in treating condyloma acuminata on pregnant women because of its known teratogenic effect. These authors, however, do indicate that there is no real evidence linking the topical application of podophyllum to fetal malformations, at the present time.

A prospective study designed to determine the incidence of laryngeal papillomas that occur in children born to mothers who have condyloma acuminata at the time of delivery, coupled with the information about the passage of the papovavirus across the placenta might help mold an approach to treating condyloma acuminata in pregnancy that could prevent the problem of childhood laryngeal papillomas.

FRANCES J. STORRS, MD
Portland, Ore

5. Perez-Figaredo RA, Baden HP: The pharmacology of podophyllum. *Prog Derm* 10:1-4, 1976.

In Reply.—Dr Storrs has made some very important additional points about condylomata acuminata in children. In our discussions with the families of the patients, reported previously and recently, there was no evidence of sexual molestation by adults as far as we could determine.

We have worked with the Department of Otolaryngology of the Medical Center of the University of Cincinnati for more than 15 years on the familial incidence of laryngeal papillomas in children and on the use of autogenous wart extracts for therapy. These extracts are prepared from both small bits of excised laryngeal papillomas and from digital warts of adults and children in the family. We have found digital and plantar warts in the family and the child that were associated with the laryngeal lesions, but we found no such associations with genital warts, like those that Powell et al had reported. As with any therapy for warts without controls,

there is difficulty in evaluating the use of wart extracts for treatment. Because autogenous wart extracts often fail to prevent recurrent laryngeal papillomas, the carbon dioxide laser is now used effectively for treatment.

In cases of warts in the vaginal vault of the pregnant woman, especially when the warts are extensive, our Obstetric Service has done caesarean section. When the warts are not extensive on the labia or in the vault of the pregnant woman, the routine is now the use of the carbon dioxide laser for treatment instead of electrosurgery. Importantly, the current epidemic of condylomata acuminata involves also pregnant women. We will watch for increased incidence of laryngeal papillomas during this epidemic.

Malignant Melanoma in a Thermal Burn Scar

To the Editor.—Last year we reported a case of malignant melanoma that arose in a thermal burn scar.[1] It was alleged by us that this was the first report of such an association in the literature. It was also the first case of an occupationally induced malignant melanoma in a burn scar. The patient was a 47-year-old San Francisco fireman who sustained burns while in the line of duty in 1964. In 1973 a malignant melanoma was excised from burn-scarred skin on the leg. The pigmented lesion was first noted in 1966. (Despite conventional and aggressive surgery and immuno- and chemotherapy, he died on Nov 30, 1975, of metastic disease).

After publication of our previous letter—as is often the case—we came upon an incidental comment about a melanoma that arose in a burn scar, published in 1965.[2] The authors presented 25 primary cancers that arose among 21 patients who were seen during a period of 20 years at Duke University. The breakdown was as follows: 18 squamous cell carcinomas, one basal cell epithelioma, one adenoacanthoma, and one melanoma. In their article, the authors did not elaborate on the latter case, nor was the uniqueness of that patient remarked upon. No details were given.

We corresponded earlier this year with the authors (Drs Pickrell and Gilbin). Unfortunately, none of the original work sheets were available to discuss the background and findings of their one case.

Recently, a monograph on malignant melanoma was published.[3] In the section on "The Relationship of Trauma to Melanoma," the author wrote: "Such a case of melanoma arising in a pigmented scar resulting from burns has been observed at Royal Prince Alfred Hospital." Whether the "burns" were thermal or chemical was not mentioned. Specific details of the case were not presented.

Pruritus in Secondary Syphilis

To the Editor.—The article by Cole et al in the April ARCHIVES (113:489-490, 1977), entitled "Secondary Syphilis Presenting as a Pruritic Dermatosis," reaffirms the teachings of the late and great Dr Simeon Landy, who for decades taught his students that follicular syphilid occurring in black persons was frequently an extremely pruritic disorder. A clinical and serological two-year follow-up of 100 cases of proved secondary syphilis (to be reported in detail shortly) revealed eight patients (all black persons) with moderate to severe pruritus.

The article by Cole et al is but another step in the right direction toward updating the thinking about a disease that is so protean in its manifestations that it boggles the mind, and toward dispelling the antiquated dogmas of the past.

BURTON ALLYN, MD

Photochemotherapy in Erythrodermic Seborrhoic Dermatitis

To the Editor.—Recurrences of erythrodermic seborrhoic dermatitis (SED) have often warranted the use of systemic corticosteroids.[1,2] The difficulties in tapering the corticosteroids, as well as their side effects, are well known.[3]

We report two cases of relapsing SED in long-term corticosteroid therapy, where clearing of the erythroderma and withdrawal of systemic steroids were made possible by concomitant photochemotherapy with psoralens and ultraviolet light A (PUVA).[4,5] A third case of recurrence after cessation of systemic steroid was cleared by photochemotherapy, too. Clinical findings are given in the table.

On this background, we advocate (1) that PUVA therapy is used as a therapeutic cover during withdrawal of systemic corticosteroids in patients

Clinical Findings

Finding	Patient 1	Patient 2	Patient 3
Duration of seborrhoic dermatitis, yr	12	7	3
Duration of systemic steroid therapy, mo	7	45	12
Cumulative dose of steroid, mg	11,392.5	5,383	4,160
Number of relapses after decrease of steroid dose	3	4	2
Duration of treatment with PUVA* (treatment from 0.5 to 3 joule/sq cm), mo.	7	1	2
Number of treatments with PUVA	9	18	32
Cumulative dose of 8-methoxypsoralen, mg	360	720	1,100
Side effects attributed to systemic corticosteroids	Arterial hypertension dyspnea, glucosuria	Cushingoid moon face	Arterial hypertension, elevated blood glucose
Follow-up Without relapse of seborrhoic dermatitis	9	6	...
With relapse of seborrhoic dermatitis	...	...	76. 16/2

*Psoralens plus ultraviolet light A.

with SED who are already receiving this drug and (2) that PUVA therapy is used instead of systemic corticosteroids in cases of SED as a new and better therapeutic alternative.

A Simple Permanent Mount of *Sarcoptes scabiei*

To the Editor.—In the current epidemic of scabies, more extensive efforts are being made to try to demonstrate the parasites. In some dermatological centers, at least in the past, it was required that to make a diagnosis of scabies the parasites had to be demonstrated. Most of the current techniques used for microscopic studies of skin scrapings are usually moist preparations. It is difficult to preserve such preparations for detailed search or for permanent preparations for records or for teaching purposes.

A simple technique for preserving the parasite is to select what you consider the primary fresh lesion. This is scraped gently on a clean slide and immediately sprayed with hair spray such as is done for permanent preparations of Papanicolaou smears. May-Grünwald Giemsa stain may be used after this to help identify the parasites and the ova especially when scanning under low power. A coverslip is applied and the preparation is now a permanent mount. This technique may also be used for canine scabies in dogs for permanent mounts for teaching and collection, although this parasite is easy to demonstrate in dogs. This technique has probably been used before but is not well known.

Permanent hair spray mount of *Sarcoptes scabiei* (May-Grünwald Giemsa stain, original magnification ×200).

Alopecia Areata and Vitiligo Associated With Down's Syndrome

To the Editor.—Nineteen cases of alopecia areata (AA) and four cases of vitiligo were noted in the skin of 214 patients with Down's syndrome. Patients with Down's syndrome are predisposed to immunological deficiency and thymus-dependent (T-cell) function. Drs Carter and Jegasothy suggested that immunological factors might contribute to the increased incidence of AA and vitiligo seen in patients with Down's syndrome.[1] In the May ARCHIVES (113:688, 1977), a marked depression in peripheral blood T-cell values of our patients with AA was compared with the values of 51 controls. The mean percentage of T-lymphocytes in AA was 58.9% compared with the control population of 74.9%. The number of T cells per cubic millimeter was 1,184 in patients with AA compared with the normal control of 1,461/cu mm. The T-cell percentage and T-cell number in AA patients was significantly different from the controls ($P < .001$).

Ninety-seven percent of our patients with AA had depressed (< 70%) T-cell levels in the peripheral blood. The T-cell levels in the peripheral blood in 24 patients with vitiligo were determined by the same method because of the frequent association with AA.[2] The patients ranged in age from 9 to 58 years, with a mean age of 35.9 years. The mean percentage of T-lymphocytes in patients with vitiligo was 55.2% compared with the control of 74.9%. The number of T cells per cubic millimeter in patients with vitiligo was 1,089.5 compared with the 1,460.7/cu mm value for the controls. The T-cell percentage and T-cell number in patients with vitiligo was significantly different from the controls ($P < .05$, and $P < .001$, respectively). Ninety-two percent of our patients (22/24) with vitiligo had depressed (< 70%) T-cell values in the peripheral blood. Two of these patients (11- and 18-year-old females) had Down's syndrome, Hashimoto's thyroiditis, and vitiligo. The 18-year-old patient with Down's syndrome had vitiligo and AA. Her normal brother had AA. Sixteen of our vitiligo patients were female, and eight were male; there were three black patients. There was no apparent relationship between age of the patient, and the number and the percent T cells. Duration of disease did not alter our results. The observation by Carter and Jegasothy[1] of tinea pedis (76.6%) in Down's syndrome is notable, although the identification of the dermatophyte would have been helpful. We have noted tinea corporis from *Trichophyton rubrum* in several patients with AA.[3]

Twenty-two of 24 vitiligo patients were tested for lymphocytotoxicity to our melanoma tumor cell line (M40) with an average percent toxicity of 80.8. The technique used was similar to that of Olkowski et al,[4] except that melanin-containing tissue culture cells were used and were identified as M40, melanoma tumor cell line. The lymphocytotoxicity results from 82 patients with AA against the same melanoma cell line (M40) averaged 71.2%. These percentages are not statistically different from one another.

We agree that the association of AA and vitiligo in Down's syndrome lends support to the proposition that immunological factors contribute to the development of AA and vitiligo. Our studies also indicate a decrease in the number and percentage of T cells in patients with vitiligo and AA. Lymphocytotoxicity tests of 82 AA and 22 vitiligo patients against the same melanoma tumor cell line (M40) were not statistically different.

Weight Loss and Psoriasis

To the Editor.—In reply to Drs Nowlin and Solomon (ARCHIVES 112:1465, 1976), I wish to draw their attention to a report[1] describing the remission of three cases of pustulosis palmaris et plantaris after intestinal shunt surgery for obesity. The relation of pustulosis palmaris et plantaris to psoriasis is still controversial; however, in case 1 the authors describe "previous rubrosquamous lesions on the elbows" that were considered "as probable psoriasis" that coexisted with the obesity and the pustulosis palmaris et plantaris.

An Unusual Contact Photosensitizing Reaction

To the Editor.—The increase in the patch testing of materials and products by companies, individual testing laboratories, and physicians may uncover unusual reactions.

The study of the photosensitizing potential of a yet unmarketed surgical scrub was undertaken. The total product was applied to the back of volunteers as was the vehicle control. Test materials were applied daily for five days (excluding weekends) for two weeks. On Tuesday and Thursday of each week, the patch areas were left uncovered for 30 minutes after application of the test materials. The test sites were exposed then to twice the subjects' minimal erythema dose (MED) using an ultraviolet lamp (Atlas xenon arc). Patches (Parke-Davis Readi-Band Clear Plastic Patches with nonwoven Webril centers) were used.

On Wednesday of week 2 (ten days after starting the test), one subject reacted on every test and control site. Ultraviolet irradiation had been administered 24 hours earlier. After the reactions subsided, 1% isopropyl alcohol and plain tap water were applied under Elastoplast patches and the Readi-Band patches (total of four patches). Isopropyl alcohol was chosen because it was the common ingredient in both of the original test materials. After 30 minutes, the new patch test sites were exposed to 2 MED as before. Twenty-four hours later both Readi-Band sites were 2+ to 3+ positive while the Elastoplast patch test sites were normal.

Prior to the photosensitizing study, this subject participated in a Human Repeat Insult Patch Test study with the same materials and had no reactions through the entire five-week study even though the Readi-Bands were used. No photosensitization studies were done during that test.

Apparently, a photosensitizing ingredient was leached out of the Parke-Davis patches. The specific chemical responsible for the photosensitization was not isolated.

Immunofluorescence Findings in Juvenile Bullous Disease

To the Editor.—We read with interest the case of Prystowsky and Gilliam (ARCHIVES 112:837-838, 1976) and their finding of a linear band of IgA and C3 immunofluorescence (IF) along the basement membrane. We have reported a similar case[1] that corresponds clinically to the IF negative benign chronic bullous disease of childhood.[2] For two years, a 6-year-old girl had recurrent crops of large, tense, nonitchy bullae predominantly about the mouth and vulva that were of decreasing severity. The condition responded only partially to acediasulfon sodium (sulfon) therapy. We found on direct IF of peribullous and normal skin "continous" IgA but not C3 along the basement membrane as described in some cases of adult dermatitis herpetiformis.[3] No circulating basement membrane or reticulin antibody was detected. A jejunal biopsy specimen did not show evidence of coeliac disease as found in true dermatitis herpetiformis.[4] It has been suggested[5] that serial sections of repeated biopsy specimens of juvenile bullous disease will always show IF. This may be so, but there would seem to be some cases in which clinical and IF findings do not match those of adult bullous diseases. Therefore, bullous disorders of childhood have yet to be completely characterized.

More recently, the finding of Esterly et al (ARCHIVES 113:42-46, 1977) of linear IgA at the basement membrane zone on direct IF in one of two cases of benign chronic bullous dermatosis of childhood would support a contention that this IF finding may be a characteristic feature of the condition.

Pain With Synoviomas

To the Editor.—Ever since Kersting and Helwig[1] noted pain caused by eccrine spiradenomas, the association has been firmly established for certain nonneural lesions. For neural lesions, the solitary glomus tumor had long earned a reputation for exquisite pain. Three painful subcutaneous neurolemomas in a patient with neurofibromatosis,[2] the traumatic neuroma arising in instances of disorganized nerve repair,[3] and examples of Morton's neuroma[4] further emphasize this symptom association with nerve lesions. During the past 50 years, data have been accumulating suggesting the surprising contention that synovial sarcomas may have a place in the spectrum of nerve tumors. Although a little less than half of these cancers are painful, 18.3% have pain before emergence of other signs and symptoms,[5] indicating that the tissue giving rise to the cancer must be in especially close proximity to the nerves. Gross continuity with nerves, histologic documentation of unmyelinated nerves in the smallest and, therefore, the earliest stage of the cancer reported,[6] calcium deposits, and interstitial mucin possibly related to psammoma bodies of neural coverings and to mucin of neurofibromas are supportive of this contention. The mucin has staining characteristics of hyaluronic acid.[7,8] The relation between synoviomas and the neural system may be more than coincidental and seems to be weighing against the current belief of the synovial lining relation of the tumor.

Regardless of its histogenesis, the fact that a substantial number of synovial sarcomas cause sustained pain or tenderness in an area of skin that is clinically normal is important for the recognition of this cancer in its pretumor phase. Even though most of the lesions are periarticular in location and would more likely be seen by the orthopedic surgeon, the occasional synovial sarcoma found in the panniculus of the abdominal wall, the finger, or the fascia just deep to the subcutis in the anterior upper thigh are of immediate interest to the

dermatologist. Unexplained pain sustained for more than six weeks should encourage a biopsy inclusive of subcutis, superficial fascia, and a small stratum of underlying muscle. Since this pretumor phase of pain has a lengthy average duration of 4.7 years,[6] the tendency to delay biopsy is not only understandable but permits some leeway in timing the biopsy. The timing should be tempered with caution for another reason. In this particular group of synovial sarcomas, physician culpability has already resulted in a measurable reduction of the survival rate,[2] clearly of adverse legal interest. Nevertheless, the detection and eradication of the cancer by local excision in the pretumor stage has a reasonable prospect of a 100% cure rate as contrasted to the current five-year cure rate of 50% after more radical surgery for the usually encountered larger lesions.

Cutaneous Reaction to Chlorambucil

To the Editor.—Chlorambucil is an oral alkylating agent that has been used since early 1950, particularly for the treatment of chronic lymphatic leukemia. The side effects are gastrointestinal symptoms, such as nausea and vomiting, and bone marrow depression. Allergic skin reactions are extremely rare.

This report refers to a patient with chronic lymphatic leukemia in whom a rash was produced when repeatedly challenged with a small dose of chlorambucil. The common features of the known three cases of skin reaction to chlorambucil are described.

Report of a Case.—A 69-year-old man had breathlessness on exertion and on examination was found to have a firm liver, just palpable, and an enlarged spleen extending to the left iliac fossa. There was no lymphadenopathy. The results of the investigations done at the time of admission were as follows: hemoglobin level, 78%, 11.0 gm/100 ml; WBC count, 36,000/cu mm, 88% of which were lymphocytes, platelet count, 86,000/cu mm; ESR 12 mm/hr. Bone marrow examination showed infiltration of the marrow with large numbers of mature lymphocytes consistent with a diagnosis of chronic lymphatic leukemia. He was followed up at regular intervals with no specific therapy. After a retinal hemorrhage, he was treated with 12 mg of chlorambucil daily, allopurinol 50 mg twice a day, and prednisolone 20 mg on alternate days. After eight days, an intense generalized urticarial erythema developed on the trunk, limbs, and face. There was considerable periorbital edema. All drug therapies were discontinued except for prednisolone therapy. The rash cleared within seven days. Chlorambucil and allopurinol therapies were restarted, but a similar eruption appeared within two days, including severe periorbital edema.

Although his clinical condition remained satisfactory with no treatment, within five months his WBC count rose to 70,000/cu mm and severe pressure symptoms developed on the bladder because of the enlarged spleen. Again within two days of restarting chlorambucil therapy, 6 mg daily, the eruption developed. To confirm that the reaction was caused by the chlorambucil and not by any other compound in the tablet or by any other medication, he was admitted to hospital for a challenge dose of purified chlorambucil. All other medication was discontinued and his informed consent was obtained. After a 4-mg dose of purified chlorambucil, the acute periorbital edema reappeared with a widespread urticarial erythema on the trunk that spread within 24 hours to the limbs. There was a curious pustular eruption on the mouth and chin that spread to the cheeks. These follicular lesions had no surrounding area of erythema. This faded within three days. A swab taken from these pustular lesions was sterile, with no organisms evident on Gram stain. A skin biopsy specimen from the trunk showed increased vascularity with moderate chronic inflammatory cell infiltrate around the blood vessels. The inflammatory infiltrate contained some pleomorphic cells suggestive of leukemic cells. Direct immunofluorescence of the skin was negative. The skin sensitivity was examined by patch, scratch, and intradermal tests. Patch tests to 0.01%, 0.1%, and 1% chlorambucil in soft paraffin were negative after 48, 72, and 96 hours. Scratch and intradermal tests were performed to chlorambucil in concentrations of 10^{-5}, 10^{-6}, and 10^{-4} mg/ml. These were also negative.

Comment.—Despite the widespread use of chlorambucil, rashes caused by its administration are so uncommon that only one case has been reported[1] and one other recent case was related to us by W. D. Brenckman, Jr (personal communication, 1975).

The remarkable feature of these three cases is the consistency of the clinical appearance. The rash occurred early in the therapy. The widespread urticated erythema with marked periorbital edema was a feature in all of the cases. Resolution occurred within ten days of discontinuance of the drug therapy. The patients in these cases showed an increasingly severe response after repeated challenge, and no drug tolerance was noted. The delay between taking the drug and the appearance of the eruption became shorter and the extent of the eruption became wider. The pustular eruption on the chin and cheeks in this patient was not seen in the other cases but has been reported with other drugs.[2] The patient was tested to purified chlorambucil, as it was possible that some other compound in the chlorambucil tablet, such as azo dye[3] was causing the reaction. The results of skin testing gave no indication as to the mechanism of the sensitivity reaction in our patient although it most probably is via a hapten. Interestingly, Knisley et al[1] concluded that their patient had a delayed-type hypersensitivity on the basis of late positive patch and scratch tests to pure chlorambucil. The absence of fever, arthralgia, and vasculitic lesions tends to exclude an Arthus phenomenon. Direct immunofluorescence of the skin did not show deposition of immunoglobulin, complement, or fibrin.

Although cutaneous reactions to chlorambucil seem to be extremely rare, the reported cases do show a consistent clinical picture. This may be a useful guide for patients taking chlorambucil in whom a drug eruption develops.

Herpes Gestationis

To the Editor.—In reference to the article by Dr Hertz et al on herpes gestationis (ARCHIVES 112:1543-1548, 1976), a broad differential diagnosis was considered. In our experience, the clinical and histological pattern described would not distinguish herpes gestationis from a bullous drug eruption. In the absence of immunologic studies, that distinction seems to me to be difficult, if not impossible. I would appreciate if the authors would elaborate on the distinctive features that they might have found helpful separating drug eruption from herpes gestationis and why they did not include it in their differential diagnosis.

KURT S. STENN, MD
New Haven, Conn

In Reply.—Reactions to drugs may clinically simulate almost every dermatitis and may elicit histological patterns similar to that of almost every inflammatory reaction in the skin. Among the most common are the lichenoid, acneiform, and urticarial. Furthermore, drugs are among the most common causes of bullous dermatitides, such as erythema multiforme and toxic epidermal necrolysis, and of allergic vasculitis. The fixed drug eruption is evoked by drugs.

In our experience, however, a drug has yet to provoke histological changes such as those of herpes gestationis and for that reason that condition was not included among our differential diagnoses. Oral contraceptives, however, may exacerbate herpes gestationis as in case 1. We think that, apart from bullous pemphigoid, the histological features of herpes gestationis are rather specific and not imitated by any drug eruption.

Cutaneous Leishmaniasis: Inefficacity of Treatment With Metronidazole

To the Editor.—It was with great interest that we read the recent reports about successful treatment of cutaneous leishmaniasis with orally administered metronidazole.[1,2] Cutaneous leishmaniasis is endemic in our region of the world and any simple and safe form of therapy that is rapidly effective and easily administered would be of considerable value. We, therefore, decided to try this medication on some of our patients. Six consecutive patients were given oral metronidazole according to the schedule suggested by Long.[1] Three of the patients had nodular lesions, two had nodular-ulcerative lesions, and in one patient, the lesions were papular. The duration of the lesions was two months in three cases, three months in two cases, and six months in one case. The diagnosis was confirmed in all cases by positive smears and cultures. No clinical improvement was observed in any one of the patients at the end of treatment, and in one case the lesion grew larger and two small satellite lesions appeared during metronidazole therapy. Repeated smears and cultures were taken in five of the patients after the third course of the medication and in all of them they were still positive.

The lack of accordance between the results obtained in our patients and those obtained by previous authors[1-3] could be explained by possibly different sensitivities of different species or even different strains of the parasite to metronidazole. The cases of Beltran et al[3] and Long[1] were acquired in Mexico and Panama, respectively, whereas the case of Pedersen and Sawicki[2] was acquired in Afghanistan. In the later case, the duration of the lesions before initiation of therapy was seven months. It is a well-known fact that the process of spontaneous healing, which usually occurs in early leishmaniasis, begins after six months from onset.[4] Thus, the resolution of the lesions in that case could be part of the natural course of the disease and must not be obligatorily attributed to the therapeutic effect of metronidazole.

Although our experience is limited to a small number of patients, we believe that metronidazole therapy is ineffective in cutaneous leishmaniasis of Middle Eastern origin.

The Presence of Benzocaine in Sunscreens Containing Glyceryl PABA (Escalol 106)

To the Editor.—Escalol 106 (glyceryl para-aminobenzoate) has long been used in the United States in sunburn preventative preparations. In 1949, Meltzer and Baer[1] described a patient with allergic sensitization to monoglyceryl para-aminobenzoate (glyceryl PABA) from its presence in a sunscreen. This patient showed a considerable reaction to benzocaine. Similarly, in 1951, Curtis and Crawford[2] described a patient who in addition to an allergic reaction to a sunscreen that resulted from the presence of glyceryl PABA also exhibited a strong reaction to benzocaine.

Recently, I[3] reported four cases of allergic sensitivity to glyceryl PABA in sunscreens, in all of which similar strongly positive patch test reactions to benzocaine were seen.

It is not surprising that benzocaine (ethyl aminobenzoate) and glyceryl PABA, which are both chemically related esters of para-aminobenzoic acid should show cross-reactions. However, it was thought that the phenomenon of "cross-reactions" did not entirely explain why in every single reported instance of allergic hypersensitivity to glyceryl PABA in a sunscreen, there was an equally strongly positive reaction to benzocaine. It has been my experience that cross-reaction patterns are usually not so exactly uniform.

It was suspected that in the manufacture of Escalol 106 from para-aminobenzoic acid, benzocaine is inadvertently formed. Chemical analysis has revealed that this indeed proved to be the situation. Escalol 106 (glyceryl PABA) itself, and all of the sunscreens containing Escalol 106 were shown to contain "free benzocaine" in varying amounts, from 18% to 1%.

The following sunscreens, listed as containing glyceryl PABA (Escalol 106) must thus be avoided by benzocaine-sensitive individuals: Eclipse (which also contains octyl dimethyl PABA), Expose Suntan Liquid, Negasol, Sea & Ski Dark Tanning Lotion, Sea & Ski Suntan Lotion, Tanfastic Dark Tanning Lotion, and Tanfastic Suntan Lotion with Cocoa Butter.

Padimate A (Escalol 506 [amyl paradimethyl PABA]) and padimate O (Escalol 507 [octyl dimethyl PABA]) did not cross-react with either Escalol 106 or benzocaine in my four patients. On chemical analysis, padimate A and padimate O proved to be free of

benzocaine.

In addition, it should be noted that glyceryl PABA and benzocaine may show cross-reactions with such "para" compounds as para-aminobenzoic acid, para-amino salicylic acid, paraphenylenediamine anilin, procaine, sulfaguanidine, sulfanilamide, and saccharin.

Frequency of Skin Lesions in Chronic Drinkers

To the Editor.—I read Dr J. Margolis's letter on "Frequency of Skin Lesions in Chronic Drinkers" in the ARCHIVES (112:1326-1327, 1976) and was surprised to see that he was unable to find any reference in medical literature. In 1971, I published with Mr G. Oki, a paper on "Skin Diseases in Alcoholics" in the *Quarterly Journal of Studies in Alcohol* (32:1017-1024). The purpose of this study was to assess the prevalence of skin diseases in a population of alcoholics and to compare our findings with those reported by other investigators.

A total of 355 patients (307 men and 48 women) were admitted to the inpatient unit of a public hospital for the treatment of alcoholism during a period of two years. Nearly all were examined by a dermatologist within two to three days after admission; a few within a week. In addition to a complete physical examination, information was obtained on the history of previous skin diseases and their behavior during periods of heavy drinking.

As could be expected in such a fairly large group, a wide range of skin conditions was encountered; 44% of the men had one or more skin conditions compared to 33.3% of the women. A total of 34 different entities was found, most of them probably of little clinical importance or statistical significance. The following common dermatoses had an incidence of 1% or more: acne rosacea, 5.6%; acne vulgaris, 1.7%; black hairy tongue, 1.1%; dermatophytosis, 3.7%; eczema, dyshidrotic, 2.3%; eczema, intertriginous, 2.0%; leukoplakia, 1.7%; neurodermatitis, 2.5%; psoriasis, 3.4%; seborrhea capitis, 10.1%; and seborrheic dermatitis, 7.3%.

It was my belief that only a few entities showed an incidence higher than that of a normal population: acne rosacea, leukoplakia, black hairy tongue, and seborrheic dermatitis. Five of the patients with psoriasis volunteered information that their condition was aggravated by heavy drinking. Unfortunately, we were unable to compare the incidence of these conditions with that in the normal population since no data are available regarding the incidence of common dermatoses except for a few entities. No definite pattern of behavior could be established. Some patients volunteered information that their eruption was aggravated by heavy drinking. Others were unable to correlate the course of the disease with alcohol intake.

Toronto

'Stockbroker's Knee'

To the Editor.—A stockbroker appeared at my office with a chief complaint of hypesthesia in a palm-sized area over the left suprapatellar area of several months' duration. Another physician had ordered roentgenograms of the lumbar spine, which were normal. Physical examination showed hypesthesia and obvious hair loss over the involved area.

Careful questioning revealed that the telephone in his office was so placed that reaching for it necessitated turning his body more than 90° to the right. This motion was always accompanied by scraping the anterior surface of his left lower thigh (the affected area) against the kneehole of the desk.

In a follow-up visit, he reported that in discussing his now famous knee with his office colleagues, another stockbroker with the same telephone-desk configuration came forward with an almost identical complaint of hypesthesia in the left suprapatellar area.

Perhaps an appropriate diagnosis in these two cases would be "stockbroker's knee."

DANIEL S. J. CHOY, MD

Bone Involvement in Early Syphilis

To the Editor.—In their article "Hepatitis and Bone Destruction as Uncommon Manifestations of Early Syphilis: Report of a Case" (ARCHIVES 112:1451-1454, 1976), Drs Longstreth, Hoke, and McElroy reported uncommon manifestations of early syphilis with hepatitis and bone destruction. As they mentioned, many cases of this type presumably go unrecognized.

At the end of the primary stage, most of the treponemas leave the blood stream and invade the tissues. This intrusion of *Treponema pallidum* into the tissues of the body leads to the development of the generalized lesions that are called secondary syphilis. In the secondary eruptions on skin and mucous membranes, *T pallidum* can be demonstrated in very great numbers. Probably all tissues of the body are invaded but not all react by demonstrable changes.

The patient often complains of the following commonly named constitutional symptoms of a rather nonspecific character: general tiredness, headache, low grade fever, pains of joints and muscles that are usually most pronounced at night, hoarseness, moderate anemia, enlargement of the spleen, and a slight albuminuria. The headache is often followed by early syphilitic meningitis with increased intracranial pressure and pleocytosis. Hepatitis with jaundice and periostitis with "ostecopic pains" may also appear. Even the changes of the aorta probably start very early but do not, as a rule, manifest themselves clinically for ten to 20 years.

If one carefully examined all organs in patients with secondary syphilis and constitutional symptoms, in many cases one would, without a doubt, be able to demonstrate syphilitic changes in biopsy specimens and occasionally also *T pallidum*, as it has been shown for instance in the liver and the eye. However, we usually do not do this because these patients are seen on an outpatient basis, and, from an epidemiological point of view, we must treat the patient at once. Furthermore, it is an old clinical experience that all symptoms disappear after a few injections with penicillin or another antitreponemal drug.

This universal infection is, however, much more pronounced in early congenital syphilis. During my stay in Uganda from 1969 to 1973, as head of the Department of Dermatology at Mulago Hospital, we diagnosed 30 to 40 cases of early congenital syphilis each year. Beside the mucocutaneous

symptoms, the many cases with osteochondritis, with or without pseudoparalysis, were very impressive. Symptoms of ostitis or osteochondritis were so common that the paramedical staff in the general outpatient clinic also learned to refer infants only with osteogenic symptoms to the venereal disease clinic.

During the last six to seven months of my stay in Uganda, we made full skeletal roentgenographic examinations (except the skull) of all infants with early congenital syphilis. Among approximately 25 children, we found many with bone changes, and these changes were much more extensive and widespread than suggested from the clinical examination.

When I left Uganda for reasons outside my control, I was not able to take with me the records and the x-ray films of these cases. Therefore, I am unfortunately not able to present documentation for our findings.

PROF GUNNAR LOMHOLT

Biting Insect Summary

To the Editor.—Again this year I am compiling a biting insect summary and would appreciate any case reports of unusual allergic reactions, especially systemic (sneezing, wheezing, urticaria), to bites of insects, ie, mosquitoes, fleas, gnats, kissing bugs, bedbugs, chiggers, black flies, horseflies, sandflies, deerflies, etc. I would like physicians to supply me with case reports of those patients who have had unusual reactions to such insects. Include in your reports the type of reactions (immediate and delayed symptoms), treatment, the age, sex, and race of the patient, the site of the bite(s), the season of the year, and any other associated allergies. If skin tests and hyposensitization were instituted, I would like the report of both. Please note that it is the biting (not stinging) insect in which I am interested.

If you have found any insect repellent, local treatment, or insecticides of value, I would also appreciate this information.

Please send your information to 4-C Doctors Park, Asheville, NC 28801.

Atopic Dermatitis Reactions to Methacholine

To the Editor.—In the May ARCHIVES, Uehara and Ofuji presented an evaluation of the abnormal vascular reactions in atopic dermatitis (113:627-629, 1977). In their discussion of the methacholine reaction, they stated that all of their patients showed normal reactions to methacholine when the tests were performed on normal skin.

I believe that this is misleading, since the test was performed with the use of a topical application of methacholine rather than with the intradermal injection that represents the standardized methacholine test.

In a study of IgE levels in atopic dermatitis (*Arch Dermatol* 108:806-811, 1973), 58 patients with a diagnosis of atopic dermatitis received a methacholine test administered in the standard fashion: 0.1 ml of methacholine chloride diluted 1:1,000 in isotonic saline solution applied to an *uninvolved* area of the back, if such an area was to be found. In 78% of the cases, a moderate to strongly positive delayed blanch reaction was found.

The disparity between these findings and the findings of Uehara and Ofuji may be attributable to the failure of methacholine, when applied to normal skin, to penetrate the stratum corneum and get to the small blood vessels. This would also explain the fact that the reaction does occur when the material is applied to eczematized or lichenified skin. Their findings do not, however, challenge the theory that the abnormality in vascular responsiveness is present throughout the atopic skin, and may simply be explained by failure of penetration of the drug when topically applied.

Azaribine, Homocystinemia, and Thrombosis

To the Editor.—Although azaribine has been shown to be an effective drug in the treatment of psoriasis, the Food and Drug Administration has recently prohibited the use of this antimetabolite because of the possibility of an associated increased incidence of thromboembolism. We present a hypothesis and some preliminary supporting data that may explain this adverse effect.

In 1969, high dosages of azaribine (400 mg/kg/day) were shown to result in the urinary excretion of various amino acids, including homocystine.[1,2] Until recently, this appeared to be a mere biochemical curiosity. However, with the report of vascular complications in patients who were on a regimen of azaribine, similar to those complications found in patients with hereditary homocystinuria, we screened our patients who were receiving azaribine for the presence of homocystine in the blood and the urine. As homocystine is normally not present in either the blood or the urine, detectable levels are considered abnormal.

Urine specimens were immediately refrigerated or frozen without preservative, and subsequently analyzed for amino acids by ion-exchange column chromatography. Plasma determinations of amino acids were performed on heparinized blood samples, which had been deproteinized immediately and frozen until they were analyzed.

Twenty-nine psoriatic patients were screened. None of these patients had a history of phlebitis, thromboembolism, cardiac disease, or diabetes. Thirteen of the patients were on a regimen of azaribine in dosages ranging from 100 to 175 mg/kg/day. The remaining sixteen control psoriatic patients had never received azaribine.

None of the sixteen control patients developed homocystinuria or vascular problems. Five of the thirteen patients receiving azaribine developed homocystinuria and homocystinemia. Of these patients, one developed a thrombotic episode. Following the appearance of homocystine in the blood and urine, this patient developed thrombophlebitis of the right calf. When treatment with azaribine was discontinued, the patient's homocystinemia disappeared, and the thrombosis resolved. Upon readministration, homocystinemia reappeared. The remaining eight patients who were treated with azaribine and did not develop homocystinemia failed to suffer any thrombotic complications.

Laboratory work supports a pathogenic role for abnormal levels of homocystine in the development of vascular disease. One investigator showed disruption of the vascular endothelium in baboons following infusion of homocystine, with subsequent development of platelet thrombi and arterial and venous occlusion.[3] These laboratory findings and the clinical observations of patients with hereditary homocystinuria suggest that elevation of plasma homocystine may cause thrombotic disease. Therefore, possibly the thrombotic vascular disease that is seen with azaribine occurs only in those patients who develop homocystinemia.

Until more information is available, urinary screening for homocystine

should be performed in all patients who are receiving azaribine. This procedure may identify those patients who are at risk of developing a thrombosis.

Melanoma Treatment With Phenolic or Catecholic Compounds

To the Editor.—In a recent ARCHIVES editorial (113:421, 1977), Lerner and Nordlund suggested that selected cases of melanoma be treated with phenolic or catecholic compounds after resection of the primary tumor. The inference was that such a program would improve survival of patients with melanoma.

I have also been interested in this same question, and I attempted to answer it with the use of the Fortner melanotic melanoma No. 1 hamster series. I selected for study four highly active depigmenting agents—one each from the hydroquinones, the mercaptoethylamines, the catechols, and the parasubstituted phenols. These compounds were injected intralesionally into small tumor papules five days a week for four weeks. No inhibition in tumor growth or in survival was obtained.[1] Frenk and Ott had a similar result in their experiments.[2] These data do not support the concept that depigmenting compounds may be useful in the treatment of malignant melanoma.

Minocycline and Thyroid Function

To the Editor.—I wish to call attention to an article from the *British Journal Medical* that was abstracted in the February 14 issue of the *Journal of the American Medical Association* (237:705, 1977):

A black thyroid has not been reported in man, but has been found in monkeys, dogs, and rats during trials with minocycline. A uniformly black thyroid was found in a 69-year-old man who died in respiratory failure from bronchiectasis and emphysema.... The monofluorescent pigmentation of the thyroid is attributed to the specific concentration of minocycline in the thyroid and increased lipofuscin deposition. Because previous experimental studies with minocycline have demonstrated an antithyroid effect, patients receiving prolonged minocycline therapy should have their thyroid function monitored.

Do those of us who prescribe minocycline for acne now need to monitor thyroid function?

Zinc Sulfate and Axillary Perspiration Odor

To the Editor.—Because of the recent interest in the use of zinc for the treatment of acrodermatitis enteropathica and acne, I would like to report still another possible indication for the use of this agent.

About two years ago, I saw a patient who was being given 220 mg of oral zinc sulfate (equivalent to 50 mg of elemental zinc) three times daily by his surgeon as part of the management of recurrent leg ulcers. This observant gentleman noted that while he was taking zinc there was a marked reduction in axillary perspiration odor. This problem, which had been most distressing to him for most of his adult life, returned within days after the zinc was discontinued. When he again started taking the capsules, the odor again markedly diminished (confirmed by his wife).

Based on this observation, I have given zinc sulfate to five other persons, with uniformly good results. Most responded to daily doses as low as 20 mg of elemental zinc. All had tried a wide variety of deodorants and antiperspirants without success. This report is submitted in hope of helping other unfortunate persons who suffer from socially incapacitating perspiration odor.

Isolated Familial Benign Chronic Pemphigus

To the Editor.—Familial benign chronic pemphigus (FBCP), or Hailey-Hailey disease, is a rare hereditary disorder that is characterized by recurrent vesicles and bullae in the intertriginous areas, such as the axillae and groin. The eruption is rarely confined to one area of the body.

Report of a Case.—A 29-year-old woman was examined in November 1975 for pruritus vulvae of seven months' duration. Numerous small, flat, white papules and thickened lichenified skin were found on the vulvar surface. A skin biopsy specimen of a papule showed suprabasilar clefts, villi, and acantholytic epidermal cells characteristic of FBCP. The results of the rest of the skin examination were noncontributory. Fungal and yeast cultures grew no organisms, and pelvic and breast examination results were normal. There was no family history of recurrent bullous disease. The FBCP has not responded to steroid creams, antimonilial creams and suppositories, antifungal creams, steroid antibiotic combination cream, sulfa cream, vinegar douches, or oral wide-spectrum antibiotics.

Comment.—In most patients with FBCP, the disease is found in several areas and is found only rarely in one site, such as in the case presented. Cooper reported a 21-year-old man with the disease localized to the perianal skin.[1] Lyles and associates reported a 22-year-old woman whose disease appeared during pregnancy and was localized to the vulva.[2] The eruption disappeared after successful treatment of postpartum leukorrhea.

Transient Bullous Eruption

To the Editor.—We have also seen a patient with a transient bullous eruption similar to the three cases reported in the ARCHIVES by Waisman et al (112:1440-1441, 1976).

Report of a Case.—An 89-year-old man with senile dementia had a two-week history of pruritic bullae and erosions that commenced on his hands and gradually spread to involve his trunk and limbs. There were no known precipitating causes. Biopsy specimen showed a subcorneal vesicle containing some acantholytic cells. Direct

and indirect immunofluorescence were negative. The lesions resolved within six weeks with the use of only topical corticosteroids. He has been symptom-free for 18 months.

Comment.—We would prefer to emphasize the subcorneal level of vesiculation and the close clinical and pathological similarities to pemphigus foliaceus in any title used for this condition rather than regard it as a bullous variant of Grover's disease. We have seen a similar solitary subcorneal lesion occurring as an incidental finding in the skin of a mastectomy specimen. Perhaps there is a whole spectrum of subcorneal as well as suprabasal acantholytic dermatoses.

Propranolol Therapy

To the Editor.—Alopecia has been caused by a number of medications, especially antineoplastic agents, anticoagulants, and certain hormones. I had occasion to see a woman in whom alopecia developed while taking propranolol hydrochloride. Since this drug is in widespread use for the treatment of cardiac disorders and hypertension, this case is presented to alert other physicians to this interesting and unusual side effect.

The patient is a 55-year-old woman. On Sept 5, 1976, she was started on a course of propranolol hydrochloride 30 mg daily because of atrial fibrillation. Approximately three weeks later, she noted hair loss that progressively became more profuse. Her only other medication was conjugated estrogens that she had taken for six years. She denied exposure to toxic chemicals of any kind. Examination on Dec 10, 1976, revealed diffuse patchy alopecia of the scalp. The eyebrows, axillary hair, pubic hair, and nails appeared normal. Numerous hairs could be plucked easily from the scalp with gentle traction by the fingers. The serum iron and thyroid profile were within normal limits, and the VDRL test was negative. Propranolol therapy was discontinued on Dec 10, 1976, and one month later the hair loss had essentially ceased. The patient refused rechallenge with the drug.

Pilomatricoma

To the Editor.—"Pilomatrixoma" is just as incorrect as "appendixitis" would be, and for just the same reason, the root ends in "c", not "x". Drs Gregg and Cannon (ARCHIVES 113:232) had the example of at least one of their three references before them, but were not warned.

Perhaps it would be a good idea to have someone edit LETTERS TO THE EDITOR, for the protection of the contributors thereto and of the reputation of American physicians for writing correctly.

HARRY L. ARNOLD, JR, MD
Honolulu

In Reply.—Thank you for forwarding Dr Arnold's letter regarding the spelling of pilomatricoma. We were aware at the time of submitting our LETTER TO THE EDITOR of the correct spelling of pilomatricoma; however, because of current usage and the appearance of the word pilomatrixoma in all of the current text, we elected to perpetuate an unfortunate error. Certainly Dr Arnold is entirely correct in his spelling of the calcifying epithelioma of Malherbe.

Thanks again to Dr Arnold for again reminding us of this repeated error.

Suggested Sequence of Testing for Acne Patients Receiving Long-Term Tetracycline Therapy

To the Editor.—After completion of my study on the safety of long-term tetracycline therapy for acne (*Arch Dermatol* 112:1603-1605, 1976), it seemed to me that physicians would appreciate some suggestions concerning blood testing for acne patients who are receiving long-term tetracycline therapy. The following sequence for testing is suggested, but this is not meant to be restrictive.

First, take a good history from your patient. If the patient relates unusual medical problems, take appropriate tests including a complete blood cell count (CBC) and blood chemistry studies using an automated 12-factor analysis system. Next, if the patient has been receiving long-term antibiotic therapy for one year or longer, previous to your first visit, get a 12-factor blood chemistry analysis test and a CBC. Third, if you institute antibiotic therapy, give the patient an information sheet stating in a few words the mild nonserious side effects and the fact that there appear to be no serious side effects in the great majority of patients treated with long-term tetracycline therapy. Inform the patient also that tetracycline should not be taken during pregnancy. Fourth, after two years of continuous tetracycline therapy get a 12-factor blood chemistry analysis test and a CBC. Repeat these tests at two-year intervals if the patient remains on continued therapy. Finally, do not give unlimited refills on antibiotic prescriptions. For instance, if the patient is taking 500 mg of tetracycline hydrochloride a day, then an original prescription for 100 capsules and two refills could be given to the patient.

Elastosis Perforans Serpiginosa Associated With Penicillamine

To the Editor.—The May ARCHIVES (113:630-635, 1977) contains an interesting report of a case of elastosis perforans serpiginosa (EPS) induced by penicillamine. Although there have now been a number of reports of patients with EPS who have received penicillamine therapy for Wilson's disease, it is still unclear as to whether it is the drug alone that is responsible for the eruption (or perhaps some underlying predisposition in patients with Wilson's disease to effects of penicillamine).

For the past few months I have been following up on the case of an individual with EPS who has extensive involvement of neck, arms, and thighs and who had been receiving penicillamine for nine years for cystinuria. This additional case of EPS associated with penicillamine therapy may add to the evidence for the etiologic significance of this drug.

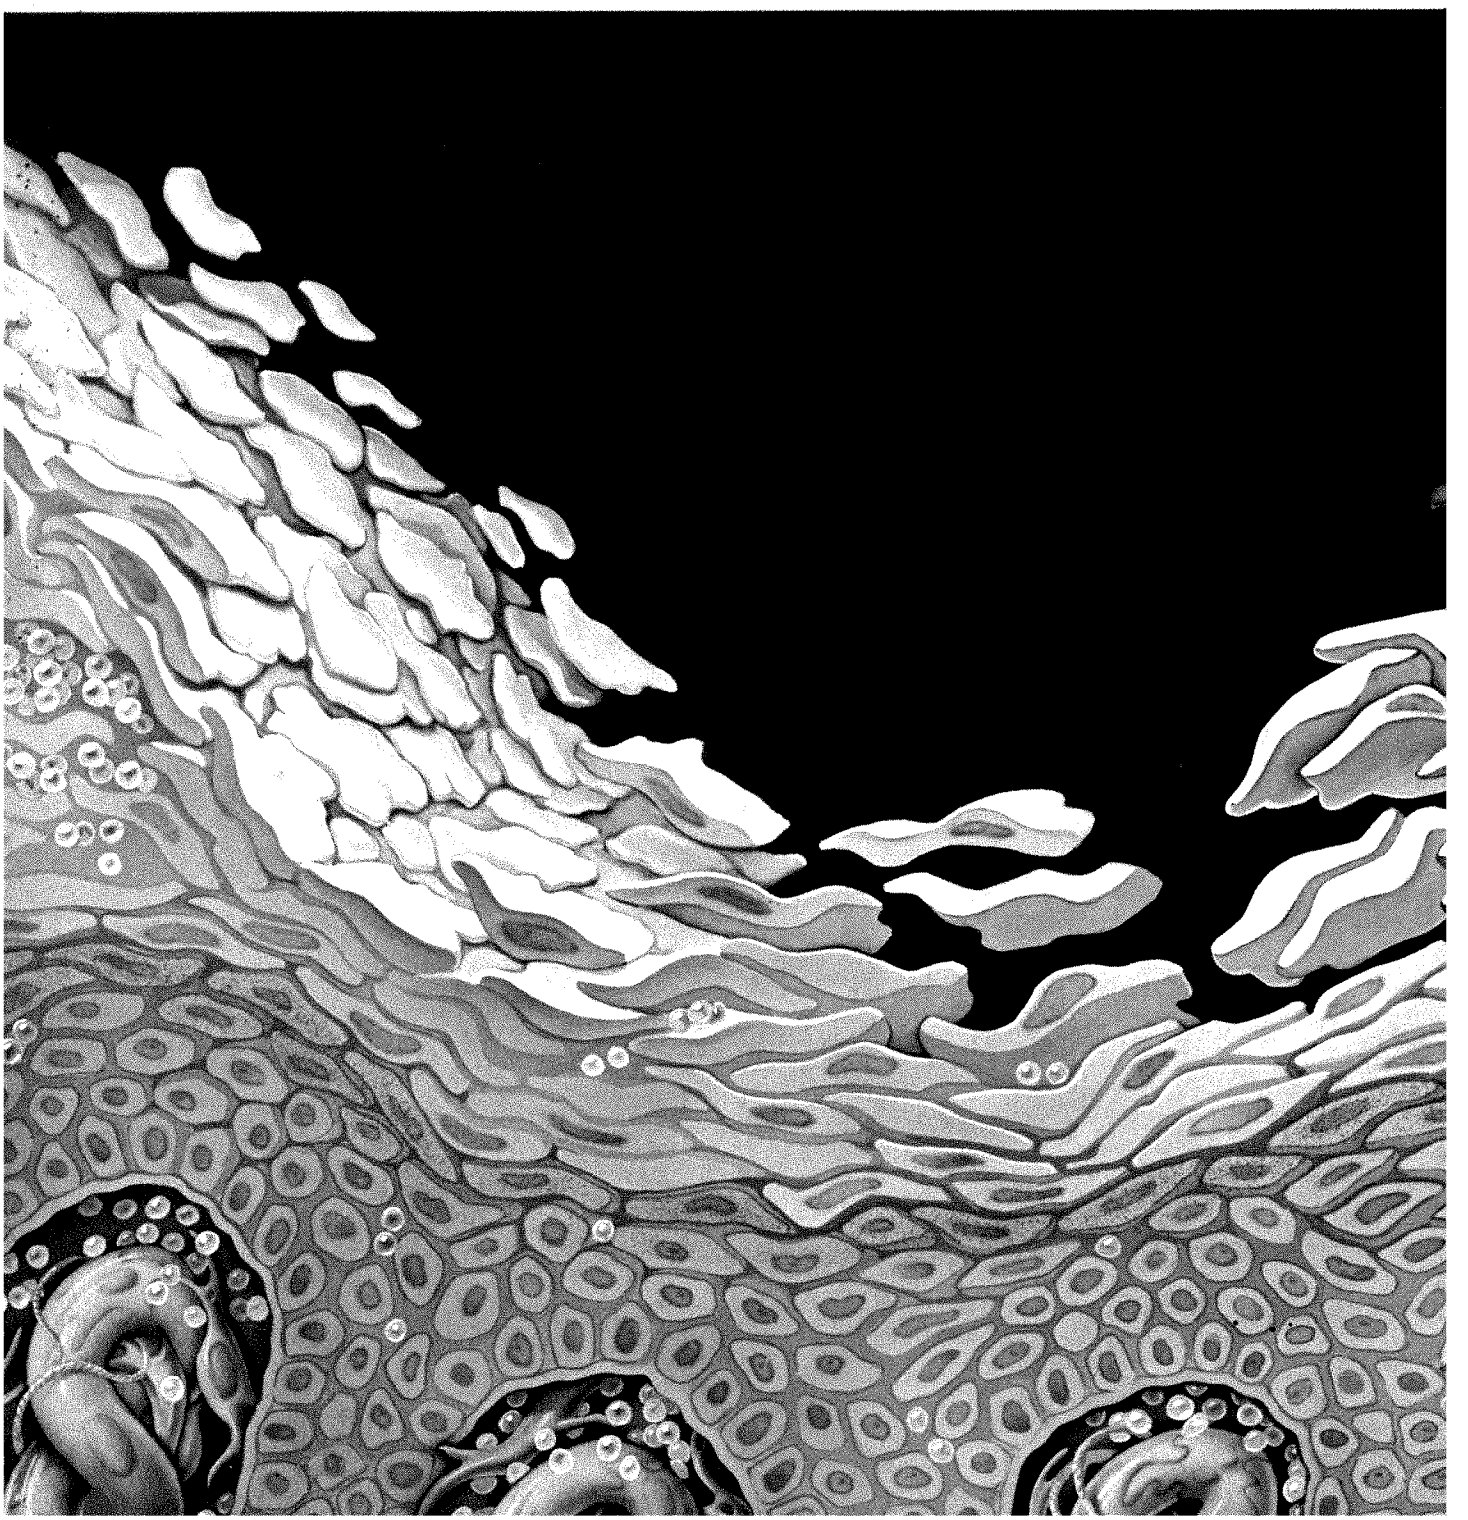
PSORIASIS
The Capricious Dermatosis

LIDEX® (fluocinonide) 0.05%
A Stabilizing Influence

Psoriasis. Mere mention of the word ca
make an afflicted patient cringe. And,
because of the capricious, unpredictab
nature of the disease, the patient rarely
knows where or when it will recur.

Obviously, the goal is control. And,
though varied treatment modalities are
available today, none offers universal



icacy for all patients, all of the time.
Yet, very often a highly effective topical
eroid, like Lidex, (fluocinonide) can
lp stabilize psoriasis.
Lidex. A highly effective topical steroid
th anti-inflammatory, vasoconstrictive,
tipruritic actions.
100% dissolved for optimal penetration,
important in stages that exhibit thickened,
scaly lesions.
Totally free of preservatives.
Available in cream, ointment, and
Topsyn® (fluocinonide) gel.

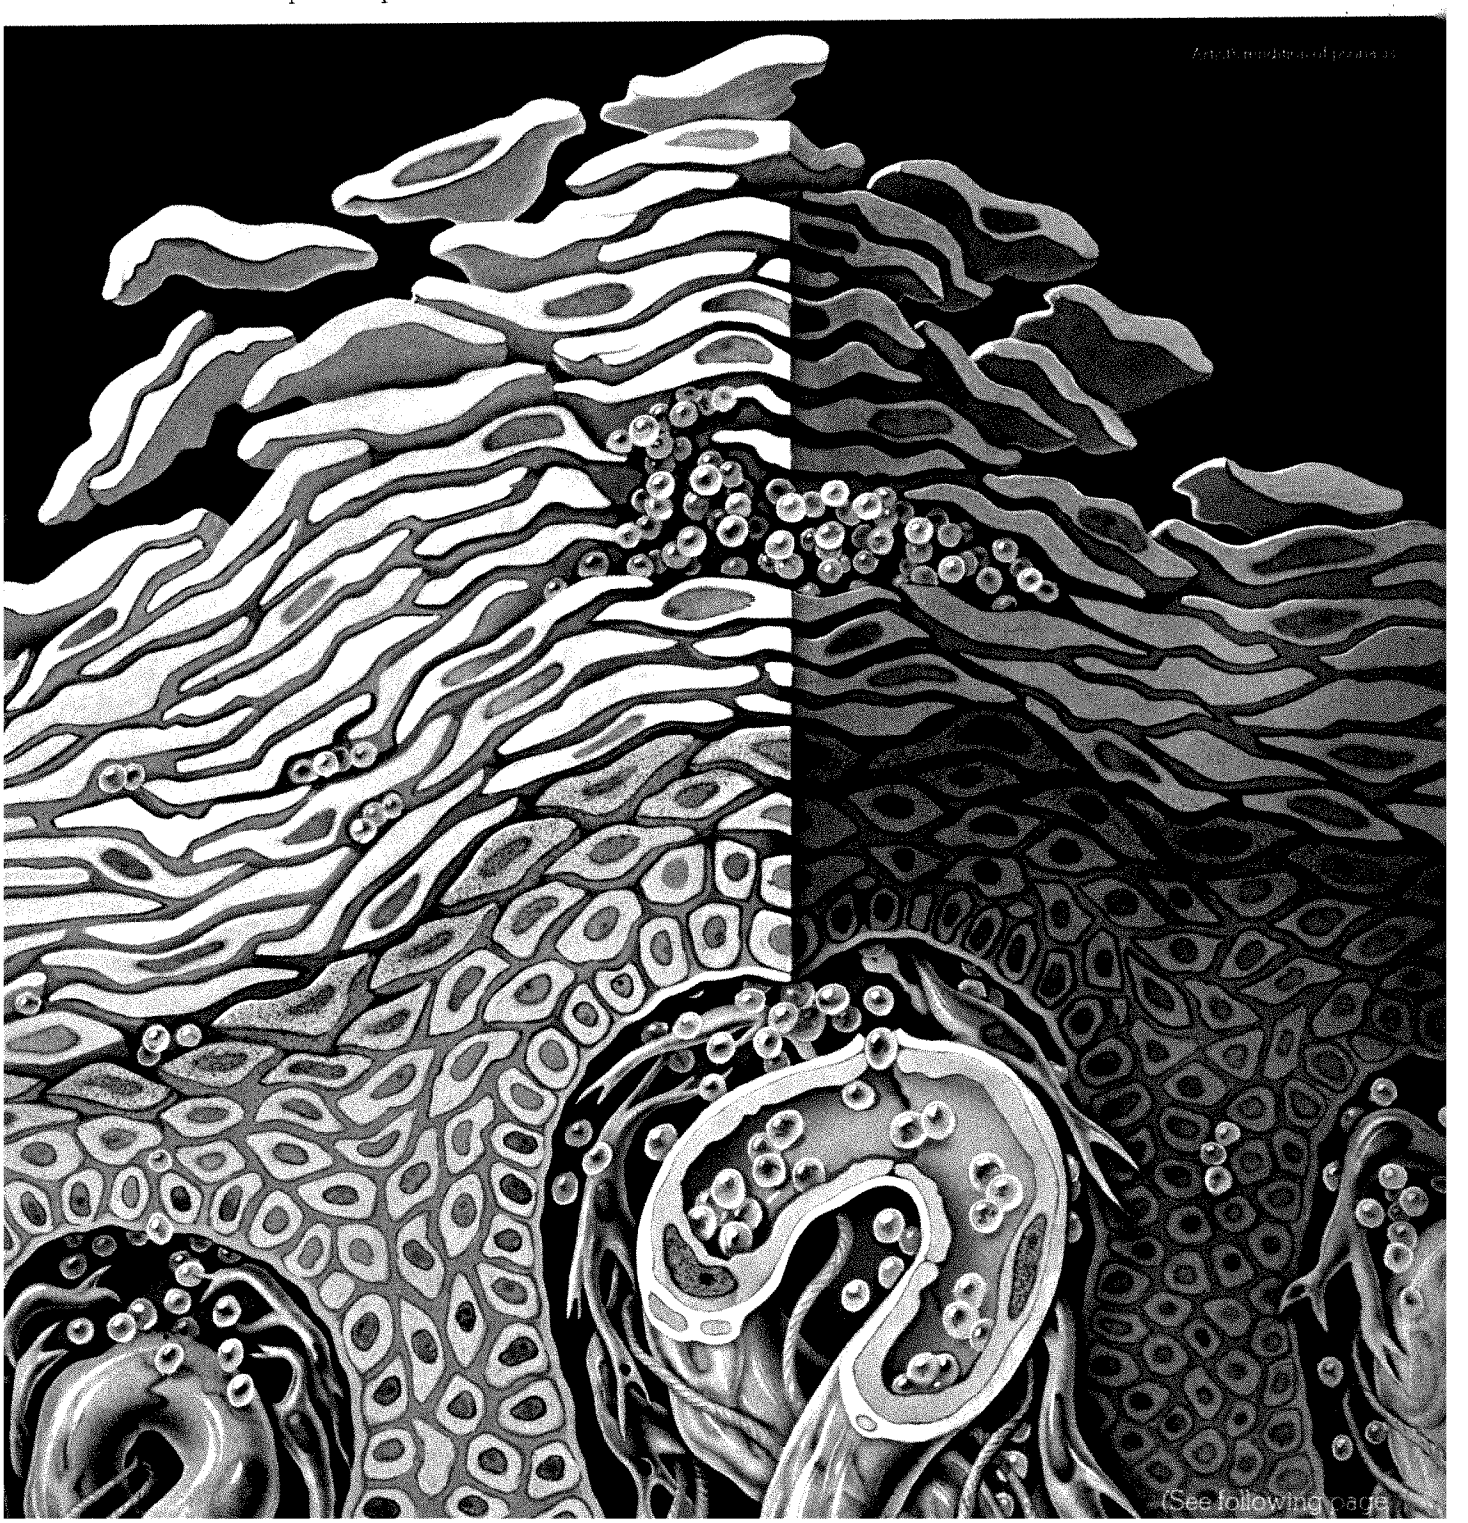
SYNTEX LABORATORIES, INC.
PALO ALTO, CALIFORNIA 94304



(See following page)

LIDEX® (fluocinonide)
0.05% Cream and Ointment

TOPSYN® (fluocinonide)
0.05% Gel

Summary of prescribing information

Description

LIDEX cream 0.05%, LIDEX ointment 0.05% and TOPSYN gel 0.05% contain the active compound fluocinonide. Fluocinonide, which is the 21-acetate ester of fluocinolone acetonide, has the chemical formula 6α, 9α, -difluoro-11β, 16α, 17α, 21-tetrahydroxypregna-1,4-diene-3, 20-dione, cyclic 16, 17-acetal with acetone 21-acetate. LIDEX cream contains fluocinonide in FAPG® cream, a specially formulated cream base consisting of stearyl alcohol, polyethylene glycol 6000, propylene glycol, 1, 2, 6-hexanetriol and citric acid. This white cream vehicle is greaseless, non-staining, anhydrous and completely water miscible. The base provides emollient and hydrophilic properties. In this formulation, the active ingredient is totally in solution.

LIDEX ointment contains fluocinonide in a specially formulated ointment base consisting of Amerchol CAB (mixture of sterols and higher alcohols), white petrolatum, propylene carbonate and propylene glycol. It provides the occlusive and emollient effects desirable in an ointment. In this formulation the active ingredient is totally in solution.

TOPSYN gel contains fluocinonide in a specially formulated gel base consisting of propylene glycol, propyl gallate, disodium edetate, and Carbopol 940 (carboxypolymethylene) with NaOH and/or HCL added to adjust the pH. This clear, colorless, thixotropic vehicle is greaseless, non-staining and completely water miscible. In this formulation, the active ingredient is totally in solution.

Indications

LIDEX cream and ointment and TOPSYN gel are intended for the relief of inflammatory manifestations of corticosteroid responsive dermatoses.

Contraindications

Topical steroids are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions

If irritation develops, the cream, ointment or gel should be discontinued and appropriate therapy instituted. In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted.

If a favorable response does not occur promptly, the corticosteroid cream, ointment or gel should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, the possibility exists of increased systemic absorption and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

LIDEX® (fluocinonide) cream and ointment and TOPSYN® (fluocinonide) gel are not for opthalmic use.

Adverse reactions

The following local adverse reactions have been reported with topical corticosteroids:

burning	folliculitis
itching	acneform eruptions
irritation	hypopigmentation
dryness	striae
secondary infection	skin atrophy

Dosage and administration

A small amount should be gently massaged into the affected area three or four times daily, as needed.

How supplied

LIDEX 0.05% Cream—15 g 30 g and 60 g tubes.
LIDEX 0.05% Ointment—15 g 30 g and 60 g tubes.
TOPSYN Gel 0.05% 15 g and 60 g tubes.

Psoriasis Treated With Mycophenolic Acid. Presented by RAUL FLEISCHMAJER, MD, ROSALIE K. MARINARI, MD.

A 62-year-old woman had a 44-year history of severe generalized plaques of psoriasis. She had been treated with various agents, including tars and topical steroids. For the past six years she had been treated with methotrexate with moderate control of her psoriasis, but she had adverse reactions of nausea and alopecia. Dermatological examination revealed a moderate xerosis of the upper and lower extremities, erythema and scaling of the right index finger, and a 1-cm erythematous scaly patch on the sacrum. Laboratory data including a complete blood count, blood chemistry studies using an automated multiple analysis system (SMA-12) survey, and urinalysis were within normal limits. The patient had been treated with 2,400 mg/day of mycophenolic acid.

Discussion

DR FLEISCHMAJER: We have treated a series of 35 patients. I would estimate about 300 patients with psoriasis have been treated with mycophenolic acid in the United States.

PAUL R. GROSS, MD: Is mycophenolic acid an immunosuppressive drug?

DR FLEISCHMAJER: Initially we did not think the drug was immunosuppressive. We have had a patient with herpes zoster, and several patients have had herpes simplex. Later we found out that others have observed several cases of herpes zoster and this seems to be a unique side effect of this drug. I do not think herpes zoster has been reported with treatment with methotrexate, which does have an immunosuppressive effect.

DR MARINARI: Our experience with the 35 patients treated is that about 20% show complete clearing and about 45% show almost complete clearing with only residual erythema or individual small lesions. The guidelines for results of treatment consider any erythema as activity; thus, with residual mild erythema, we consider the area as almost completely cleared. Definite improvement (at least a 50% decrease in area of involvement) was seen in 25% of the patients and two patients (8%) showed only a slight improvement. The experience of the various groups in the United States who are studying the effect of mycophenolic acid has been that most of the patients will show clearing in seven to eight weeks, though some may take up to 12 weeks. Response seems to be slower than that with methotrexate. If relapses occur after complete withdrawal of the drug, they usually occur within three to four weeks. The major side effects that we have observed are diarrhea, soft stools, and nausea, and these seem to be dose related. Some patients have burning and pain on urination, weakness, and lassitude.

JOHN W. PETROZZI, MD: Do all of the patients experience relapse three to four weeks after mycophenolic acid treatment is stopped?

DR MARINARI: No, but the lesions in most patients will gradually recur and then an individual patch will expand, but they do not recur in an explosive manner. We do not have prolonged follow-ups.

SHELDON B. GOLDSTONE, MD: Are there any hematologic complications?

DR MARINARI: Within the first 12 to 15 weeks of treatment, we have seen a gradual decline in hemoglobin level. As treatment continues, the hemoglobin level usually returns to about normal for the patient. Several patients have been reported as having leukopenia; however, the leukocyte count reverts to normal on discontinuing treatment with the drug, but we have not observed leukopenia in our patients.

DR. FLEISCHMAJER: At the present time, mycophenolic acid does not have a brand name. It is difficult to get excited about another cytotoxic drug in the treatment of psoriasis, but the thought was that this drug would not cause bone marrow depression and would not affect the liver or the kidney. The drug is slow acting and you do not get the dramatic effect sometimes seen with methotrexate. The only serious side effect in our study has been the development of a hemorrhagic diarrhea in one patient who continued taking the drug after symptoms of colitis had developed. We plan to keep the patients on treatment for two years before a final evaluation is attempted.

Generalized Erythroderma Secondary to Atopy, R/O Sézary Syndrome. Presented by ALEXANDER EHRLICH, MD.

A 32-year-old man has had extensive atopic dermatitis since childhood. He has had frequent flares and has been hospitalized many times with a generalized erythroderma. A recent peripheral blood smear showed 9% of all lymphocytes to be abnormal and to contain PAS-positive granules. The patient has a history of amputation of the right leg following a severe burn, mild hypertension, glaucoma, bilateral cataracts, and chronic alcohol ingestion. Physical examination shows generalized lichenification with a "cobblestone" appearance on the trunk and extremities and minimal erythema. Lymph node biopsy specimens have been reported as chronic dermatopathic lymphadenitis and skin biopsy specimens as chronic dermatitis. He has been treated with

triamcinolone cream 0.1%, hydrophilic petrolatum, and bath oil.

Discussion

EUGENE J. VAN SCOTT, MD: If the abnormal cells seen on the peripheral smear have convoluted nuclei (Sézary cells), the patient should be classified as having Sézary syndrome. It is important to have a specific diagnosis and to know if the lymph nodes are involved. If the lymph nodes are involved with Sézary disease, chemotherapy for systemic effect should be instituted; whereas, if there is only skin involvement, mechlorethamine hydrochloride or electron beam therapy should be used.

WAINE C. JOHNSON, MD: I thought the histology was not entirely conclusive in that the lymph node showed changes of dermatopathic lymphadenitis and the skin biopsy specimens were consistent with, but not diagnostic of, mycosis fungoides or Sézary syndrome. I would like to know Dr Van Scott's experience regarding the concurrence of atopic dermatitis and mycosis fungoides. This patient has had severe eczema since infancy.

DR VAN SCOTT: I have seen patients with mycosis fungoides who have a long-term history of atopic dermatitis and quite a few who have had a history of nummular eczema. In some cases, we are not sure if the patients have mycosis fungoides in concurrence with atopic dermatitis. A few patients had a long history of atopic dermatitis with clinical features of Sézary disease; there was definite improvement with treatment.

March 21, 1975

Waine C. Johnson, MD, Recorder

Metastatic Squamous Cell Carcinoma. Presented by STEVEN A. GAMMER, MD, JOHN W. PETROZZI, MD.

A 56-year-old man was seen by another physician in 1969 because of a lesion on the penis that had been present for several years. Examination revealed a 1.5 × 1.7-cm red plaque at the sulcus of the penis just to the left of the frenulum. The inguinal lymph nodes were not enlarged. The patient was stated to have had a circumcision as an infant. The clinical impression was erythroplasia of Queyrat, and a punch biopsy was performed and the specimen was interpreted as erythroplasia. The lesion was treated by electrodesiccation and curettage and there was no evidence of recurrence of the penile lesion or any lymph node enlargement on examination seven months after treatment.

The patient did not return for follow-up. He apparently noted a mass in the left inguinal area in 1972 but did not seek medical evaluation until July 1974. Examination revealed metastatic squamous cell carcinoma of the left inguinal lymph nodes, an ulcerated inguinal mass, and pain and swelling of the left leg. A lymphangiogram revealed the presence of metastases in the hypogastric and left para-aortic lymph nodes. He was treated with a course of 5,500 rads of x-rays and later by a course of chemotherapy without a satisfactory response. He has been referred for further evaluation and treatment.

Metastatic squamous cell carcinoma of left inguinal area and suprapubic area.

Physical examination shows a hard, matted, foul-smelling left inguinal mass that is draining a serous exudate (Figure). A 1-cm nodule near the midline of the pubic area is also present. The penis is partially circumcised and the frenulum as well as the rest of the penis appears completely normal. The left leg shows extensive pitting edema. A chest roentgenogram, liver scan study, and bone survey did not show evidence of tumor. Pathological examinations of the left inguinal lymph node, left inguinal mass, and pubic skin nodule showed squamous cell carcinoma.

Discussion

CAPT BERNETT JOHNSON, MC, USN: The interesting aspect is whether the inguinal carcinoma represents a metastasis from the erythroplasia of Queyrat or if it is of another source.

STEVEN A. GAMMER, MD: The original biopsy specimen of the penile lesion in 1969 was interpreted as erythroplasia of Queyrat, but I have shown the sections to other dermatopathologists who do not agree with this diagnosis.

WAINE C. JOHNSON, MD: I reviewed the section presented today and I have studied sections from the initial biopsy specimen taken in 1969 and it is my opinion that the lesion of the penis was erythroplasia of Queyrat. One can raise the question as to whether there is early invasion of the underlying corium as carcinoma. I was not convinced that there was definite invasion of the corium as carcinoma, but this determination is not always clear-cut and I could understand that others might interpret the features as early invasion. It would be unusual for erythroplasia of Queyrat with such superficial invasion, if there is in fact invasion of the corium, to give rise to metastases, especially since the initial lesion was apparently cured with electrodesiccation. One has to consider the possibility of a primary squamous cell carcinoma arising in the inguinal area, or of a metastasis from an internal source not yet recognized; but the circumstantial evidence would seem to favor that the inguinal carcinoma is secondary to the lesion of the penis.

HERBERT GOLDSCHMIDT, MD: I have seen a patient with histologically confirmed Bowen's disease of the pubic area that was treated with fluorouracil with clearing of the lesion. He did not return until two years later when a new lesion had developed in the same area that was excised and histologically showed squamous cell carcinoma. Metastases to the local lymph nodes later developed. One could raise a question as to whether there is something special about the area or could it have been related to treatment with fluorouracil?

DONALD SCHETMAN, MD: The treatment of erythroplasia and Bowen's disease with fluorouracil seems to have progressed from the experimental stage to a standard procedure rather than surgery, but when you hear of recurrences and metastases, you begin to have second thoughts.

DR JOHNSON: I believe there is a distinct difference in treating erythroplasia of Queyrat, which is usually located on the glans where there are no adnexal structures, and treating Bowen's disease or extramammary Paget's disease with fluorouracil where there are adnexal structures and atypical cells extend deep into the hair follicle root sheaths and along and within the sweat ducts and sweat glands. I do not see how the atypical cells within the adnexal structures could be significantly affected by the fluorouracil. I do not see any theoretical objection to using fluorouracil on the glans or sites where there are no adnexal structures.

ALBERT M. KLIGMAN, MD: I would like to hear the opinion of the pathologists as to whether erythroplasia is identical to Bowen's disease, not just histologically but in every biological sense, or is it the same process that happens to have a special name because it is located on the glans. Since they look alike and behave similarly, it seems possible that they are not really different.

DONALD L. BAXTER, MD: The key to the answer is the biological behavior. Erythroplasia of Queyrat differs first because of the location with the absence of appendageal structures. Second, we have fairly good documentation from the work of Dr James Graham that erythroplasia of Queyrat is not associated with arsenic as is often seen in Bowen's disease, so there may be a difference in mechanisms of development. Third, erythroplasia of Queyrat has not been reported to be associated with an increased frequency of internal malignancy as is seen with Bowen's disease. The histological features of the diseases are in my opinion indistinguishable, but on the basis of the clinical and pathological correlation, I believe they are separate entities.

Waine C. Johnson, MD, Recorder

Kaposi's Sarcoma After Renal Transplantation. Presented by ROBERT I. RUDOLPH, MD.

A 42-year-old black man has had a long history of hypertension and deteriorating renal function. He had been treated with repeated dialysis and in February 1974 a

bilateral nephrectomy with transplantation of cadaver kidneys was performed. Initially receiving high doses of prednisone and azathioprine, he is now taking 20 mg of prednisone and 24 mg of azathioprine daily. Some weeks after the surgery, the patient noticed dark, painless, scaly lumps on his fingers, hands, feet, and soles. Skin biopsy specimens were interpreted as Kaposi's sarcoma in September 1974. A biopsy specimen from a mass in the left tonsillar area in October 1974 was also interpreted as Kaposi's sarcoma. Physical examination in September 1974 revealed multiple variable-sized purple keratotic papules and plaques on the fingers, hands, feet, and toes. Each extremity has been treated with 2,000 rads of 2 meV using 2 ports, and the neck has received 2,000 rads of cobalt 60 using 2 ports. The condition of all of the lesions has greatly improved following the treatment.

Discussion

HERBERT GOLDSCHMIDT, MD: Radiotherapy is an effective form of treatment in Kaposi's sarcoma. Relatively low doses are usually effective. Kaposi's sarcoma developed in this patient after renal transplantation and treatment with immunosuppressive drugs. Similar cases have been reported in patients with lupus erythematosus who were treated with immunosuppressive drugs. Patients receiving immunosuppressive drugs may have Kaposi's sarcoma develop in the younger age groups in contrast to the naturally occurring disease that usually appears in older patients and particularly in men. There is some indirect evidence that Kaposi's sarcoma may be a viral disease. In the lowlands of Central Africa, 9% of all malignant tumors are Kaposi's sarcoma, and this supports an infectious etiology. Patients with Kaposi's disease also have a higher incidence of other malignant neoplasms. The occurrence of Kaposi's disease in patients receiving immunosuppressive agents emphasizes that physicians should be cautious in using these drugs for benign disease.

CHARLES H. GREENBAUM, MD: Is there anything known about the person who donated the kidneys?

ROBERT RUDOLPH, MD: We have no information regarding the person who donated the kidneys. Dr Braverman has stated that in about 10% of the patients with Kaposi's sarcoma a second malignant neoplasm develops.

SAMUEL L. MOSCHELLA, MD: I recently saw a 67-year-old Italian man who had had Kaposi's disease of the extremities for eight years. Two years ago myasthenia gravis developed and a mediastinal mass was discovered. The lesion was excised and was interpreted as a spindle cell type of thymoma with two adjacent nodes showing Kaposi's sarcoma. Kaposi's sarcoma is associated not only with an increased frequency of lymphomas but also with other types of malignant neoplasms.

Azathioprine—*Imuran.*

Capillary and Cavernous Hemangioma: Presented for Discussion of Therapy. Presented by HOWARD SIMONS, MD.

The patient was born on May 26, 1974, and appeared normal. Lesions of the face were first seen at 2½ weeks and they have increased in number and size. There has been no respiratory distress, bleeding, or purpura.

Physical examination at this time shows a marked deformity of the face, especially the nose and right orbit, caused by masses of hemangioma. The patient was placed on a regimen of oral steroids for two weeks without any change in appearance.

Discussion

JOHN F. WILSON, MD: This is the most disfiguring hemangioma that I have ever seen. The mother stated that when the baby was only 2 days old and had an occasional coughing spell, swollen red blotches would appear at the sites now occupied by the hemangioma. This would indicate it was probably cavernous from the very beginning. I would wait in regard to treatment and hope that the expected spontaneous involution would occur.

HERBERT GOLDSCHMIDT, MD: Radiation therapy should not be used except in very rare special circumstances. In this patient, it is not indicated because there is no life-threatening complication. Radiotherapy may rarely be considered in special locations, such as around the eyes when the eyelids cannot be opened and blindness may occur. Also, when a hemangioma involving the mouth is so severe that the patient cannot eat or drink properly, radiotherapy should be tried. I believe this patient will improve spontaneously but with considerable scarring.

PETER J. KOBLENZER, MD: In children with lesions of this type, platelet sequestration does not necessarily show itself with bleeding tendencies. Also RBCs are sequestered and the patient can get a very low hemoglobin level.

DR MOSCHELLA: In 1957, I was asked to see a 9-month-old infant on a pediatric ward who had a rapidly growing hemangioma of the face. We decided to observe the child further. A few days later, I was informed that the infant had died because of a laceration in the posterior pharynx that bled into the intestinal tract. Platelet counts had not been done, and the personnel were apparently not aware of the danger. The features were consistent with Kasabach-Merritt syndrome, hemangioma with thrombocytopenia resulting from intravascular coagulation. We have used intralesional steroid therapy in five patients with congenital hemangiomas mainly of the capillary type with satisfactory results. These were ulcerated lesions located about the genitalia that were symptomatic due to the irritating effects of excreta. The lesions were injected two to three times at three-week intervals. Involution occurred in about two months.

DONALD L. BAXTER, MD: One must know if hemangioma involves only skin and subcutaneous tissue or if it also involves underlying bony structures. If bone is involved, the prognosis is much more serious.

Tuberous Sclerosis. Presented by JAY M. HOLZWINGER, MD.

A 4-year-old girl has had a history of seizures since 7 months of age. She has psychomotor retardation, with a developmental age of 18 to 30 months when tested at 40 months. Skin lesions have been present since infancy. A maternal second cousin had seizures in childhood. A maternal third cousin has had seizures and is of normal intelligence. There are skin-colored, elevated, plaque-like lesions involving the extensor aspect of the left arm and the right midback. There are hypopigmented macular lesions of both forearm extensor surfaces. An ophthalmologic examination showed early phakoma of the inferior midline aspect of the right disc. A pneumoencephalogram showed candlegutter lesions along the floor of each lateral ventricle. Skull films and long bone x-ray films were within normal limits. A chromosome study revealed 46 XX.

Discussion

THOMAS BUTTERWORTH, MD: Ophthalmologists have always been confident that they can diagnose tuberous sclerosis on the basis of the phakomas occurring in the eyes. The questions to consider are those of what you should tell the patient's family and, later on, the patient regarding the prognosis, genetic counseling, and what studies might be done to investigate the nature of the connective tissue defect. Tuberous sclerosis is an autosomal dominant disease that has a variable penetrance and expressivity. We expect only about one half of the patients to have skin manifestations. It is important to take a good family history to know which side of the family may be transmitting the trait. This couple had four children, and by the law of averages there would be two free of tuberous sclerosis who would not transmit the disease to their offspring. Of the two carrying the trait, one might show skin lesions and the other only internal manifestations. Therefore, we tell the family there is a 50% possibility that other children may have the disease. It is also important to determine which of the parents is the carrier of the trait because members may have been asymptomatic to the age of 50 or 60 years and then a seizure or brain tumor resulting in death develops. It would be ideal, too, if a method could be devised for studying the fetus in utero to determine if the trait is present, but unfortunately we cannot do so at this time. Although tuberous sclerosis has been described as a neuroectodermal disease, it is actually a mesenchymal or connective tissue problem. In all of the involved sites, whether brain, skin, or other organs, there is an abnormal proliferation of connective tissue associated with some vascular ectasia. The question arises whether this may represent a metabolic disturbance related to a deficiency of collagenase or whether there might be an excess of a collagenase inhibitor. I would like to see collagenase studies and collagenase inhibitor studies carried out in patients with tuberous sclerosis in the hope that we can learn more about the mechanism of the formation of fibromas or angiofibromas.

...or the acne hello...

ACNAVEEN® BAR

Soothes and cleans sensitive skin, and helps bring their guards down...

Hiding their embarrassment compounds the misery. Incessant picking and rubbing of acne lesions often causes more irritation. Urge them to wash with soap-free ACNAVEEN® Bar, logical adjunctive therapy in whatever treatment you've chosen:

- 2% salicylic acid and 2% sulfur provide a peeling and drying effect.
- Aveeno Colloidal Oatmeal soothes the skin and reduces irritation.

ACNAVEEN® BAR: Special mild cleansing bar for acne.

Available in 3.5 oz. bars

Cooper Cooper Laboratories, Inc., Wayne, New Jersey 07470

New fast way with spray

for contact dermatitis control

New Diprosone® Aerosol 0.1%

brand of

betamethasone dipropionate (Potency expressed as betamethasone)

Rapid improvement of moderate to very severe contact dermatitis signs/symptoms*

	Per cent of patients improved†		
	Pruritus 129 patients	**Erythema 129 patients**	**Vesiculation 77 patients**
After 3 days	**85%**	**78%**	**82%**

Schering

New Diprosone®
brand of
betamethasone dipropionate
Aerosol 0.1%

Clinical Considerations: INDICATIONS DIPROSONE Aerosol is indicated solely for the adjunctive topical management for the relief of inflammatory manifestations of acute contact dermatitis. DIPROSONE Aerosol has not been shown to be effective in any steroid-responsive dermatosis other than contact dermatitis. **CONTRAINDICATIONS** DIPROSONE Aerosol is contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of such preparations. DIPROSONE Aerosol is also contraindicated for use under occlusive dressings. **WARNINGS** Keep away from eyes or other mucous membranes. Use only as directed; intentional misuse by deliberately concentrating or inhaling the contents can be harmful or fatal. Avoid freezing of the tissue by not spraying for more than three seconds, at a distance of not less than six inches. Contents under pressure. Do not puncture. Do not use or store near heat or open flame. Exposure to temperatures above 120° Fahrenheit may cause bursting. Never throw container into fire or incinerator. Keep out of reach of children. **PRECAUTIONS** If irritation develops with the use of DIPROSONE Aerosol, treatment should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been absolutely established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time. DIPROSONE Aerosol is not for ophthalmic use. **ADVERSE REACTIONS** The following local adverse reactions have been reported with topical corticosteroids: burning; itching; irritation; dryness; folliculitis; hypertrichosis; acneiform eruptions; hypopigmentation; maceration of the skin; secondary infection; skin atrophy; striae; miliaria.

Books

Cryosurgical Advances in Dermatology and Tumors of the Head and Neck, edited by Setrag A. Zacarian, MD, FACP, many color and black and white illus, 272 pp, $33, Charles C Thomas Publisher, Springfield, Ill, 1977.

The field of "modern" (or advanced) cryosurgery has progressed at an impressive rate during the past decade. Zacarian has participated in this growth in many ways. He not only made and reported many of the basic clinical observations, but, he did much of the animal and other research projects that provided this field with the background that it required for acceptance. He brings his unique knowledge of his subspecialty to this publication. Zacarian has produced three books on the subject since 1969. In this, his third volume, the word "advances" seems to be the keynote. It is an attempt to bring the reader up to date on the latest advances, but it also reemphasizes the advances of the past. This may make the book of greater interest to the physician already in the field than to the potential beginner. Yet, this is not said in criticism.

It is a beautifully produced volume and credit for this must go to the publisher. Through the cooperation of many pharmaceutical firms, it contains many strikingly clear, reproduced color illustrations. The book is well written and quite readable; however, the use of anecdotal case reports although adding to the reader's interest does little to the scientific value of the treatise.

Like all multiauthored books, it has its high points and its low points, depending on the interest and the literacy of the individual contributors. In this volume, the overall effect is commendable. Most or all observers realize that cryosurgery will not replace x-radiation, surgery, microscopically controlled chemosurgery, etc, in the management of skin cancer. Nevertheless, few question that there is a place for this modality in our armamentarium against that disease. The complete dermatologist should be able to offer this form of therapy to his patients. This book can be recommended to any physician who uses or hopes to use this modality in his practice.

ERVIN EPSTEIN, MD
Oakland, Calif

Mechanisms of Topical Corticosteroid Activity, edited by Lyn C. Wilson and R. Marks, with illus, 150 pp, $22, Churchill Livingstone, New York, 1977.

There have been several pertinent reviews of corticosteroids recently. The first by D. Azarnoff (*Steroid Therapy,* Philadelphia, WB Saunders Co, 1975) covers systemic and topical applications whereas the second in *Dermatologica* (152, suppl 1, 1976) discusses topical activity. The present summary of a symposium on mechanisms of topical steroid activity supplements material presented in the previous two reviews. With these three books, the student of corticosteroids receives a broad view of the problems that have been solved and those that remain to be solved.

This volume has several new research contributions. These include a study of the effect of corticosteroids on skin fibrinolytic activity (Tebs and Cunliff), the fine points of the effect of corticoids on skin pulses (Tune), and several papers attempting to explain their effect on epidermal cell kinetics. A clear statement on the negative effect of corticosteroids on melanin pigmentation in the guinea pig (S. Bleehan) and several papers discussing the putative anti-inflammatory roles of these compounds are valuable.

Since the topical corticosteroids represent the most widely used drug in dermatology, any relevant fact (positive or negative) that might lead to an improvement in their properties is surely worthwhile. The editors (Wilson and Marks) are to be congratulated on producing this volume.

HOWARD MAIBACH, MD

For Skin Without Water

Neutrogena® Dry Skin products are specially formulated to supplement surface fats and aid in the retention of moisture.

- Neutrogena® Dry-Skin Soap contains humectants, lubricants, and emollients to soften and moisturize, and is nonirritating to sensitive skin.
- Neutrogena® Rainbath® Dry Skin Bath Gel is lipid-free, cleanses with a rich lather without the drying effect of ordinary soap, and leaves skin soft and smooth. Available both scented and unscented.
- Neutrogena® Hand Cream is a heavy-duty formula containing a special blend of naturally occurring oils and glycerin, and is a useful adjunct in steroid-responsive hand dermatoses.[1]

News and Notes

Hair Transplant Symposium.—The American Society for Dermatologic Surgery and the American Academy of Facial Plastic and Reconstructive Surgery are sponsoring the Annual Hair Transplant Symposium and Workshop, Feb 2 through 4, 1978 in Lucerne, Switzerland. The course moderator will be D. Bluford Stough III, MD. For further information write to Stough Dermatology and Cutaneous Surgery Clinic, Doctor's Park, Hot Springs, AR 71901.

Flaps.—The American Society for Dermatologic Surgery announces a course entitled "Dermatologic Surgery—Flaps." The course will be held at the University of California Medical Center, San Francisco, Sept 10 and 11, 1977. The course moderator will be Theodore Tromovitch, MD. For further information write to Extended Programs in Medical Education, University of California School of Medicine, San Francisco, CA 94143.

General Meeting.—The American Society for Dermatologic Surgery will hold a general membership meeting Dec 6, 1977 in Dallas. Details will be announced in the society's newsletter, or interested parties may write to Daniel E. Gormley, MD, ASDS secretary, 210 S Grand Ave, Suite 307, Glendora, CA 91740.

ASDS Annual Meeting.—The American Society for Dermatologic Surgery will hold its fourth annual Clinical and Scientific Meeting March 29 through April 2, 1978 at Vacation Village in San Diego. The course moderator will be Theodore Tromovitch. For reservation information write to Mr Robert Brown, The Incentive Co, 2207 Chestnut St, Philadelphia, PA 19103.

Meeting.—The Western Regional Meeting of the Society for Investigative Dermatology (SID) will be held jointly with the Dermatology Subsection of the Western Section of the American Federation for Clinical Research (AFCR), the Western Society for Pediatric Research, the Western Association of Physicians, and the Western Society for Clinical Research. The meeting will be held Feb 1-3, 1978, Carmel, Calif. Inquires may be addressed to Ervin Epstein, Jr, MD, 400 30th St, Oakland, CA 94609.

Abstracts are solicited and must be received by Oct 5, 1977, and should be submitted on current AFCR or SID forms.

Following the Dermatology Subsection, the SID will present a symposium entitled "Physiologic Functions of Inflammatory Mediators."

1977-1978 American Academy of Dermatology Roster Available.—The 1977-1978 Roster of the American Academy of Dermatology, including by-laws, officers, and committees, is now available, according to Bradford W. Claxton, executive director of the Academy.

A copy has been mailed to each member of the Academy. Members may obtain additional copies for $10 each. Physicians, hospitals, libraries, and educational institutions may purchase copies for $25 each. The charge to commercial users is $75 per copy.

For details, write: Membership Services, American Academy of Dermatology, 820 Davis St, Evanston, IL 60201.

European Society for Dermatological Research (ESDR) Poster Award.—The ESDR Poster Award for the best poster presentation at the annual ESDR meeting has been kindly offered by Max Ritter, Pharmaceutical Specialities, Zurich/CH.

The 1977 winners are H. Rorsman, G. Agrup, Ch. Hansson, G. Prota, A. M. Rosengren, and E. Rosengren from the Departments of Dermatology, Organic Chemistry, Biochemistry, and Pharmacology, the University of Lund and the University of Naples, for the poster "New metabolites of the melanocytes excreted in the urine."

European Society for Dermatological Research (ESDR) Symposium.—This symposium entitled "Clinical and Experimental Approaches to Skin Carcinogenesis" is to be held in Paris, Jan 13 and 14, 1978. It is a clinically orientated symposium sponsored by the ESDR. It will consist of short papers from invited speakers, discussion periods, and a session for free communications. Anyone wishing to contribute or to attend this meeting should contact Prof M. Prunieras, Laboratoire de Recherches sur les Tumeurs de la Peau Humaine, Fondation Ophthalmologique A. de Rothschild, 29 Rue Manin, 75019 Paris, France.

SYNALAR®
(fluocinolone acetonide)
CREAM 0.025%
CREAM 0.01%
OINTMENT 0.025%
SOLUTION 0.01%

Description Synalar (fluocinolone acetonide) has the chemical name 6α, 9α-difluoro-16α-hydroxyprednisolone-16, 17-acetonide.

The cream contains fluocinolone acetonide 0.25 mg./g. or 0.1 mg./g. in a water-washable aqueous base of stearic acid, propylene glycol, sorbitan monostearate and monooleate, polysorbate 60, purified water and citric acid with methylparaben and propylparaben as preservatives.

The ointment contains fluocinolone acetonide 0.25 mg./g. in a white petrolatum U.S.P. vehicle.

The solution contains fluocinolone acetonide 0.1 mg./g. in a water-washable base of propylene glycol with citric acid.

Indications For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications Topical steroids are contraindicated in vaccinia and varicella.

Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions If irritation develops, the product should be discontinued and appropriate therapy instituted.

In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled.

If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Synalar products are not for ophthalmic use.

Adverse reactions The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, dryness, folliculitis, hypertrichosis, acneform eruptions, hypopigmentation.

The following may occur more frequently with occlusive dressings than without such therapy: maceration of the skin, secondary infection, skin atrophy, striae, miliaria.

How Supplied
Synalar (fluocinolone acetonide)
Cream 0.025% — 15 and 60g. tubes and 120 and 425g. jars.
Cream 0.01% — 15, 45 and 60g. tubes and 120 and 425g. jars.
Ointment 0.025% — 15 and 60g. tubes and 425g. jars.
Solution 0.01% — 20cc. and 60cc. plastic squeeze bottles.

Also Available
Synalar-HP® (fluocinolone acetonide) Cream 0.2% 5g. and 12g. tubes.

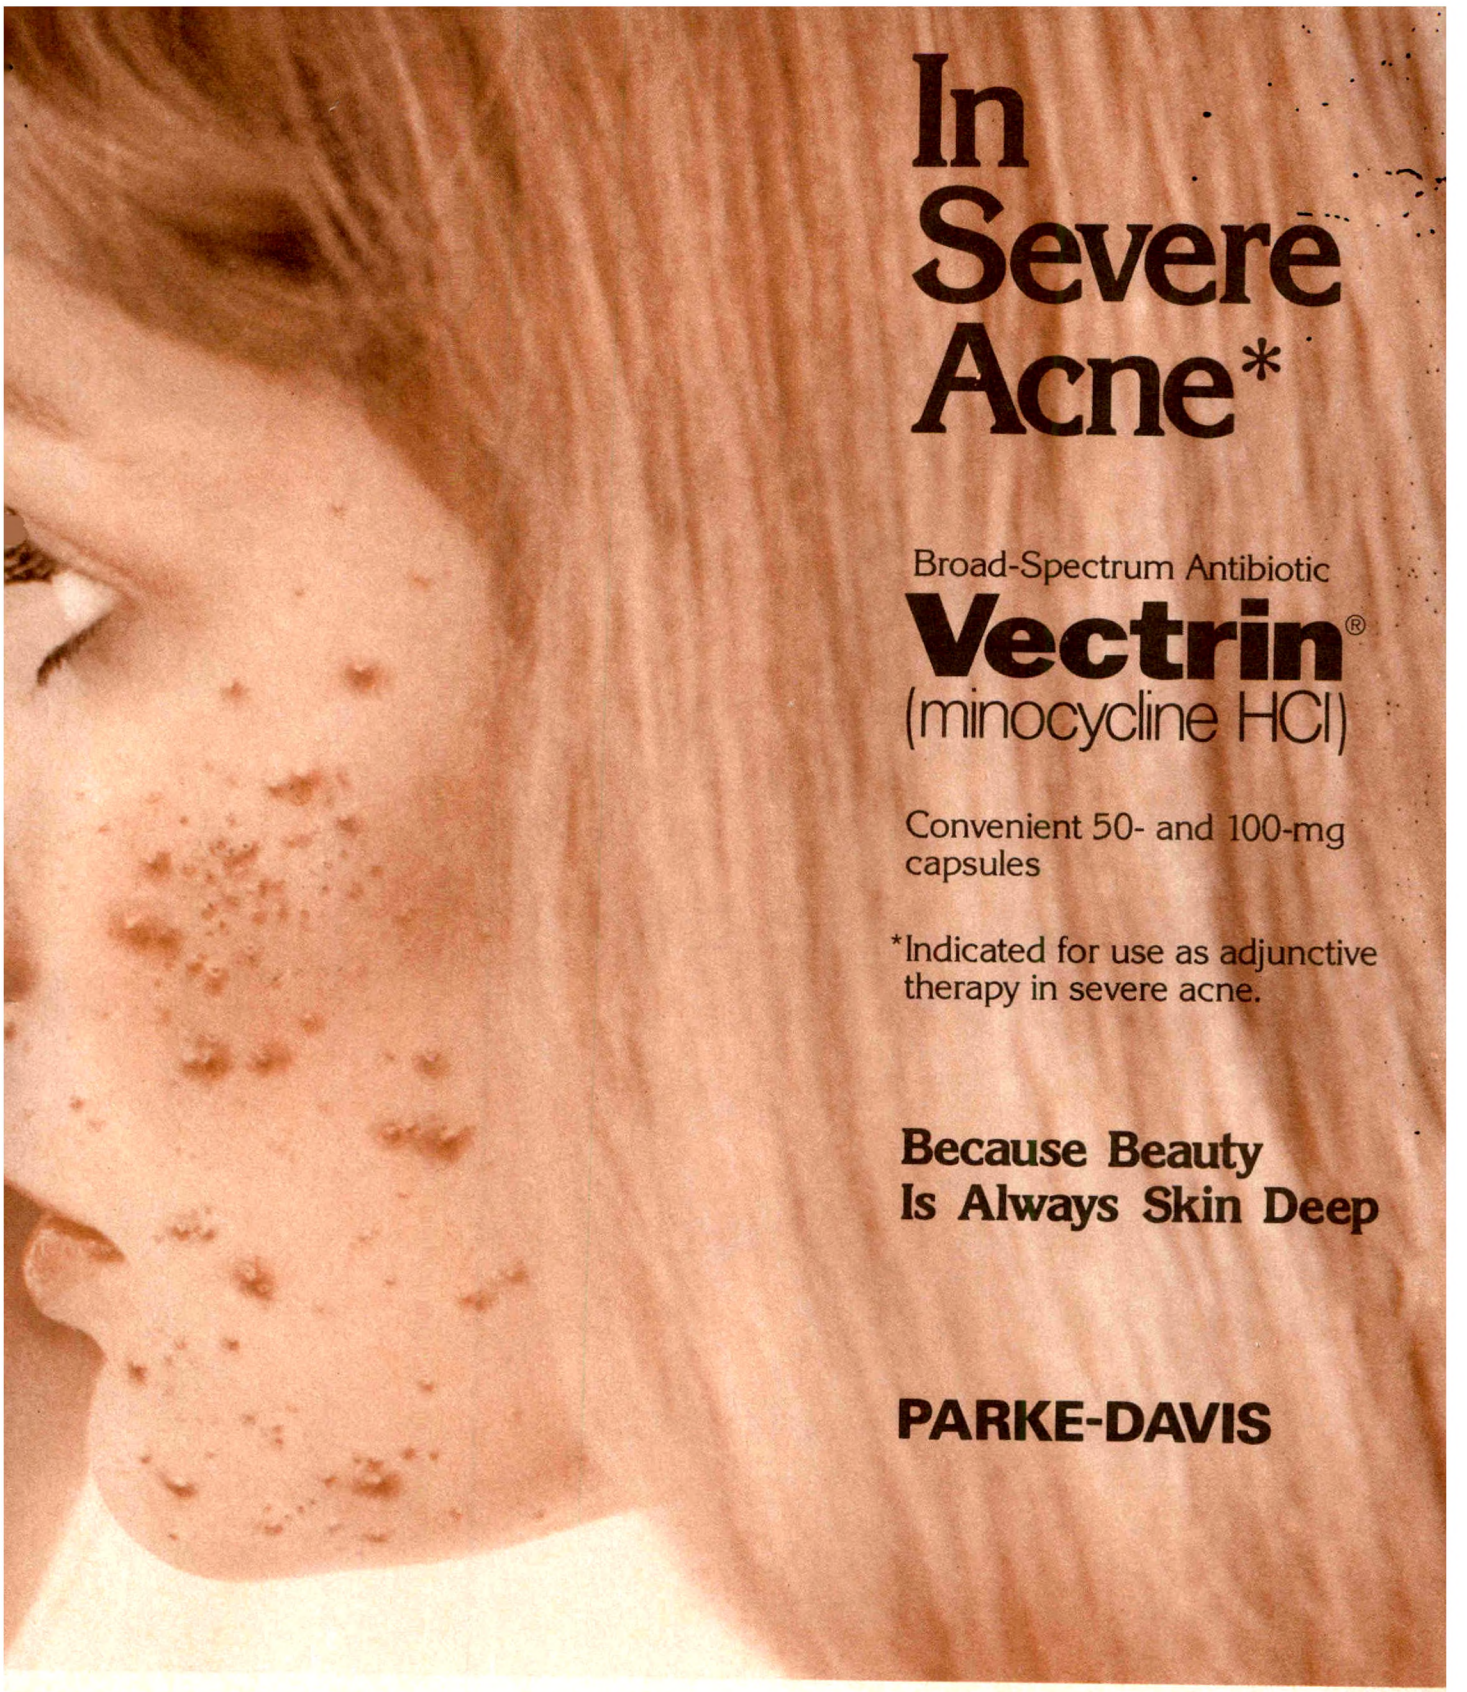
Acne illustrated by artist.

VECTRIN Capsules, 100 mg
(minocycline HCl capsules, USP)
Brief Summary of Prescribing Information

Indicated in severe acne as adjunctive therapy. Consult package insert for complete prescribing information.

Contraindication: Hypersensitivity to any tetracycline.

Warnings: When need for intensive treatment outweighs potential dangers, perform renal and liver function tests before and during therapy; also follow serum concentrations. In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, use lower total doses, and, in prolonged therapy, determine serum levels. The use of tetracyclines during tooth development (last half of pregnancy, infancy, and childhood to the age of 8 years) may cause permanent discoloration of the teeth (yellow-gray-brown). This is more common during long-term use but has been observed following repeated short-term courses. Enamel hypoplasia has also been reported. Tetracyclines, therefore, should not be used in this age group unless other drugs are not likely to be effective or are contraindicated. Photosensitivity manifested by an exaggerated sunburn reaction has been observed in some individuals taking tetracyclines. Advise patients apt to be exposed to direct sunlight or ultraviolet light that such reactions can occur, and discontinue treatment at first evidence of skin erythema. Studies with minocycline HCl indicated that photosensitivity did not occur. However, reports have been received in patients with significantly impaired renal function the antianabolic action of tetracycline may cause an increase in BUN leading to azotemia, hyperphosphatemia, and acidosis. **CNS side effects:** (light-headedness, dizziness, vertigo) have been reported, may disappear during therapy, and always disappear rapidly when drug is discontinued. Caution patients who experience these symptoms about driving vehicles or using hazardous machinery while taking this drug. **Pregnancy:** In animal studies, tetracyclines cross the placenta, are found in fetal tissues, and can have toxic effects on the developing fetus (often related to retardation of skeletal development). Embryotoxicity has been noted in animals treated early in pregnancy. The safety of minocycline HCl for use during pregnancy has not been established. **Newborns, infants, and children:** All tetracyclines form a stable calcium complex in any bone-forming tissue. Prematures given oral doses of 25 mg/kg every six hours, demonstrated a decrease in fibula growth rate reversible when drug was discontinued. Tetracyclines



In Severe Acne*

Broad-Spectrum Antibiotic

Vectrin®
(minocycline HCl)

Convenient 50- and 100-mg capsules

*Indicated for use as adjunctive therapy in severe acne.

Because Beauty Is Always Skin Deep

PARKE-DAVIS

are present in the milk of lactating women who are taking a drug in this class.

Precautions: Use may result in overgrowth of non-susceptible organisms, including fungi. If superinfection occurs, antibiotics should be discontinued and appropriate therapy instituted. In venereal diseases when coexistent syphilis is suspected, darkfield examination should be done before treatment is started and blood serology repeated monthly for at least four months. Patients on anticoagulant therapy may require downward adjustment of such dosage. Test for organ system dysfunction (eg, renal, hepatic, and hemopoietic) in long-term use. Treat all group A beta-hemolytic streptococcal infections for at least 10 days. Avoid giving tetracycline in conjunction with penicillin.

Adverse Reactions: GI: Anorexia, nausea, vomiting, diarrhea, glossitis, dysphagia, enterocolitis, inflammatory lesions (with monilial overgrowth) in anogenital region. **Skin:** Maculopapular and erythematous rashes. Exfoliative dermatitis (uncommon). Photosensitivity is discussed above. (See Warnings.) **Renal toxicity:** Rise in BUN, dose-related. (See Warnings.) **Hypersensitivity reactions:** Urticaria, angioneurotic edema, anaphylaxis, anaphylactoid purpura, pericarditis, exacerbation of systemic lupus erythematosus. In young infants, bulging fontanels have been reported following full therapeutic dosage, disappearing rapidly when drug was discontinued. **Blood:** Hemolytic anemia, thrombocytopenia, neutropenia, eosinophilia. **CNS:** (See Warnings.) When given over prolonged periods, tetracyclines may produce brown-black microscopic discoloration of thyroid glands; no abnormalities of thyroid function studies are known to occur.

NOTE: Concomitant therapy: Antacids containing aluminum, calcium, or magnesium impair absorption; do not give to patients taking oral tetracycline. Studies to date indicate that absorption of VECTRIN (minocycline hydrochloride) is not notably influenced by foods and dairy products.

Full prescribing information available upon request.

PARKE, DAVIS & COMPANY
Detroit, Michigan 48232

anti-
inflammatory
antifungal
antipruritic
antibacterial

Clear choice

When dermatoses become infected with bacteria or fungi, plain topical steroids are generally not the recommended therapeutic choice.

A clear choice, however, is Vioform® Hydrocortisone. With its unique four-way action, it supplies the kind of comprehensive treatment many common dermatoses* require.

*This drug has been evaluated as possibly effective for these indications. See brief prescribing information.

Vioform®-Hydrocortisone (iodochlorhydroxyquin and hydrocortisone)

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: Contact or atopic dermatitis; impetiginized eczema; nummular eczema; infantile eczema; endogenous chronic infectious dermatitis; stasis dermatitis; pyoderma; nuchal eczema and chronic eczematoid otitis externa; acne urticata; localized or disseminated neurodermatitis; lichen simplex chronicus; anogenital pruritus (vulvae, scroti, ani); folliculitis; bacterial dermatoses; mycotic dermatoses such as tinea (capitis, cruris, corporis, pedis); moniliasis; intertrigo. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Hypersensitivity to Vioform-Hydrocortisone, or any of its ingredients or related compounds; lesions of the eye; tuberculosis of the skin; most viral skin lesions (including herpes simplex, vaccinia, and varicella).

WARNINGS
This product is not for ophthalmic use.
In the presence of systemic infections, appropriate systemic antibiotics should be used.

Usage in Pregnancy
Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been established. Therefore, they should not be used extensively on pregnant patients in large amounts or for prolonged periods of time.

PRECAUTIONS
May prove irritating to sensitized skin in rare cases. If this occurs, discontinue therapy. May stain.
If used under occlusive dressings or for a prolonged period, watch for signs of pituitary-adrenal axis suppression.
May interfere with thyroid function tests. Wait at least one month after discontinuance of therapy before performing these tests. The ferric chloride test for phenylketonuria (PKU) can yield a false-positive result if Vioform is present in the diaper or urine.
Prolonged use may result in overgrowth of nonsusceptible organisms requiring appropriate therapy.

ADVERSE REACTIONS
Few reports include: Hypersensitivity, local burning, irritation, pruritus. Discontinue if untoward reaction occurs. Rarely, topical corticosteroids may cause striae at site of application when used for long periods in intertriginous areas.

DOSAGE
Apply a thin layer to affected areas 3 or 4 times daily.

HOW SUPPLIED
Cream, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of 5 and 20 Gm. *Ointment*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a petrolatum base; tubes of 20 Gm. *Lotion*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearic acid, cetyl alcohol, lanolin, propylene glycol, sorbitan trioleate, polysorbate 60, triethanolamine, methylparaben, propylparaben, and perfume Flora in water; plastic squeeze bottles of 15 ml. *Mild Cream*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of ½ and 1 ounce. *Mild Ointment*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a petrolatum base; tubes of 1 ounce.

Once-a-day dosage

NEW Fulvicin® P/G*

brand of griseofulvin [ultramicrosize], USP

(specially processed) **125 mg. tablets**

***"P/G" means a new polyethylene glycol system for enhanced absorption –**

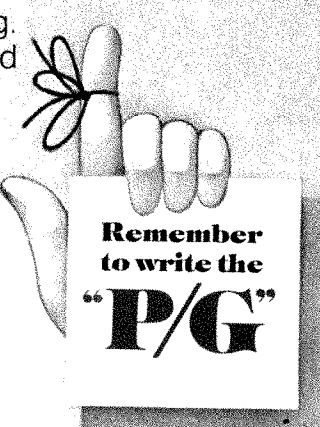
A 250 mg. daily dose (two 125 mg. tablets) of new FULVICIN P/G can replace 500 mg. of griseofulvin (microsize), USP. This is made possible by a special process in which the ultramicrosize griseofulvin crystals are partly dissolved in polyethylene glycol and dispersed through the tablet matrix for enhanced absorption.

Patient convenience –

FULVICIN P/G can be prescribed as two 125 mg. tablets once a day. Compliance is further assured by the easy-to-swallow size of the tablets.

Patient savings –

FULVICIN P/G is up to 35 per cent less expensive per dose than all microsize griseofulvin formulations.**



**Based on list-price comparison.

Schering

NEW P/G Fulvicin®

griseofulvin [ultramicrosize], USP

(specially processed) **125 mg. tablets**

Clinical Considerations: INDICATIONS FULVICIN P/G Tablets are indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: tinea corporis, tinea pedis, tinea cruris, tinea barbae, tinea capitis, tinea unguium (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes, Trichophyton interdigitalis, Trichophyton verrucosum, Trichophyton megnini, Trichophyton gallinae, Trichophyton crateriform, Trichophyton sulphureum, Trichophyton schoenleini, Microsporum audouini, Microsporum canis, Microsporum gypseum,* and *Epidermophyton floccosum*. Note: Prior to therapy, the type of fungi responsible for the infection should be identified. The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone. Griseofulvin is not effective in the following: Bacterial infections, Candidiasis (Moniliasis), Histoplasmosis, Actinomycosis, Sporotrichosis, Chromoblastomycosis, Coccidioidomycosis, North American Blastomycosis, Cryptococcosis (Torulosis), Tinea versicolor, and Nocardiosis. **CONTRAINDICATIONS** This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of hypersensitivity to griseofulvin. **WARNINGS** *Prophylactic Usage:* Safety and efficacy of griseofulvin for prophylaxis of fungal infections have not been established. *Animal Toxicology:* Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin once a week during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorogenicity, these studies were not of adequate design to form a basis for conclusions in this regard. In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals. *Usage in Pregnancy:* The safety of this drug during pregnancy has not been established. *Animal Reproduction Studies:* It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress. Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this. **PRECAUTIONS** Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic, and hematopoietic, should be done. Since griseofulvin is derived from species of penicillin, the possibility of cross sensitivity with penicillin exists, however, known penicillin-sensitive patients have been treated without difficulty. Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated. Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy. Barbiturates usually depress griseofulvin activity, and concomitant administration may require a dosage adjustment of the antifungal agent. **ADVERSE REACTIONS** When adverse reactions occur, they are most commonly of the hypersensitivity type, such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are: oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities. Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs. When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

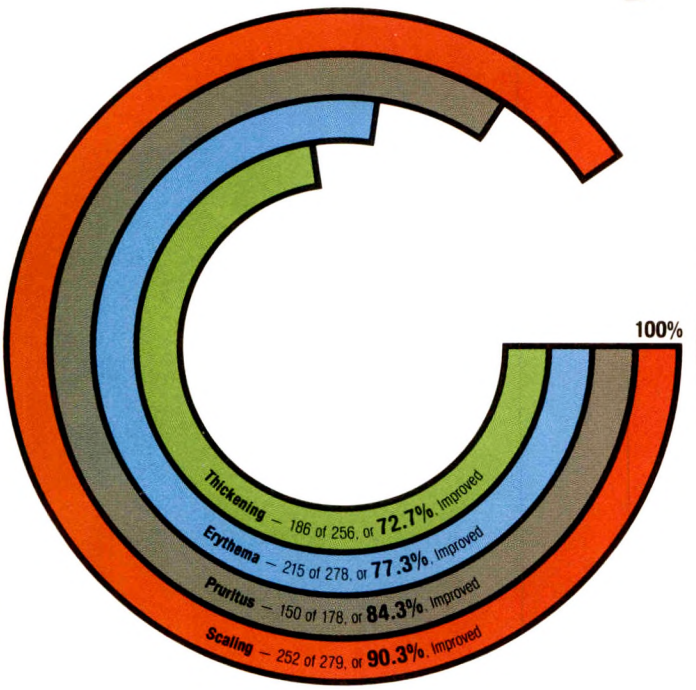
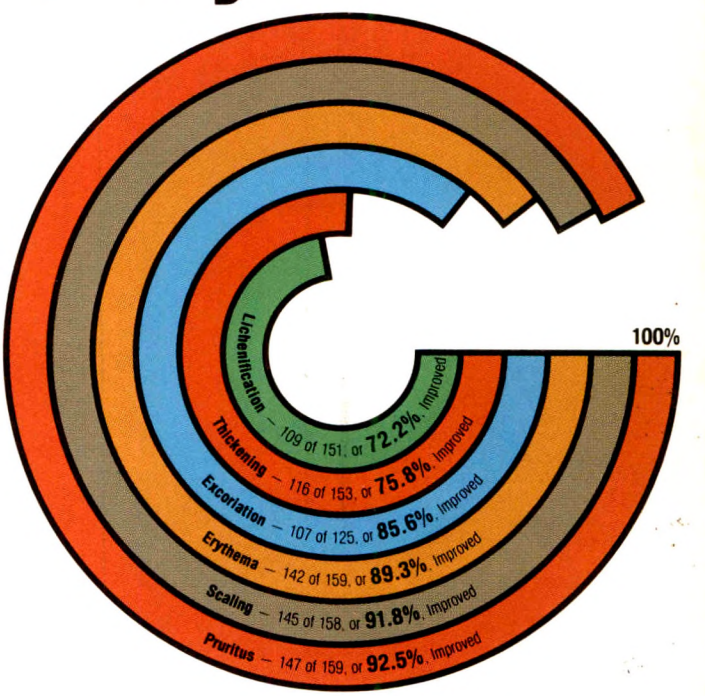
Inflammatory manifestations of psoriasis and atopic dermatitis...

Effectiveness demonstrated in only 8 days*



Psoriasis

In a study of 279 psoriatic patients



Atopic Dermatitis

In a study of 162 atopic dermatitis patients

Cordran® (Flurandrenolide)
Description: Cordran® (flurandrenolide, Dista) is a potent corticosteroid intended for topical use. **Actions:** Cordran is primarily effective because of its anti-inflammatory, antipruritic, and vasoconstrictive actions. **Indications:** For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses. **Contraindications:** Topical corticosteroids are contraindicated in vaccinia and varicella and in patients with a history of hypersensitivity to any of their components. **Precautions:** If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, an appropriate antifungal or antibacterial agent should be used. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, there is a possibility of increased systemic absorption of the corticosteroid, and suitable precautions should be taken. Although topical corticosteroids have not been reported to have an adverse effect on pregnancy, the safety of their use on pregnant women has not been absolutely established. Therefore, they should not be used extensively, in large amounts, or for prolonged periods of time on pregnant patients. These products are not for ophthalmic use. **Adverse Reactions:** The following local adverse reactions have been reported with topical corticosteroid formulations: acneform eruptions, burning, dryness, folliculitis, hypertrichosis, hypopigmentation, irritation, itching. The following may occur more frequently with occlusive dressings: maceration of the skin, miliaria, secondary infection, skin atrophy, striae. **Administration and Dosage:** For moist lesions, a small quantity of the cream or lotion should be rubbed gently into the affected areas two or three times a day. For dry, scaly lesions, the ointment is applied as a thin film to affected areas two or three times daily. [111875]

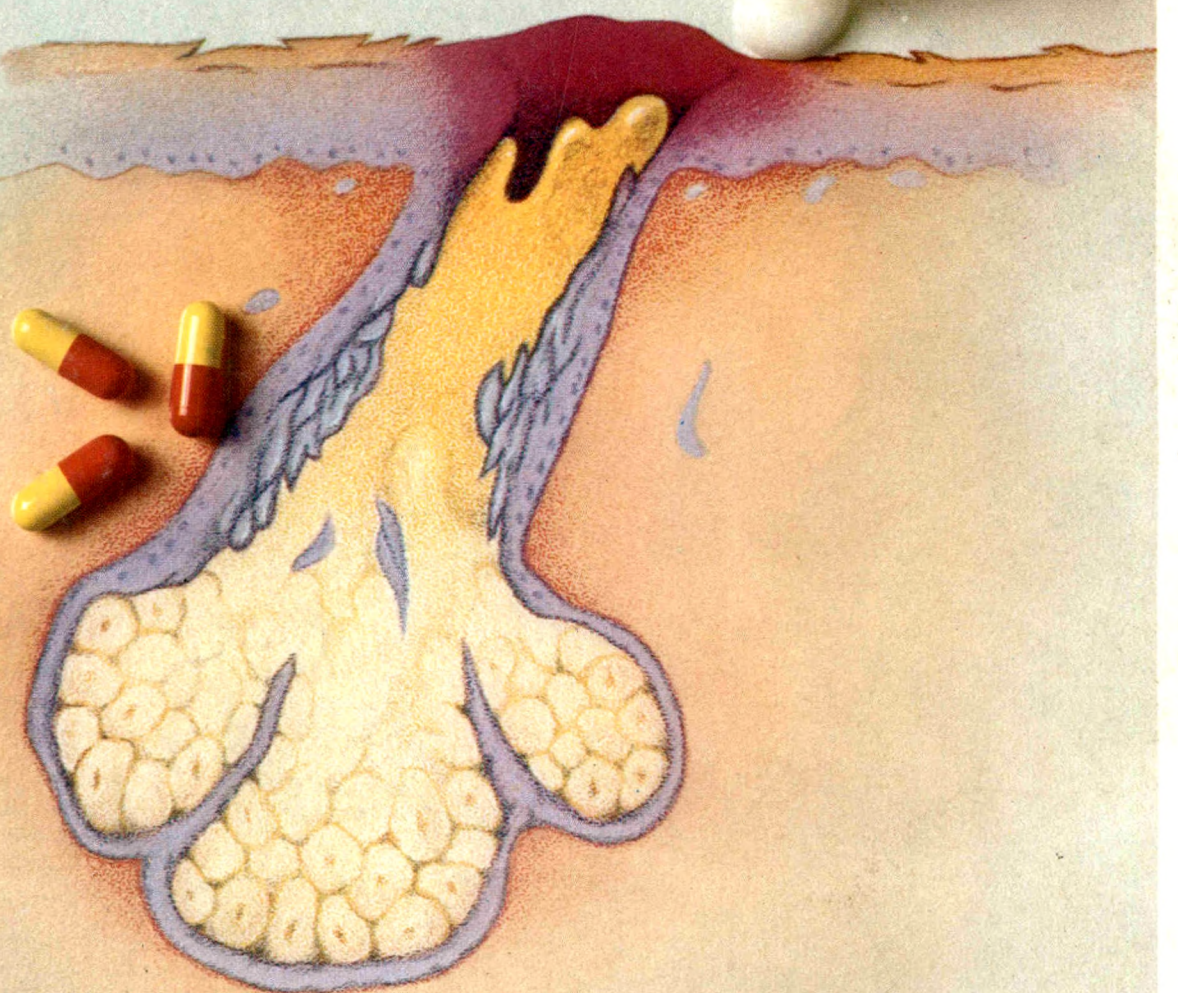
Efficacy is its strength

Desquam-X®

5 or 10% Benzoyl Peroxide 6% Polyoxyethylene Lauryl Ether

the topical side of C. acnes control



Desquam-X5®
Desquam-X10®

CONTENTS: Desquam-X 5 contains 5% Benzoyl Peroxide, 6% polyoxyethylene lauryl ether, 37% ethyl alcohol, carbomer 940, di-isopropanolamine, disodium edetate and water.

Desquam-X 10 contains 10% Benzoyl Peroxide, 6% polyoxyethylene lauryl ether, 37% ethyl alcohol, carbomer 940, di-isopropanolamine, disodium edetate and water.

INDICATION: A topical aid for the control of acne vulgaris.

ACTION: Provides the desirable drying and desquamation needed in the topical treatment of acne. Desquam-X has been demonstrated to have anti-bacterial effects, especially against Corynebacterium acnes.

DIRECTION FOR USE: After washing as instructed, rub Desquam-X into affected areas twice daily. In fair-skinned individuals or under excessively dry atmospheric conditions it is suggested that therapy be initiated with one application daily. The desired degree of drying and peeling can be obtained by modification of the dosage schedule.

CONTRAINDICATIONS: Not to be used in patients known to be sensitive to any ingredient of Desquam-X.

PRECAUTIONS: Avoid contact with eyes and mucous membranes. For external use only. Keep this and all medication out of the reach of children.

NOTE: May bleach colored fabrics.

HOW SUPPLIED: Plastic tubes 1.5 oz. (42.5 gm.)

CAUTION: Federal law prohibits dispensing without prescription.

Prevent over-abrasion. Prescribe the natural cleansing control of Komex.

For patients with oily skin or acne, the natural cleansing control of Komex offers a gentle alternative to harsh abradants. Oil, sebum, make-up and surface debris are cleansed away gently by the unique Komex combination of surface active agents and naturally occurring water soluble cleansing particles. The more water your patients use the more gently Komex cleanses.

For thorough cleansing and conditioning without over-abrasion, prescribe the natural cleansing control of Komex.

Caution: Avoid contact with eyes.
Do not use on inflamed skin.

SYNALAR®
(fluocinolone acetonide)
CREAM 0.025%
CREAM 0.01%
OINTMENT 0.025%
SOLUTION 0.01%

Description Synalar (fluocinolone acetonide) has the chemical name 6α, 9α-difluoro-16α-hydroxyprednisolone-16, 17-acetonide.

The cream contains fluocinolone acetonide 0.25 mg./g. or 0.1 mg./g. in a water-washable aqueous base of stearic acid, propylene glycol, sorbitan monostearate and monooleate, polysorbate 60, purified water and citric acid with methylparaben and propylparaben as preservatives.

The ointment contains fluocinolone acetonide 0.25 mg./g. in a white petrolatum U.S.P. vehicle.

The solution contains fluocinolone acetonide 0.1 mg./g. in a water-washable base of propylene glycol with citric acid.

Indications For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications Topical steroids are contraindicated in vaccinia and varicella.

Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions If irritation develops, the product should be discontinued and appropriate therapy instituted.

In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled.

If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Synalar products are not for ophthalmic use.

Adverse reactions The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, dryness, folliculitis, hypertrichosis, acneform eruptions, hypopigmentation.

The following may occur more frequently with occlusive dressings than without such therapy: maceration of the skin, secondary infection, skin atrophy, striae, miliaria.

How Supplied
Synalar (fluocinolone acetonide)
Cream 0.025% — 15 and 60g. tubes and 120 and 425g. jars.
Cream 0.01% — 15, 45 and 60g. tubes and 120 and 425g. jars.
Ointment 0.025% — 15 and 60g. tubes and 425g. jars.
Solution 0.01% — 20cc. and 60cc. plastic squeeze bottles.

Also Available
Synalar-HP® (fluocinolone acetonide) Cream 0.2% 5g. and 12g. tubes.

Conditions for Acceptance of Color Illustrations

Illustrations in full color are accepted for publication in ARCHIVES OF DERMATOLOGY if the editor believes that color will add significantly to the published manuscript.

When color illustrations are accepted, the American Medical Association will pay part of the expense of reproduction and printing, the remainder to be borne by the author or the institution with which he is affiliated. After deducting AMA's contribution, the author's share is $275 for up to six square finished illustrations. Additional illustrations and special effects, such as outlining, opaquing, or surprinting, will be billed to the author at cost.

Color transparencies must be submitted for evaluation. Do not send color prints unless accompanied by original transparencies. If transparencies are mounted in frames or glass, the material should be carefully packed in gauze and sent with the manuscript in a separate container or between two pieces of pressboard.

Dome

NOW... the only stable nystatin lotion available.

New Candex® (nystatin) Lotion

- ☐ for a dermatologic need
- ☐ for control of candidal infections
- ☐ for cosmetic elegance

New CANDEX Lotion offers excellent penetration around fingernails, into hairy areas and into infected tissue. It soothes inflammation and chafed or macerated skin. And it is paraben-free for the patient with that special sensitivity.

Also Available: CANDEX Creme (nystatin)

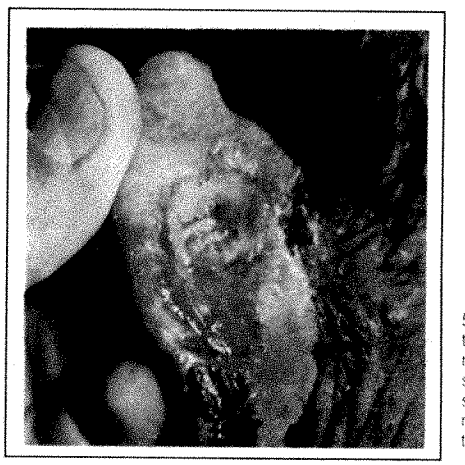
Indications: Candex (nystatin) Lotion and Creme are indicated for the treatment of cutaneous or mucocutaneous mycotic infections caused by Candida species (Monilia). A lotion is preferred on oozing intertriginous areas. **Contraindications:** Lesions caused by pathogens not susceptible to nystatin, and hypersensitivity to any of the components. **Precautions:** If irritation or sensitivity occurs and/or infection persists, discontinue use. If new infections appear, appropriate therapy should be instituted. **Caution:** Federal (USA) law prohibits dispensing without prescription. For external use only. Not for ophthalmic use. Store Candex (nystatin) Lotion below 86 F (30 C); avoid freezing; shake well. **Dosage and Administration:** Apply two or three times daily. Continue use for one week after clinical cure. **How Supplied:** Candex (nystatin) Lotion in 30 ml plastic bottles; Candex (nystatin) Creme in 15 g tubes.

Dome Laboratories

Division Miles Laboratories Inc
West Haven Connecticut 06516 U

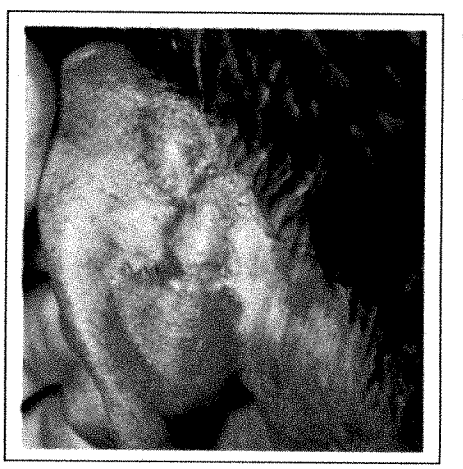
© 1977 DOME LABORATORIES, DIVISION MILES LABORATORIES, INC. ALL RIGHTS RESERVED.

2/6/70—Before treatment a 3.0 cm lesion was present behind left ear. Biopsy revealed it to be a superficial basal cell carcinoma. Treatment with Efudex (fluorouracil) 5% Cream was begun.



5/1/70—After 11 weeks' therapy, lesion site was necrotic and escharified; surrounding skin showed minimal inflammation. Treatment was terminated 4/24/70.

9/10/70—Area completely healed; posttreatment biopsy revealed no further carcinoma.



6/15/72—Patient 25 months posttreatment. No evidence of recurrence.

Management of superficial basal cell carcinoma is often complicated by multiple lesions which extend over large areas of the body. Until now, primary treatment has been surgery or radiation therapy. However, these modalities may be followed by scarring and disfigurement.

Topical chemotherapy with Efudex (fluorouracil) 5% is a valuable alternative when conventional methods are impractical. For example, it is an effective agent for the concurrent treatment of superficial lesions over large areas of the body, or for use on difficult treatment sites.

Although during treatment with Efudex the lesion and some of the surrounding skin may become inflamed and blistered temporarily, final results are cosmetically gratifying, with minimal or no scarring.

Efudex 5% Cream offers the dermatologist:

- An effective topical alternative to surgery for multiple lesions and difficult treatment sites.
- Cosmetically gratifying results, with minimal or no scarring. No systemic toxicity.
- Convenient, economical b.i.d. application. Apply with care near eyes, nose and mouth; wash hands immediately afterward if applied with fingers.

Efudex® 5% Cream
fluorouracil/Roche

An exclusive Roche formulation
Also available as 5% Efudex Solution

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Multiple actinic or solar keratoses. In 5% strength, superficial basal cell carcinoma when conventional methods are impractical, such as with multiple lesions or difficult treatment sites. Establish diagnosis before treating, as this method has not been proven effective in other types of basal cell carcinomas. Conventional techniques preferred for isolated, easily accessible lesions, as success rate is nearly 100%. Success rate with Efudex is about 93%.

Contraindications: Patients with known hypersensitivity to any of its components.

Warnings: If occlusive dressing is used, may increase inflammatory reactions in adjacent normal skin. Avoid prolonged exposure to ultraviolet rays. Safe use in pregnancy not established.

Precautions: If applied with fingers, wash hands immediately. Apply with care near eyes, nose and mouth. Solar keratoses failing to respond should be biopsied. Warn patients that treated area may be unsightly during therapy and sometimes for several weeks after. Perform follow-up biopsies in superficial basal cell carcinoma.

Adverse Reactions: Local—pain, pruritus, hyperpigmentation and burning at application site most frequent; also dermatitis, scarring, soreness, tenderness, suppuration, scaling and swelling. Also reported—insomnia, stomatitis, irritability, medicinal taste, photosensitivity, lacrimation, telangiectasia, leukocytosis, thrombocytopenia, toxic granulation and eosinophilia.

Dosage and Administration: When Efudex is applied erythema occurs, then vesiculation, erosion, ulceration, necrosis, epithelization. *Actinic or solar keratosis*—apply sufficient quantity to cover lesions, twice daily. Usual length of therapy is 2 to 4 weeks. *Superficial basal cell carcinomas*—apply sufficient quantity **(only 5% strength recommended)** to cover lesions, twice daily. Continue treatment for at least 3 to 6 weeks, but possibly as long as 10 to 12.

How Supplied: Solution, 10-ml drop dispensers containing 2% or 5% fluorouracil on a weight/weight basis. Cream, 25-Gm tubes containing 5% fluorouracil in a vanishing cream base.

Instructions for Authors

Send manuscripts by first-class mail to the Chief Editor, John H. Epstein, MD, 450 Sutter St, San Francisco, CA 94108. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

In addition, in view of *The Copyright Revision Act of 1976*, generally effective Jan 1, 1978, all transmittal letters to the editor must contain the following language before manuscripts can be reviewed for possible publication: "In consideration of AMA's taking action in reviewing and editing my (our) submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA." We regret that transmittal letters not containing the foregoing language signed by all authors of the manuscript will necessitate return of your manuscript.

Author Responsibility.—All accepted manuscripts are subject to copy editing. The author will receive an edited typescript rather than galley proofs for approval. The author is responsible for all statements in his work, including changes made by the copy editor.

Designate one author as correspondent and provide his address and telephone number. Order reprints at the time the typescript is returned after editorial processing. Specify address to which requests for reprints should be sent.

Manuscript Preparation.—Submit an original typescript and two high-quality copies of the entire manuscript. All copy (including references, legends, and tables) must be typed double-spaced on 22 × 28-cm (8½ × 11-inch), heavy-duty white bond paper. Ample margins should be provided.

Refer to patients by number (or, in anecdotal reports, by fictitious given names). Real names or initials should not be used in the text, tables, or illustrations.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines, if possible. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Style of Writing.—The style of writing should conform to acceptable English usage and syntax. Slang, medical jargon, obscure abbreviations, and abbreviated phrasing are to be avoided.

Informed Consent.—Manuscripts reporting the results of experimental investigations of human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Abstract.—Provide an abstract (135-word maximum) of the article, including statements of the problem, method of study, results, and conclusions. The abstract replaces the summary.

References.—List references in consecutive numerical order (not alphabetically). Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communications should not be listed as references. References to journal articles should include (1) author(s), (2) title, (3) journal name (as abbreviated in *Index Medicus*), (4) volume number, (5) inclusive page numbers, and (6) year, in that order. References to books should include (1) author(s), (2) chapter title (if any), (3) editor (if any), (4) title of book, (5) city of publication, (6) publisher, and (7) year. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. The author is responsible for the accuracy and completeness of the references and for their correct text citation.

Metrication.—All measurements must be in metric units. English units may also be given parenthetically if the measurements were originally done in English units.

Illustrations.—Use only those illustrations that clarify and augment the text. Submit illustrations in duplicate, *unmounted* and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Magnification and stain should be provided when pertinent. Illustrations should preferably be in a proportion of 12.5 × 18 cm (5 × 7 inches).

An experienced medical illustrator should be employed whenever possible for the preparation of all artwork. Template lettering or preset type is preferred to hand-lettered labels. If halftone artwork with labels is submitted, affix type and leaders to a clear acetate overlay registered to the base drawing. Labels and leaders should be applied directly to the drawing board surface if the artwork consists only of line ink technique.

Illustrations in full color are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay part of the expense of reproduction and printing color illustrations, the remainder to be borne by the author or his sponsor. After deducting the ARCHIVES contribution, the author's share is $275.00 for up to six square-finished illustrations that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35 mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies. All transparencies should be carefully packed and sent with the manuscript.

Legends.—Legends should be typed double-spaced, beginning on a separate sheet of paper. Length should be limited to a maximum of 40 words.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: author(s), title of article, title of journal or book, volume number, page(s), month, and year. The publisher's permission to reprint should be submitted to the ARCHIVES after the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluations should include the name and affiliation of the statistical reviewer.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm (8½ × 11-inch) paper. Do not use larger size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

IN SKIN INFECTIONS, WHERE CLEANLINESS REQUI MORE THAN SOAP

BETADINE® Skin Cleanser

Degerms as it cleanses

'atients can use BETADINE Skin Cleanser to degerm and cleanse face, hands and body, gently an' 'articularly when it is essential to prevent autoinoculation of new sites, as may be the case in infecte

BETADINE Skin Cleanser, with its rich, golden lather, provides these advantages:

- Prompt, broad-spectrum microbicidal action—kills both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts.
- Maintains microbicidal activity in the presence of blood, pus and serum.
- Virtually nonirritating to skin and muc
- Nonstaining to skin and natural fabric

Supplied: 4 fl. oz. plastic bottles.

*In the rare instance of local irritation or sensitivity, by the individual.

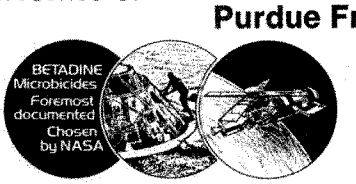
NORWALK, CONN. 06856



Superior to the most widely used brand of topical steroid in psoriasis and atopic dermatitis.

Based on the evidence.

In double-blind, parallel studies,* Topicort® (desoximetasone) Emollient Cream 0.25% demonstrated greater efficacy than betamethasone valerate cream 0.1% in the two most common corticosteroid-responsive dermatoses.

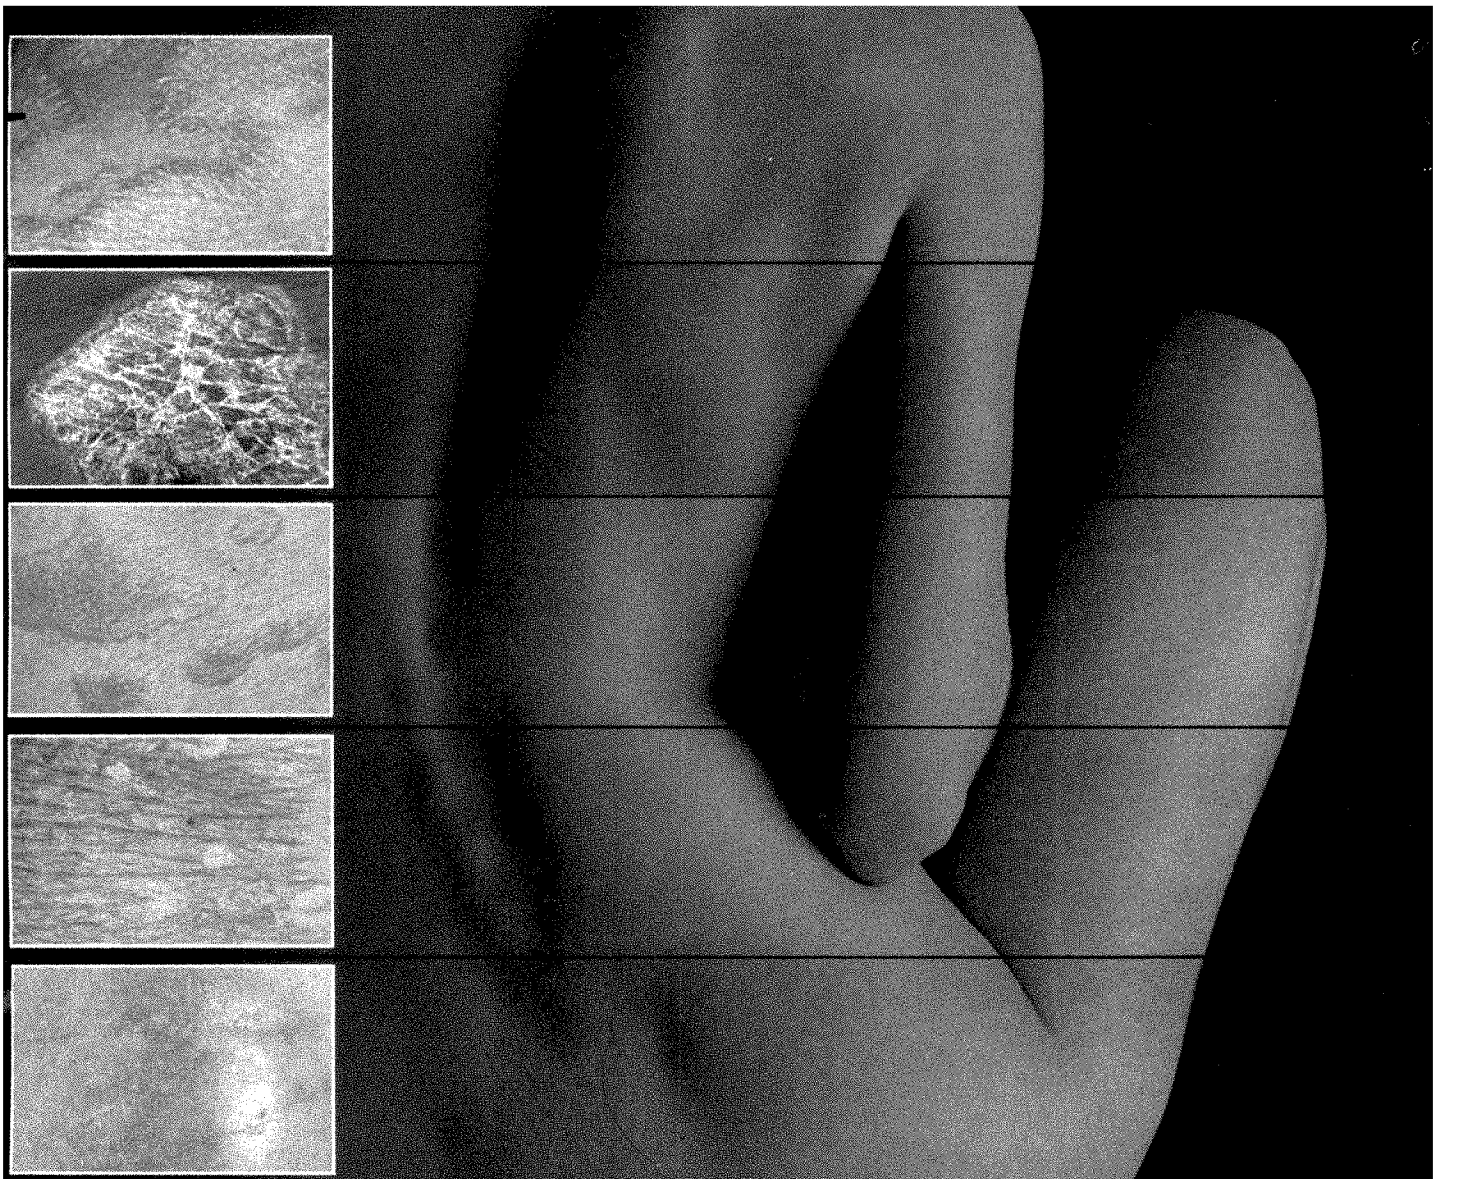
		NO. OF PATIENTS	Overall Evaluation: EXCELLENT & GOOD	Overall Evaluation: EXCELLENT (CLEARANCE OF DISEASE)
ATOPIC DERMATITIS	TOPICORT	39	100%	77%
	BETAMETHASONE VALERATE	41	90%	54%
PSORIASIS	TOPICORT	61	84%	43%
	BETAMETHASONE VALERATE	56	63%	21%

These recently conducted U.S. studies confirm the outstanding worldwide acceptance of Topicort in more than 30 countries for up to 4 years.

*Data on file and available upon request from Hoechst-Roussel Pharmaceuticals Inc.,

Less than 1% incidence of side effects.
Of 488 patients in the clinical trials, side effects were seen in only 4 (0.8%).* And in 2 of the 4 patients, the relationship of side effects to the drug was uncertain.

The convenience of b.i.d. dosage. And the uniqueness of a preservative-free, emollient cream base.
The specially developed, preservative-free Topicort base combines the emollience of an ointment with the cosmetic acceptability of a cream in a water-in-oil emulsion. This makes Topicort (desoximetasone) especially useful in psoriatic and

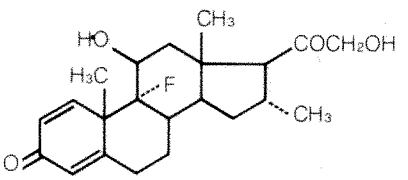


TOPICORT®
(DESOXIMETASONE)
EMOLLIENT CREAM 0.25%

An important innovation from the research laboratories of
Hoechst-Roussel Pharmaceuticals Inc.

TOPICORT® (desoximetasone) EMOLLIENT CREAM 0.25%

Description: Topicort® (desoximetasone) Emollient Cream 0.25% contains the active synthetic corticosteroid desoximetasone. The chemical name of desoximetasone is 9α - fluoro - 11β, 21 - dihydroxy - 16α - methylpregna - 1,4 - diene-3,20-dione. The chemical structure is:



Each gram of Topicort® (desoximetasone) Emollient Cream 0.25% contains 2.5 mg desoximetasone in an emollient cream consisting of isopropyl myristate, cetylstearyl alcohol, white petrolatum, mineral oil, lanolin alcohol and purified water.

Actions: Topicort® (desoximetasone) Emollient Cream is primarily effective because of its anti-inflammatory, antipruritic and vasoconstrictive actions.

Indications: Topicort® (desoximetasone) Emollient Cream is indicated for the relief of inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications: Topical steroids are contraindicated in vaccinia, varicella and in those patients with a history of hypersensitivity to any of the components of the preparation. This preparation is not for ophthalmic use.

Precautions: If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled.

Although systemic side effects associated with absorption of topical corticosteroid preparations are rare, their possible occurrence must be kept in mind when these preparations are used over large areas or for an extended period of time, or if occlusive technique is used.

If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Adverse Reactions: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria.

Dosage and Administration: Apply a thin film of Topicort® (desoximetasone) Emollient Cream 0.25% to the affected skin areas twice daily. Rub in gently.

How Supplied: Topicort® (desoximetasone) Emollient Cream 0.25% is supplied in 15-gram tubes.

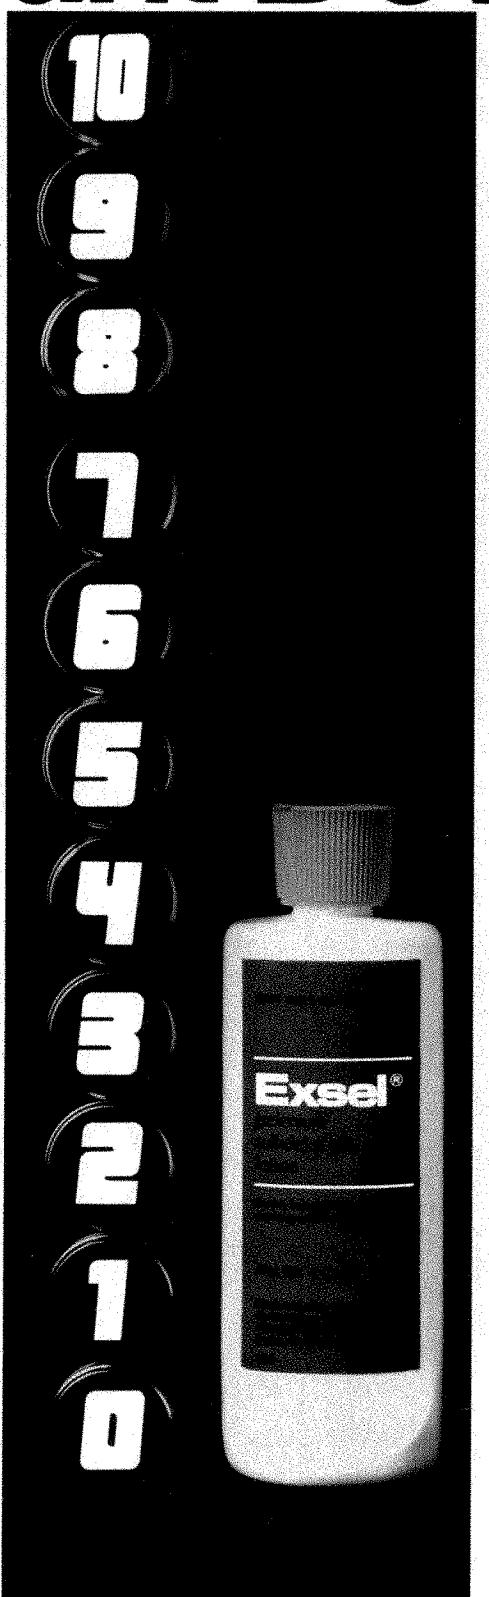
The Corneocyte Count Down.

A high corneocyte count means scaling, flaking and an itchy scalp. Unsightly and unwanted by your dandruff patients.

Chances are they have tried the TV-promoted brands before consulting you about their problem.

Prescribe Exsel® (selenium sulfide) 2.5%. Clinically proven the most potent dandruff shampoo available. It gets rid of the unwanted corneocyte scales and retards their redevelopment for days.*

And Exsel offers one distinct advantage over other Rx anti-dandruff preparations: cosmetic elegance. Pleasing, fragrant lime-scented Exsel shampoo lathers richly, therefore assuring greater patient acceptability and better compliance with your instructions.



Exsel® (selenium sulfide) 2.5% Lotion- CONTAINS: selenium sulfide...2.5% with: edetate disodium; bentonite; sodium linear alkylate sulfonate; alphaolefin sulfonate; glyceryl monoricinoleate; silicone; titanium dioxide; citric acid monohydrate; sodium phosphate monobasic, monohydrate; perfume and purified water. ACTIONS: The mechanism of action of selenium sulfide in seborrheic dermatitis is unknown. INDICATIONS: Selenium sulfide is indicated in the treatment of seborrheic dermatitis of the scalp, including dandruff. CONTRAINDICATIONS: The product should not be used by patients allergic to any of its components. WARNINGS: Safety for use in infants has not been established. PRECAUTIONS: 1. Chemical conjunctivitis may result if this preparation enters the eyes. 2. The product should be used with caution when acute inflammation or exudation is present as an increase in absorption may occur. ADVERSE REACTIONS: 1. Hair loss has been reported with the use of the product. 2. Discoloration of the hair may follow the use of selenium sulfide. This can be minimized by careful rinsing of the hair after treatment. 3. Oiliness of the hair and scalp may increase following the use of this product.

for dry and itchy winter skin...

EMULAVE® BAR

non-alkaline, soap-free, not only cleans but helps keep moisture in.

Here's why EMULAVE satisfies patients...and you:

- More available natural emollients than any other cleansing bar. EMULAVE is enriched with 29% skin-softening emollients, which help replenish skin lipids and provide the protective coating that seals in normal skin moisture.
- Contains no soap. A special skin-tested synthetic agent provides the cleansing and sudsing action... with minimal drying effect.
- Contains 30% AVEENO Colloidal Oatmeal for soothing, anti-pruritic, anti-inflammatory action.
- EMULAVE pH approximates that of normal skin.

Available in 3-oz. bars.

When patient acceptance is half the problem

sebutone®

is the answer.

Tar is effective therapy, but it has one big drawback . . . most shampoos look like tar and, worst of all, they smell like it, too.

Sebutone® provides tar therapy with unique patient acceptance.

- Itching usually stops after the first shampoo.
- It has a clean, fresh odor patients will like.
- It is a rich, lathering shampoo with a pleasant color.
- It contains the first chemically and biologically standardized tar, developed by Westwood.
- Sebutone's tar is bioassayed to insure therapeutic activity from batch to batch.
- Available in both lotion and cream.
- In addition to 0.5% Westwood® Tar, Sebutone contains 2% sulfur and 2% salicylic acid, for increased effectiveness.
- Wood's light shows that microfine particles remain on the scalp for up to three days to provide sustained antiseborrheic action.

sebutone® Therapeutic Tar Shampoo

. . . Substantive therapy...proven by Wood's light.

Available—Sebutone in 4 and 8 oz. bottles; Sebutone Cream in 4 oz. tubes.

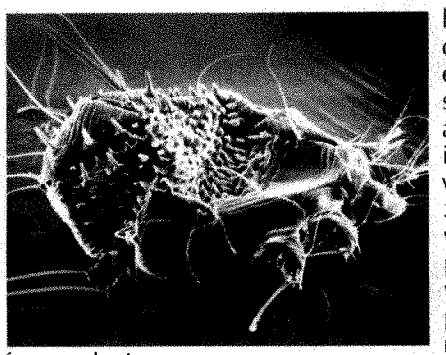
SWW-9340

THE ONLY WAY TO END THE EPIDEMIC IS OVER HER DEAD BODY.

Kill the female itch mite (*sarcoptes scabiei*) and you've stopped the current scabies epidemic. Because when she burrows deep into the stratum corneum, she defies diagnosis and resists removal by surface-acting medications and cleansers. Her success has been making headlines around the country—with reports of scabies outbreaks in rural and suburban areas as well as in the cities.



A quick and simple diagnosis. Scabies can mimic a number of dermatological conditions,[1-3] such as urticaria, furunculosis and dermatitis—as well as syphilis with which it may coexist. But there's an almost foolproof way to recognize it. Even in the absence of the fierce nocturnal itching[3] and the lesion distribution characteristic of the disease (hands, wrists and elbows in 9 out of 10 cases),[1] a quick microscopic look can confirm your scabies diagnosis.

To demonstrate the itch mite, look for an unscratched, inhabited burrow (wherever the patient says he itches at that very moment is a likely spot). Use a strong light, a magnifying glass and a surgical blade to which a drop of mineral oil is added. Scrape several sites. Transfer the material to a slide, cover and examine under low power magnification.[1,3,4] (If you don't spot any parasites in egg, larvae or adult stages, look for their red fecal compactions. They can be just as diagnostic.)

Kwell: penetrating action to kill mites, their eggs and larvae. Once you've found scabies, there's a positive way to eradicate it. Kwell (1% gamma benzene hexachloride) Lotion or Cream. It penetrates to reach the scabietic burrows, kills the female mites and, of course, the less tenacious males, as well as their eggs and any larvae that may have hatched. In fact, Kwell works so consistently and well against scabies that it has been the most widely prescribed scabicide for three decades.

Nearly 100% effective. The clinical record of Kwell has never been surpassed by any other pediculicide. It is "nearly 100% effective,"[1] and often works with a single application (a second or third application may be made at weekly intervals, if needed). Your patients will appreciate the low risk of sensitization and irritation.[5,6] And you will appreciate that Kwell works so predictably that it serves to confirm your diagnosis of scabies. Not many pharmaceutical preparations can match *that* record of dependability.

Contraindications: Kwell is contraindicated in individuals who develop hypersensitivity to the product or to any of its components.

Precautions: If accidental ingestion occurs, prompt institution of gastric lavage will rid the body of large amounts of the toxicant. However, since oils favor absorption, saline cathartics for intestinal evacuation should be given rather than oil laxatives.

Central nervous system manifestations can be antagonized by the administration of pentobarbital or phenobarbital in sufficiently large doses to the limit of their therapeutic effectiveness. It is not desirable to depress the patient to the point of hypnosis. However, persons poisoned with stimulants may tolerate large doses of barbiturate without undue depression and with great benefit. Intravenous calcium gluconate may be used in conjunction with the barbiturates. Epinephrine should not be used because ventricular fibrillation may result.

If accidental contact with eyes occurs, flush with water. If irritation or sensitization occurs, discontinue the product and consult physician.

Adverse Reactions: Eczematous eruptions due to sensitization of this product have been reported.

Available on prescription as Kwell Lotion in 2 and 16 fl. oz. bottles, and as Kwell Cream in 2 oz. and 1 lb. jars. See package insert for complete prescribing information.

KWELL® gamma benzene hexachloride

THE SCABICIDE OF CHOICE.

An unsurpassed standard of therapy

antifungal
antipruritic
antibacterial
anti-
inflammatory
TAXI

Clear choice

When dermatoses become infected with bacteria or fungi, plain topical steroids are generally not the recommended therapeutic choice.

A clear choice, however, is Vioform® Hydrocortisone. With its unique four-way action, it supplies the kind of comprehensive treatment many common dermatoses* require.

*This drug has been evaluated as possibly effective for these indications. See brief prescribing information.

Vioform®-Hydrocortisone (iodochlorhydroxyquin and hydrocortisone)

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: Contact or atopic dermatitis; impetiginized eczema; nummular eczema; infantile eczema; endogenous chronic infectious dermatitis; stasis dermatitis; pyoderma; nuchal eczema and chronic eczematoid otitis externa; acne urticata; localized or disseminated neurodermatitis; lichen simplex chronicus; anogenital pruritus (vulvae, scroti, ani); folliculitis; bacterial dermatoses; mycotic dermatoses such as tinea (capitis, cruris, corporis, pedis); moniliasis; intertrigo.
Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Hypersensitivity to Vioform-Hydrocortisone, or any of its ingredients or related compounds; lesions of the eye; tuberculosis of the skin; most viral skin lesions (including herpes simplex, vaccinia, and varicella).

WARNINGS
This product is not for ophthalmic use.
In the presence of systemic infections, appropriate systemic antibiotics should be used.

Usage in Pregnancy
Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been established. Therefore, they should not be used extensively on pregnant patients in large amounts or for prolonged periods of time.

PRECAUTIONS
May prove irritating to sensitized skin in rare cases. If this occurs, discontinue therapy. May stain.
If used under occlusive dressings or for a prolonged period, watch for signs of pituitary-adrenal axis suppression.
May interfere with thyroid function tests. Wait at least one month after discontinuance of therapy before performing these tests. The ferric chloride test for phenylketonuria (PKU) can yield a false-positive result if Vioform is present in the diaper or urine.
Prolonged use may result in overgrowth of nonsusceptible organisms requiring appropriate therapy.

ADVERSE REACTIONS
Few reports include: Hypersensitivity, local burning, irritation, pruritus. Discontinue if untoward reaction occurs. Rarely, topical corticosteroids may cause striae at site of application when used for long periods in intertriginous areas.

DOSAGE
Apply a thin layer to affected areas 3 or 4 times daily.

HOW SUPPLIED
Cream, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of 5 and 20 Gm. *Ointment*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a petrolatum base; tubes of 20 Gm. *Lotion*, 3% iodochlorhydroxyquin and 1% hydrocortisone in a water-washable base containing stearic acid, cetyl alcohol, lanolin, propylene glycol, sorbitan trioleate, polysorbate 60, triethanolamine, methylparaben, propylparaben, and perfume Flora in water; plastic squeeze bottles of 15 ml. *Mild Cream*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a water-washable base containing stearyl alcohol, cetyl alcohol, stearic acid, petrolatum, sodium lauryl sulfate, and glycerin in water; tubes of ½ and 1 ounce. *Mild Ointment*, 3% iodochlorhydroxyquin and 0.5% hydrocortisone in a petrolatum base; tubes of 1 ounce.

LIDEX® (fluocinonide)
0.05% Cream and Ointment

TOPSYN® (fluocinonide)
0.05% Gel

Summary of prescribing information

Description
LIDEX cream 0.05%, LIDEX ointment 0.05% and TOPSYN gel 0.05% contain the active compound fluocinonide. Fluocinonide, which is the 21-acetate ester of fluocinolone acetonide, has the chemical formula 6α, 9α-difluoro-11β, 16α, 17α, 21-tetrahydroxypregna-1,4-diene-3, 20-dione, cyclic 16, 17-acetal with acetone 21-acetate. LIDEX cream contains fluocinonide in FAPG® cream, a specially formulated cream base consisting of stearyl alcohol, polyethylene glycol 6000, propylene glycol, 1, 2, 6-hexanetriol and citric acid. This white cream vehicle is greaseless, non-staining, anhydrous and completely water miscible. The base provides emollient and hydrophilic properties. In this formulation, the active ingredient is totally in solution.

LIDEX ointment contains fluocinonide in a specially formulated ointment base consisting of Amerchol CAB (mixture of sterols and higher alcohols), white petrolatum, propylene carbonate and propylene glycol. It provides the occlusive and emollient effects desirable in an ointment. In this formulation the active ingredient is totally in solution.

TOPSYN gel contains fluocinonide in a specially formulated gel base consisting of propylene glycol, propyl gallate, disodium edetate, and Carbopol 940 (carboxypolymethylene) with NaOH and/or HCL added to adjust the pH. This clear, colorless, thixotropic vehicle is greaseless, non-staining and completely water miscible. In this formulation, the active ingredient is totally in solution.

Indications
LIDEX cream and ointment and TOPSYN gel are intended for the relief of inflammatory manifestations of corticosteroid responsive dermatoses.

Contraindications
Topical steroids are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions
If irritation develops, the cream, ointment or gel should be discontinued and appropriate therapy instituted. In the presence of an infection the use of an appropriate antifungal or antibacterial agent should be instituted.

If a favorable response does not occur promptly, the corticosteroid cream, ointment or gel should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, the possibility exists of increased systemic absorption and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

LIDEX® (fluocinonide) cream and ointment and TOPSYN® (fluocinonide) gel are not for ophthalmic use.

Adverse reactions
The following local adverse reactions have been reported with topical corticosteroids:

burning	folliculitis
itching	acneform eruptions
irritation	hypopigmentation
dryness	striae
secondary infection	skin atrophy

Dosage and administration
A small amount should be gently massaged into the affected area three or four times daily, as needed.

How supplied
LIDEX 0.05% Cream—15 g 30 g and 60 g tubes.
LIDEX 0.05% Ointment—15 g 30 g and 60 g tubes.
TOPSYN Gel 0.05% 15 g and 60 g tubes.

Pure mild Ivory is one of the safest possible soaps you can recommend for delicate skin. More doctors recommend Ivory than any other soap.

It makes sense. Ivory's absence of many extra ingredients helps minimize chances of irritation.

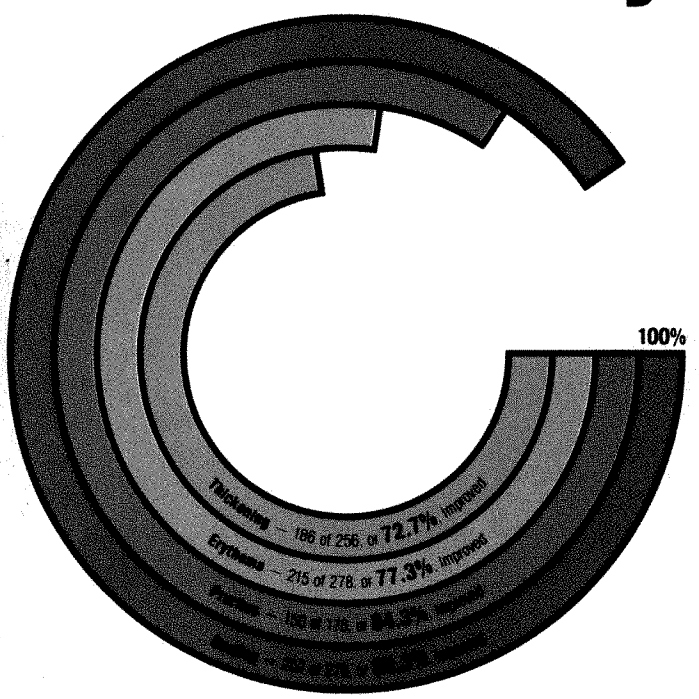
Thirty-eight years of laboratory testing—including patch tests and arm immersion experiments—confirm that Ivory is one of the mildest least irritating soaps you can recommend.

And 89 years of safe consumer use support this clinical experience.

Ivory may safely be used as an adjunct to treatment of scabies, seborrhea and impetigo.

Inflammatory manifestations of psoriasis and atopic dermatitis...

Effectiveness demonstrated in only 8 days*



Psoriasis

In a study of 279 psoriatic patients

Atopic Dermatitis

In a study of 162 atopic dermatitis patients

Cordran® (Flurandrenolide)

Description: Cordran* (flurandrenolide, Dista) is a potent corticosteroid intended for topical use. **Actions:** Cordran is primarily effective because of its anti-inflammatory, antipruritic, and vasoconstrictive actions. **Indications:** For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses. **Contraindications:** Topical corticosteroids are contraindicated in vaccinia and varicella and in patients with a history of hypersensitivity to any of their components. **Precautions:** If irritation develops, the product should be discontinued and appropriate therapy instituted. In the presence of an infection, an appropriate antifungal or antibacterial agent should be used. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, there is a possibility of increased systemic absorption of the corticosteroid, and suitable precautions should be taken. Although topical corticosteroids have not been reported to have an adverse effect on pregnancy, the safety of their use on pregnant women has not been absolutely established. Therefore, they should not be used extensively, in large amounts, or for prolonged periods of time on pregnant patients. These products are not for ophthalmic use. **Adverse Reactions:** The following local adverse reactions have been reported with topical corticosteroid formulations: acneform eruptions, burning, dryness, folliculitis, hypertrichosis, hypopigmentation, irritation, itching. The following may occur more frequently with occlusive dressings: maceration of the skin, miliaria, secondary infection, skin atrophy, striae. **Administration and Dosage:** For moist lesions, a small quantity of the cream or lotion should be rubbed gently into the affected areas two or three times a day. For dry, scaly lesions, the ointment is applied as a thin film to affected areas two or three times daily. [111875]

Cream

Cordran®

Flurandrenolide

Efficacy is its strength

Wet dressings may need no introduction to you, but Aluwets® do because they provide

A new dimension in wet dressing therapy:

Potent Antibacterial Action

AluWets™

(aluminum chloride hexahydrate, N.F.)

Wet Dressing Crystals

In *in vivo* tests, **Aluwets** provided substantially greater antibacterial action against resident flora than a commonly-used aluminum acetate (Burow's) solution.[1]

May potentiate steroid and antibiotic activity

When used in combination with topical steroids or steroid-antibiotic combinations, **Aluwets** Wet Dressings—because of their anti-inflammatory and antibacterial effects—may enhance your therapy by reducing the dependency on topical steroids and antibiotics.

1. Kligman, A.M.: Report on file at Stiefel Research Institute.

Contains: Each packet contains 12.9 grams aluminum chloride hexahydrate, N.F.

Available: Boxes of six packets each.

Directions: Thoroughly dissolve contents of one packet in approximately 12 oz. of cool or lukewarm water to make a 2% aluminum chloride solution.

Soak clean dressing or bandage in solution and apply loosely on the inflamed skin.

Remove, re-moisten and reapply dressings every 10-15 minutes. DO NOT LET DRESSINGS DRY OUT. Continue this procedure for 4 to 8 hours or as needed.

Dressing material and used solution should be discarded *daily* and not reused.

CAUTION: FOR EXTERNAL USE ONLY. Avoid contact with the eyes. Keep this and all medications out of the reach of children. If irritation occurs or persists, discontinue use.

KENALOG® IN ORABASE®
Triamcinolone Acetonide Dental U.S.P.

CONTRAINDICATIONS: Fungal, vira bacterial infections of the mouth or hypersensitivity to any product component.

WARNING: Safe use of this preparat during pregnancy has not been established with respect to possible adverse reactions on fetal developn therefore, it should not be used in w of child-bearing potential and partic during early pregnancy unless the physician or dentist feels that the pc benefits outweigh the possible haza

PRECAUTIONS: Patients with tuberculosis, peptic ulcer, or diabet mellitus should not be treated with corticosteroids without the advice o patient's physician. Bear in mind tha topical corticosteroids depress the normal defensive responses of oral tissues; virulent strains of oral microorganisms may multiply witho producing the usual warning sympt oral infections. When used as recommended, systemic effects are unlikely; however, they are a possib when topical corticosteroids are use over a long period of time. If local irri or sensitization should develop, discontinue the medication and inst appropriate therapy. Additional investigation into etiology of the oral lesion is advised if no significant regeneration or repair of oral tissues occurred in 7 days.

ADVERSE REACTIONS: Prolonged administration may elicit the adverse reactions known to occur with syste steroid preparations; for example, adrenal suppression, alteration of glucose metabolism, protein catabo peptic ulcer activations, and others. These are usually reversible and disappear when the hormone is discontinued.

For full information, consult packa insert.

HOW SUPPLIED: Kenalog® in Orabas (Triamcinolone Acetonide Dental Pa U.S.P.) is available in 5 gram tubes providing 1 mg. (0.1%) triamcinolon acetonide per gram.

Vitiligo and Juvenile Diabetes Mellitus

Chamel Macaron, MD; Robert J. Winter, MD; Howard S. Traisman, MD;
Barry D. Kahan, MD; Alan E. Lasser, MD; Orville C. Green

• Five juvenile diabetics had vitiligo. In two children, the vitiligo preceded the onset of diabetes. Four of the five patients had thyroid, adrenal, or gastric antibodies or a combination of these. In three children HLA-B8 antigens were detected, and one additional patient had HLA-Bw15. Of eight nondiabetic children with vitiligo, one had abnormal glucose tolerance. To the evidence supporting an autoimmune form of diabetes mellitus we add another observation: the association of insulin-dependent diabetes and childhood vitiligo.

(*Arch Dermatol* 113:1515-1517, 1977)

Diabetes mellitus (DM) and vitiligo have been considered autoimmune disorders by some investigators.[1,2] It is hypothesized that vitiligo results from a self-destruction of the melanocytes, and antimelanin antibodies have been detected in the serum of these patients.[1] Vitiligo has been associated with many organ-specific autoimmune diseases such as Graves' disease, pernicious anemia, adrenocortical insufficiency, and idiopathic hypoparathyroidism.[3-9] One isolated report identified selective IgA deficiency in a few patients.[10] Even in the absence of clinical manifestations of these autoimmune diseases, a markedly increased frequency of parietal cell, thyroid, and adrenal autoantibodies has been documented in patients with vitiligo.[11-13]

Diabetes mellitus is recognized as a heterogenous disorder, and the evidence for a true autoimmune form of DM is accumulating.[2] An autoimmune or a viral insult of a susceptible individual may precipitate insulin-dependent diabetes (IDD).[2,14] Susceptible individuals may be identified by HLA typing: HLA-B8 and/or HLA-Bw15 have been found in two thirds of patients with IDD.[15,16] Genes that determine specific immune response or viral-induced disease have been linked to these types.[15,16] In addition, autoimmune involvement in the pathogenesis of diabetes is supported by the following factors: (1) the autopsy finding of insulinitis with lymphocytic infiltration in the pancreata of few newly diagnosed cases of IDD[17]; (2) the detection in IDD of islet cell antibodies (AB) and cell-mediated immunity to human pancreas[18-22]; (3) the increased frequency of gastric, adrenal, and thyroid autoantibodies seen in DM[23,24]; and (4) the clinical association of diabetes with other diseases believed to be autoimmune, such as idiopathic adrenal insufficiency, Graves' disease, Hashimoto's thyroiditis, pernicious anemia, myasthenia gravis, and vitiligo.[3,4] We have recently described an increased incidence of carbohydrate intolerance in children with preexisting autoimmune thyroiditis.[30]

The association between vitiligo and DM has been described for maturity-onset diabetes.[25,26] To our knowledge, this association has not been reported in diabetic children. The purpose of this report is to describe five juvenile diabetic patients with vitiligo and compare them to eight children with vitiligo only, in regard to their HLA typing and a variety of autoantibodies.

METHODS

Subjects

Thirteen patients were studied, five juvenile diabetics with associated vitiligo and eight nondiabetic children affected with vitiligo. They ranged in age from 4 to 19 years. At the time of the study, none of the patients had evidence of an intercurrent illness by history, nor was any patient obese. All of the studies and physical examinations were performed at the Clinical Research Center of Children's Memorial Hospital. Signed informed consent was obtained from the parents and patients studied.

Oral Glucose Tolerance Testing

The eight vitiligo patients were given written and oral instructions for a 300-gm carbohydrate diet to be consumed for at least three days prior to the performance of an oral glucose tolerance test (OGTT). Trioxsalen, when prescribed, was discontinued for a week prior to the test. With the patient recumbent after an overnight fast, two baseline specimens were withdrawn; a dextrose solution was ingested in a dose of 1.75 gm/kg of body weight, to a maximum of 100 gm. Sequential blood specimens were obtained at 30 minutes, one, two, and three hours after glucose ingestion.

Criteria

The criteria used for evaluation of the OGTT have been described.[27] Glucose intolerance was defined when the sum of fasting one-, two-, and three-hour serum glucose values was greater than 600 mg/100 ml. Our results did not change when children's adjusted criteria were used.[28]

Accepted for publication June 1, 1977.

Biochemical, Hormonal, and Immunologic Determinations

Serum glucose was measured by the glucose oxidase method. Thyroxine was measured by competitive protein displacement; the plasma specimens for cortisol and insulin were stored at −20 C, then measured by a specific double-antibody radioimmunoassay in the same run to eliminate interassay variations. The immunologic profile was obtained by measuring serum immunoglobulin levels, antinuclear antibody (ANA), thyroid, gastric, and adrenal antibodies. Antithyroglobulin AB was tested by the hemagglutination technique, while the cytoplasmic, adrenal, and gastric AB were evaluated by the indirect Coons fluorescent technique.[22] Antibody titers were considered significant if positive at a dilution of 1:4 or more. We tested for HLA antigens by the lymphocyte microcytotoxic test with 112 well-characterized alloantisera to HLA.

Five Patients With Diabetes and Vitiligo

The clinical data are shown in Table 1 (patients 1 through 5). They did not have diabetic ketoacidosis. Their diabetes was in relatively good control requiring only one dose of intermediate-acting insulin. None had insulin hypertrophy or lipoatrophy at the sites of insulin injection. In two patients, the clinical recognition of the vitiligo preceded the onset of diabetes. No characteristic distribution was detected in our patients.

Table 2 (patients 1 through 5) provides the pertinent laboratory data. In four of five patients, the HLA antigens were identical to those described in the majority of insulin-dependent diabetics,[15,16] three being HLA-B8 and one HLA-Bw15.

The immunoglobulin values were within normal limits. Only one patient had no laboratory evidence of autoimmune phenomenon.

Eight Vitiligo Patients

The clinical data are presented on Table 1 (patients 6 through 13). There was a great deal of variation in the duration of the vitiligo, as well as its distribution. Only patient 6 had a first-degree diabetic relative. Seven patients (patients 6 through 12) displayed a normal OGTT by the criteria defined above. Patient 7, whose HLA type was HLA-B8, had a borderline OGTT with a one-hour value of 165 mg/100 ml and a two-hour value of 145 mg/100 ml. Patient 12 had an abnormal two-hour value of 140 mg/100 ml. Only patient 13 had an abnormal OGTT: fasting serum glucose, 103 mg/100 ml; 30 minutes, 184 mg/100 ml; one hour, 212 mg/100 ml; two hours, 162 mg/100 ml; three hours, 180 mg/100 ml. The corresponding serum insulin values are 12, 80, 85, 97, and 104 μU/ml. He was not insulin deficient, but the peak of insulin release was delayed. None of his first-degree relatives was diabetic, and his HLA type was not typical of the IDD. Thus, one vitiligo patient of eight had chemical diabetes. The remainder of the laboratory data are depicted on Table 2 (patients 6 through 13). Not included are the immunoglobulin values, which were normal.

COMMENT

Our study of 13 children with vitiligo confirms many of the reported features concerning the clinical presentation of this entity. Lerner, in his classical study, said that vitiligo is often inherited as an autosomal dominant trait, without any sex predominance and that 50% of the patients notice their skin abnormality before the age of 20.[9] This was reflected in our study by the fact that patients 2 and 7 had parents with vitiligo. In addition all of our patients had the onset of their disease before the age of 15. That seven of eight nondiabetic children were female may simply reflect pure chance or could be explained by the fact that they are more interested in the treatment this skin disfiguring disorder. Si vitiligo does not shorten life exp tancy, the males are more likely to seen when affected by a sec disease as exemplified by our f male diabetic children. On the ot hand, the family history did reveal association of vitiligo with ot organ-specific autoimmune disea such as pernicious anemia (patient and Hashimoto's thyroiditis (pati 4). A family history of DM was elici in eight patients.

None of our patients manifes clinical or biochemical evidence idiopathic adrenocortical insuffici cy, pernicious anemia, or thyr disorders. However, thyroglobu adrenal, and gastric cell autoa bodies occurred singly or in combi tion in eight patients. Irvine et detected ANA and mitochondrial in only 1% of the diabetics and in 1%

†Patients 6 through 13 had vitiligo only.

the control subjects.[24] They concluded that the prevalence of tissue-specific AB (as compared to humoral AB) does not seem to be increased in the diabetic population. Our finding of two diabetic vitiligo patients with ANA may be a pure coincidence. Neither had signs or symptoms of systemic lupus erythematosus. In addition, none of our 13 patients had complete IgA deficiency, although minor decrements were seen.

The HLA-B8 has been associated with many diseases believed or suspected to be autoimmune, ie, Graves' disease, idiopathic Addison's disease, and IDD. Six of 13 vitiligo patients—three being diabetic—had HLA-B8 antigens. No significant association can be drawn from this small population. Nevertheless, we intend to observe the three vitiligo patients to see if they develop diabetes in the future.

The association between DM and vitiligo has been well established in the adult population.[4-6,25,26,29] The majority of these diabetics were not insulin-dependent, and some of them had other endocrine deficiencies. An increased incidence of DM in the relatives of patients with vitiligo has also been reported.[3] To our knowledge, our study is the first report of childhood vitiligo associated with juvenile diabetes. Even though the course of their diabetes has been mild, the vitiligo adds an additional burden to the adolescent diabetic. The combination of these two diseases disrupts their normal life pattern. The incidence of this association cannot be precisely ascertained; we detected these five children among 300 juvenile diabetics; the prevalence of vitiligo in our juvenile diabetics would be estimated to be 1.6%, which is higher than the prevalence of vitiligo in the general population (approximately 0.7%).[25] The finding of an abnormal OGTT in one vitiligo patient need not indicate that vitiligo patients are at a greater risk for the development of carbohydrate intolerance.

To the mounting evidence that supports the concept of a true autoimmune clinical form of DM, we hereby add another factor: the association of IDD and childhood vitiligo.

HLA-A10 in Pemphigus Among Japanese

Koji Hashimoto, MD; Yoshiharu Miki, MD; Seizo Nakata, MD; Masamichi Matsuyama, MD

• The frequency of the major histocompatibility antigen, HLA-A10, was significantly increased (corrected $P < .025$) in 43 unrelated patients with pemphigus vulgaris (41.9%) and in 25 patients with pemphigus foliaceus (48.0%), when compared with 60 unrelated healthy controls (16.7%).

No significant correlations with other HLA or differences between pemphigus vulgaris and pemphigus foliaceus were observed. Both forms of pemphigus were considered to link with the HLA-A10.

(*Arch Dermatol* 113:1518-1519, 1977)

In 1973, major histocompatibility antigens, HL-A10 (later designated as HLA-A10 by the World Health Organization in 1975) and HL-A13 (HLA-B13), were separately reported to be significantly increased among whites with pemphigus.[1,2] It was then postulated that a pemphigus susceptibility gene linked with these specific HLA antigens.

Between December 1974 and March 1975, 16 unrelated Japanese patients with pemphigus vulgaris were studied, and both HLA-A10 and HLA-Aw30 were shown to be significantly increased in these patients when compared with 77 unrelated healthy controls.[3]

The present study was carried out to see which of the above HLA antigens were significantly increased in a larger number of Japanese patients, and also to see the differences, if any, between pemphigus vulgaris and pemphigus foliaceus.

MATERIALS AND METHODS

A total of 43 unrelated pemphigus vulgaris (16 male and 27 female) and 25 pemphigus foliaceus (5 male and 20 female) patients were subjected to HLA typing and were compared with 60 unrelated healthy controls. This included 13 of 16 patients with pemphigus vulgaris who were studied previously,[3] though the typing was made again on these patients with a new set of antisera in the present study.

The geographic distribution of the patients is given in Table 1. All 60 controls were blood donors at the University of Osaka.

The diagnosis of the patients was based on clinical and histologic examinations. In addition, intercellular antiepithelial IgG deposits were demonstrated by indirect and/or direct immunofluorescent studies in 37 pemphigus vulgaris and 21 pemphigus foliaceus patients. Pemphigus erythematosus or Senear-Usher's syndrome was included in pemphigus foliaceus, because there was no clear-cut separation of the clinical entities from the data submitted to us.

The HLA typing was done between January and June 1976 by the modifi microdroplet lymphocyte cytotoxicity tes using 112 antisera of 25 defined specifi ties. Typing was performed immediate after the blood samples were drawn fro 22 patients with pemphigus vulgaris and patients with pemphigus foliaceus. In t remainder of the patients, it was pe formed within two to four days after t blood samples were obtained at each ins tution and mailed to us.[5]

RESULTS

Table 2 shows the result of HL frequencies in patients with pempl gus compared with healthy contro Among 25 specificities tested, HL A10 was found in 41.9% of 43 patien with pemphigus vulgaris and in 48.0 of 25 patients with pemphigus foli ceus as compared to 16.7% of controls.

The statistical significance of t antigen frequencies was tested by t χ^2 method. The increase was consi ered statistically significant $P < .001$. The corrected P value aft multiplication by 25 (number of spe ificities tested) was $< .025$.

The HLA-B16 in patients wi pemphigus vulgaris and Bw22 those with pemphigus foliaceus we also increased when compared wi

the controls, but they were not statistically significant at $P > .05$ after multiplication by 25.

The HLA-A10 was further subclassified into Aw25 and Aw26; all patients and controls belonged to the Aw26 classification. There were no other HLA specificities that were significantly increased when compared with the controls or with the other type of pemphigus. The sexual differences were not compared because of the small size of the groups.

COMMENT

The HLA-A10 was significantly increased in the Japanese patients with pemphigus vulgaris and pemphigus foliaceus in the present study. This finding was consistent with the report by Krain et al on pemphigus vulgaris,[1] where HL-A10 (HLA-A10) was found in 60.7% of 28 Jewish patients and in 20.2% of 94 Jewish controls, while it was only in 20% of 15 non-Jewish patients and in 11% of 870 non-Jewish controls. The report by Katz et al, in which both Jewish and non-Jewish subjects were included and no clinical types were mentioned, showed that HLA-A10 was in 22.2% of 18 patients with pemphigus and in 15.5% of 251 normal controls.[2] The frequency of HL-A13 (HLA-B13) in the series of Katz et al[2] was not greater in our series.

In pemphigus vulgaris the HLA-Bw16, which was not typed in the previously published reports on pemphigus, and Bw22 in pemphigus foliaceus were increased in the present study, though the increases were not statistically significant.

The W30 (HLA-Aw30), which was significantly increased in the previous report on 16 patients with pemphigus vulgaris,[3] was not significantly increased in our larger number of patients.

The HLA frequencies among Japanese do not vary greatly by geographic location within Japan; the HLA-A10 frequency was 13.5% in Hokkaido, 13.4% in Tokyo, 20.8% in Nagoya, 16.2% in Osaka, and 17.3% in Fukuoka (Table 1).[6] Such ethnic uniformity might have contributed to the higher correlation of pemphigus with the HLA-A10 among Japanese.

Recent studies showed close correlation of specific HLA and autoimmune diseases, including ankylosing spondylitis, psoriasis, celiac disease, myasthenia gravis, and multiple sclerosis. This suggests that genes in the HLA region control immune responses critical for the disease susceptibility.[7] Both HLA antigens and the immune response gene are located in close association on chromosome 6.

Intercellular antiepithelial antibody is found both in pemphigus vulgaris and in pemphigus foliaceus, including Senear-Usher's syndrome or pemphigus erythematosus. Therefore, such autoimmune response in pemphigus may also be correlated with the HLA antigen. Katz et al demonstrated that the anti-HLA sera did not react with the pemphigus interepithelial antigen in an indirect immunofluorescent test.[2]

In the present study, patients whose conditions were diagnosed as Senear-Usher's syndrome or pemphigus erythematosus were included in the pemphigus foliaceus group because clear-cut separation was not feasible from the data submitted to us. Significantly increased HLA-A10 frequencies in both types of pemphigus found in the present study indicate a common disease susceptibility gene.

This study was supported in part by the Research Grant for Specific Disease from the Japanese Ministry of Health and Welfare.

Paul I. Terasaki, PhD, supplied the antisera and Drs Shigemi, Nagata, Sakamoto, Nishikawa, Asahi, Imamura, Ishikawa, Nakano, Masutani, Tokumaru, Sasaki, So, Arata, Ueki, Sasai, Yoshikawa, Igarashi, Sakata, Mishima, Tanabe, and Tanaka assisted in collecting blood samples of pemphigus patients.

Oral Pemphigus Vulgaris

A Report of Ten Cases

Michael Meurer, MD; John L. Millns, MD; Roy S. Rogers III, MD; Robert E. Jordon, MD

• The conditions of ten patients were diagnosed as pemphigus vulgaris limited to the oral cavity. In eight patients the histopathologic findings were consistent with oral pemphigus. Direct immunofluorescence demonstrated intercellular substance (ICS) deposition of C3 either alone or in combination with IgG, IgA, IgM, C4, C1q, properdin, and factor B in all nine patients tested. Circulating ICS antibodies were detected initially in eight of the ten patients, nine of whom had positive titers at a later date, without subsequent development of cutaneous lesions.

Physicians should be alerted to a diagnosis of pemphigus in patients who have chronic erosive disease confined to the oral cavity. Prompt diagnosis by means of routine histopathologic and immunofluorescence studies followed by early initiation of treatment are warranted.

(*Arch Dermatol* 113:1520-1524, 1977)

The oral mucous membranes are involved in nearly all patients with pemphigus vulgaris, with up to two thirds of these patients developing oral lesions as the site of initial involvement.[1,2] The disease may remain localized to the oral mucosa for months before the eventual progression to extraoral sites; this usually occurs within a few weeks to a year.[1,3]

The presence of only oral lesions makes the diagnosis of pemphigus vulgaris difficult, as the transient picture of typical vesicular and bullous lesions is often obscured by repeated trauma and secondary infections, both of which can clinically and histologically result in a nonspecific picture.

The wide variety of systemic as well as localized diseases leading to bullous and ulcerative oral lesions also makes correct and early diagnosis difficult. Systemic diseases with oral involvement that can mimic pemphigus vulgaris include bullous pemphigoid, dermatitis herpetiformis, cicatricial pemphigoid, lichen planus, lupus erythematosus, erythema multiforme, systemic vasculitis, hand-foot-mouth disease, and Behcet's disease. More localized and self-limited diseases presenting a similar picture in and around the oral cavity include acute necrotizing gingivostomatitis, recurrent aphthous stomatitis, acute herpetic stomatitis, and contact stomatitis.

Within the past ten years, immunofluorescence (IF) techniques have become an important tool in the diagnosis of pemphigus vulgaris. Using indirect IF staining, Beutner and Jordon[4] demonstrated a circulating antibody in the sera of patients with active pemphigus vulgaris, which reacts with intercellular substance (ICS) of skin and mucosa at the site of the primary histopathologic lesion. In addition, direct IF staining has been used to demonstrate ICS deposition of IgG and complement components mainly of the classical pathway in the skin of patients with pemphigus vulgaris.[5-7] Bean et al[8] first reported ICS deposition of IgG in the oral mucosa of a patient with oral pemphigus vulgaris. Hasler[9] and Eversole et al[3] were the first to demonstrate circulating ICS antibodies in the sera of patients with pemphigus vulgaris localized to the oral mucosa.

This report describes a series of ten cases of pemphigus vulgaris evaluated at the Mayo Clinic between 1967 and 1975 with lesions confined to the oral mucosa. Diagnosis was confirmed by routine histopathologic examination, direct IF staining of biopsy sections of the oral mucosa, and indirect IF with use of the patients' sera. Our experience with these patients illustrates the importance of early and vigorous diagnostic measures for troublesome ulcerative and blistering lesions of the mouth.

Accepted for publication May 11, 1977.

PATIENTS

The clinical features and previous treatment of the ten pemphigus patients are summarized in Table 1. Eight of the patients were women, two were men; the age distribution ranged from 25 to 77 years with a mean of 59 years.

All patients had a history of erosive or ulcerative lesions in the oral mucosa and adjacent areas for a duration of 2 to 15 months (mean, seven months) prior to initial evaluation at the Mayo Clinic. Distinctive blisters or bullae were reported infrequently. In most cases, the oral and pharyngeal lesions were extremely painful and bled easily; they showed little tendency to heal. Complaints of increased salivation, hoarseness, and dysphagia with resultant weight loss were also noted.

No antecedent history of oral or cutaneous, ulcerative or blistering lesions was noted in any patient prior to the onset of the presenting illness.

The oral lesions were variable in appearance. Most patients had circumscribed, denuded areas or erosions 1 to 5 cm in diameter (Fig 1 and 2). In many patients, the lesions were covered by a whitish exudate and occasionally surrounded by a collar of detached epithelium at the periphery. In three patients, intact blisters or bullae were present.

Buccal mucosal involvement was present in nine of the ten cases, the hard and soft palate in six, the dorsum of the tongue in five, the sublingual area and the gingiva in four, the lower lip in three, and the larynx in three cases. Perianal and nasal mucosal lesions were found to coexist with laryngeal ulcerations in one patient. Physical examination, both at the time of initial evaluation and during subsequent follow-up visits, failed to disclose any associated skin lesions.

REPORT OF CASES

CASE 1.—A 78-year-old woman was referred for evaluation of chronic oral and perianal ulcerations of five months' duration. Her illness began with the development of an erythematous, blistering eruption in the perianal area, which rapidly progressed to involve the mouth and oropharynx with subsequent dysphagia and bleeding. A 5.3-kg weight loss to 40 kg prompted hospitalization in her local community where a diagnosis of chronic aphthous stomatitis was made. After vigorous inpatient therapy with oral gargles of nystatin suspension, an antiseptic preparation (Chloraseptic) and hydrogen

Table 1.—Clinical Findings and Treatment

Patient	Age, yr/Sex	Duration of Disease, mo	Type of Lesion and Area of Involvement	Pretreatment Regimen
1	76/F	4	Ulcerative lesions of tongue, pharynx, tonsillar pillars, nasal and perianal mucosa	2-mo history of nystatin mouthwash, oral clindamycin
2	25/F	13	Erosions and white exudates of buccal mucosa, tongue, lower lip, tonsillar pillars	Intermittent course of tetracycline mouthwash, oral nystatin, multivitamins
3	44/M	15	Discrete blisters of buccal mucosa, gingiva, hard and soft palate	None
4	46/M	8	Ulcerative lesions less than 1 cm in diameter on tongue, gingiva, buccal mucosa	None
5	77/F	5	Erosions and blisters of tongue, buccal mucosa, gingiva	Prednisone begun at 40 mg every other day, tapered to 5 mg every other day prior to initial examination
6	75/F	2	Erythematous macular ulcerations of the buccal mucosa, tongue, soft palate, lower lip	None
7	76/F	8	Superficial erosions and purulent exudates of buccal mucosa, tongue, lower lip	None
8	58/F	5	Membranous ulcerations with white exudates on buccal mucosa, pharynx	None
9	55/F	3	Desquamative lesions of buccal mucosa, pharynx	Prednisone, 80 mg daily tapered to 60 mg daily two months prior to initial examination
10	62/F	6	Erosive ulcerations of buccal mucosa, tongue, soft palate	Several courses of prednisone, triamcinolone, corticotropin, hydroxyzine hydrochloride, diphenhydramine hydrochloride over 4-mo period

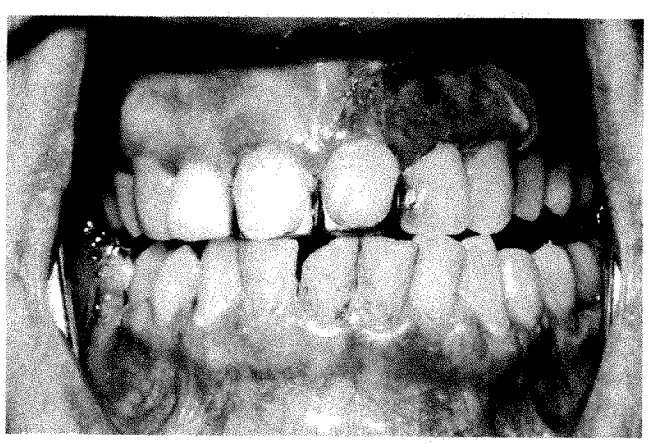

Fig 1.—Superficial, erythematous, gingival ulceration (patient 10).

Fig 2.—Irregular, superficial ulceration of soft palate (patient 3).

peroxide 50:50 in water, and a short course of orally administered clindamycin, 150 mg four times per day, the patient's condition showed little improvement and she was transferred to another hospital where her progressive debility prompted admission at Rochester Methodist Hospital for further evaluation.

Physical examination revealed multiple, superficial erosions of the nasal mucosa and several 3 to 5-mm superficial ulcerations on an erythematous base in the anal area. Oral examination showed marked erythema of the buccal mucosa and tongue with multiple 5 to 15-mm marginated, superficial ulcerations of the buccal mucosa, soft palate, lower lip, and oropharynx.

Laboratory findings included the following: hemoglobin level, 11.2 gm/100 ml; hematocrit reading, 35.3%; leukocyte count 41,000 cu mm, with a differential cell count of 54% neutrophils, 30% lymphocytes, 8% monocytes, 7.5% eosinophils, and 0.5% basophils; normal urine and electrolytes, and albumin, 2.7 gm/100 ml. Biopsy of the palate for direct IF demonstrated deposition of IgG and C3 in the ICS. Biopsy sections of the palate and anus were interpreted histologically as consistent with pemphigus vulgaris. Indirect IF studies were positive for ICS antibodies, titer of 160, and for antinuclear antibodies, titer of 80. Follow-up titers over the ensuing six weeks were 640, 320, and 640. A complete medical evaluation was noncontributory.

During hospitalization, the patient was treated with 2% viscous lidocaine and 0.1% betamethasone valerate cream four times daily to the oral lesions, 0.05% triamcinolone acetonide cream to the anal lesions, and gold sodium thiomalate, 25 mg intramuscularly on a weekly basis. High-dose steroid therapy originally planned was withheld because of impending cardiac decompensation secondary to severe aortic stenosis/insufficiency. After 22 days of hospitalization, her nasal and anal lesions had completely resolved yet she continued to have a few residual ulcerations on her soft palate. Her weight at discharge was 28 kg.

After discharge, the patient continued on the same regimen of medications outlined during her hospitalization, but she

Table 2.—Histopathologic and IF Findings

Patient	Histopathologic Findings	Direct IF (ICS)	Indirect IF (ICS)	
			Initial Titer	Subsequent Titers
1	Suprabasilar separation with superficial dermal lymphocytic infiltrate and normal salivary gland tissue	IgG, C3, C4, C1q	160	60, 320, 640
2	Suprabasilar bulla, marked acantholysis, and mixed cellular infiltrate in papillary dermis	IgG, IgM, C3, C4, C1q, fibrin	320	60, 80, twice neg
3	Suprabasilar clefting with microscopic hemorrhage and dense lymphohistiocytic and eosinophilic infiltrate	IgG, IgM, IgA, C3	Neg*	40, 80, 160, 80, 40, 80
4	Suprabasilar clefting and acantholysis with lymphohistiocytic dermal infiltrate	Not done	20	40, 20
5	Nonspecific	IgG, IgM, IgA, C3, C1q, properdin, factor B	Neg	—
6	Suprabasilar clefting minimal acantholysis, lymphohistiocytic dermal infiltrate	IgG, IgA, C3	320	60, 20, 80
7	Suprabasilar bulla formation with ulceration and mixed papillary dermal infiltrate	C3	320	—
8	Ulceration, suprabasilar clefting, dense dermal lymphohistiocytic infiltrate	C3, fibrin	20	Neg, 20, neg, 20, thrice neg, 40, neg, 20, thrice neg, 80, 160, 320, neg
9	Ulceration, suprabasilar bulla with acantholysis and dense lymphohistiocytic and plasma cell infiltrate	C3, fibrin	80	80
10	Nonspecific dermal lymphohistiocytic and plasma cell infiltrate	IgG, IgM, IgA, C3, C4	80	20, twice neg

*Negative.

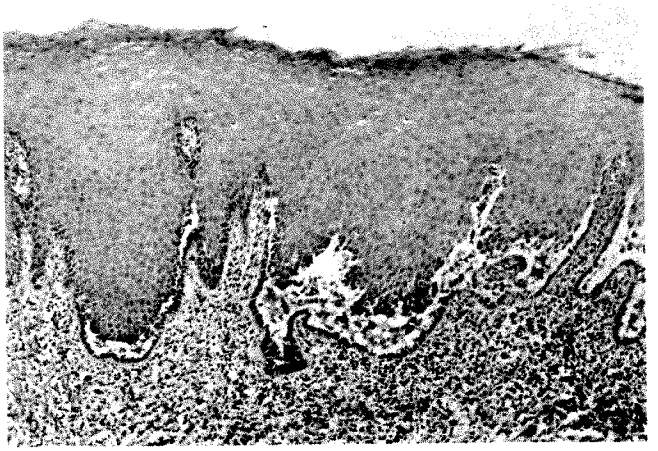

Fig 3.—Suprabasilar clefting and acantholysis with dense, lymphohistiocytic dermal infiltrate (patient 4) (hematoxylin-eosin ×100).

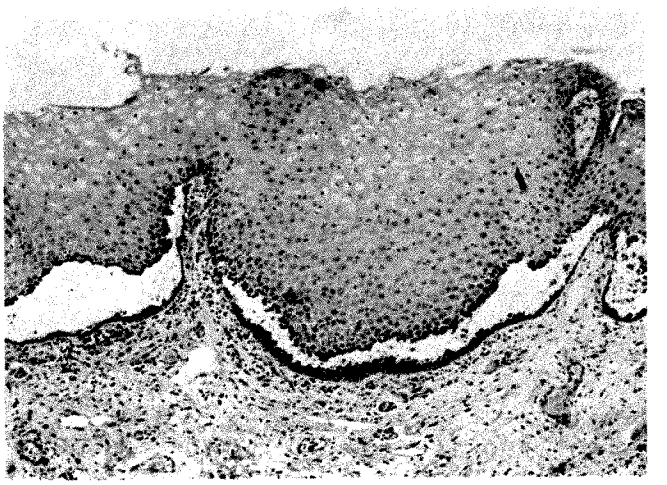

Fig 4.—Suprabasilar bulla formation with acantholysis and mixed cellular infiltrate in papillary dermis (patient 2) (hematoxylin-eosin ×100).

continued to have recurrent anal and oral lesions. Due to painful dysphagia, her weight continued to drop, and she died two months after discharge. Postmortem examination disclosed a 13-cm superficial ulceration of the pyriform sinus with microscopic sections of the dorsal tongue, pharynx, proximal esophagus and anus demonstrating suprabasilar clefting, bulla formation, acantholysis, and submucosal inflammation.

CASE 2.—A 25-year-old woman developed groups of canker sores in her mouth in April 1974, which were unresponsive to local therapy. Continued episodes of these lesions in July and August led her to consult an allergist who believed she had viral aphthae. The lesions resolved when she received a short course of systemic steroids but returned shortly after the steroids were discontinued. A two-week course on high-dose systemic prednisone tapered to 10 mg/day for two additional weeks and eventually 10 mg every other day for two months caused only a short-term remission. Adjunctive therapy with nystatin oral solution, triamcinolone acetonide in water/oil base, and tetracycline hydrochloride mouthwash gave only transient relief.

In January 1975, her oral lesions flared and vaginal ulcerations developed. An estrogen-dominant birth control pill was substituted into her regimen. By March, a severe exacerbation occurred with the development of ulcerative desquamation of her tongue and buccal mucosa and a weight loss of 6.7 kg. Indirect IF, performed in March, demonstrated the presence of ICS

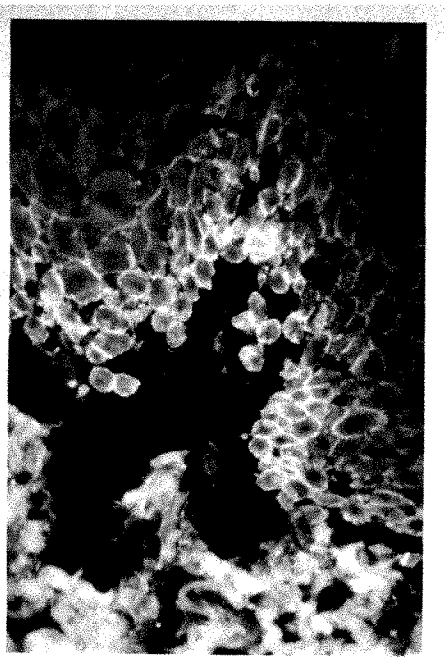

Fig 5.—Direct IF staining of pemphigus oral mucosal lesion demonstrating ICS deposition of C3 (patient 2) (×200).

Fig 6.—Direct IF staining of pemphigus oral mucosal lesion demonstrating ICS deposition of IgA (patient 6) (×200).

antibodies, titer of 320. With a tentative diagnosis of pemphigus vulgaris, the patient was referred for further evaluation.

Examination at the Mayo Clinic revealed bullae and erosions of the dorsal tongue, lower lip, buccal mucosa, and the tonsillar pillars with focal areas of white membranous exudates on the tongue.

Histopathologic examination of a fresh bulla from the oral mucosa was diagnostic of pemphigus vulgaris. A mucosal specimen studied by the direct IF examination demonstrated epidermal intercellular deposits of IgG, IgM, C3, and fibrin. Serum for indirect IF demonstrated ICS antibodies with a titer of 160. Cultures from the mouth produced normal flora. A CBC was normal with a leukocyte count of 4,900/cu mm. The differential cell count showed 11.5% eosinophils but was otherwise normal. Results of other studies, including urinalysis, chest x-ray film, serologic test for syphilis, lupus erythematosus clot test, and ESR, were within normal limits.

The patient began a regimen of prednisone, 50 mg/day, and tapered at 2.5 mg/wk until a dose of 20 mg/day was reached, whereupon the dose was increased to 50 mg every other day and tapered over the ensuing year to 10 mg every other day. As of April 1976, there have been no recurrent lesions, and her most recent test for indirect IF antibodies was negative.

CASE 3.—A 44-year-old man came to the Mayo Clinic in September 1973 with a 15-month history of recurrent oral lesions that appeared at varying intervals and tended to resolve spontaneously over periods of one to two weeks. He denied any history of cutaneous, ocular, nasal, genital, or anal lesions and volunteered that the only exacerbating factor was the ingestion of hot foods.

On examination he was found to have superficial blisters on the soft palate and buccal mucosa without evidence of other lesions.

Biopsy specimens of fresh bullae obtained from the oral mucosa were interpreted histopathologically as showing suprabasilar, acantholytic bullae consistent with pemphigus vulgaris. Sections examined by direct IF showed deposits of IgG, IgA, IgM, and C3 in the ICS. Indirect IF was negative at that time but became positive within a month. Results of other tests, including chest x-ray film, CBC, serologic test for syphilis, ESR, urinalysis, serum electrolytes, serum total thyroxine, and viral culture of the oral lesions, were normal or negative.

The patient began a regimen of prednisone, 60 mg every other day and tapered to a dose of 25 mg every other day within four weeks of the time of diagnosis. During that month he experienced a single, recurrent 3-mm ulceration of the soft palate. A second indirect IF titer to ICS was 80. By January 1974, his prednisone dose had been tapered to 15 mg every other day with a slight rise in his indirect IF titer to ICS of 80 with no notable change in his disease status. From January 1974 until January 1975, he was maintained at 10 mg prednisone every other day with the occasional occurrence of palatal ulcerations usually related to trauma. By April 1975, his prednisone was discontinued, and he has remained free of lesions in spite of persistent titers of ICS antibodies on indirect IF in the range of 80 to 160.

MATERIALS AND METHODS

Biopsy specimens from all patients were obtained from the edge of a fresh lesion and were studied after fixation and staining by routine light microscopy. Half of the specimen, however, was frozen in liquid nitrogen and stored at −70 C. Direct IF staining, performed by previously outlined methods,[5-7] was carried out using monospecific labeled goat antisera to IgG, IgM, IgA, C3, and fibrin. All conjugated antisera were checked for specificity and sensitivity by both immunoelectrophoresis and double immunodiffusion. Antibody protein assays, units of antiserum, and fluorescein to protein ratios conformed to previous standards.[5-7] The dilutions at which the various antisera were used varied depending on results of the latter tests.

Rabbit antiserum to human factor B was prepared and assayed according to the method of Götze and Müller-Eberhard.[10] Antiserum to human properdin was prepared in a goat after properdin was isolated according to the method of Pensky et al.[11] Some biopsy specimens were stained for the presence of C1q, C4, factor B, and properdin by means of modified indirect IF techniques.[12]

Venous blood for indirect IF was collected under sterile conditions, separated, aliquoted, and stored at −20 C until tested. The indirect IF staining was performed on monkey esophageal sections with use of monospecific conjugated antiserum against human IgG at a concentration of 0.25 units/ml. Details of this procedure have also been outlined elsewhere.[5-7] In nine of the ten patients, serial indirect IF studies were obtained during a follow-up period of one month to seven years.

RESULTS

Table 2 summarizes the histopathologic and IF data on the ten patients. By routine histopathologic evaluation, the biopsies of eight patients were consistent with the diagnosis of pemphigus vulgaris, as depicted in Fig 3 and 4. In two patients (5 and 10), the specimens were interpreted as nonspecific. The direct IF test performed in nine of the ten patients at the time of their initial evaluation demonstrated ICS deposition of immunoglobulins and/or complement components and fibrin in the lesional mucosal epithelium (Fig 5 and 6). In one patient, the direct IF was initially performed six years after the onset of the disease and demonstrated ICS deposition of C3 and fibrin. The immunoglobulin IgG alone or in combination with other immunoglobulins (IgA and IgM) was present in seven patients. All biopsies demonstrated ICS deposition of C3, three of which showed binding of C3 in the absence of immunoglobulins. In three patients, the binding of C1q and/or C4 and in one patient the binding of factor B and properdin was apparent, while deposition of fibrin occurred in three specimens.

At the time of the initial evaluation, circulating serum antibodies reactive with the ICS were present in eight patients. Of the two remaining patients who had negative indirect IF at that time, serum samples from one patient subsequently became positive two months later.

The initial titers of ICS antibodies ranged between 20 and 320, the majority being 80 or greater (Table 2). Also outlined are the subsequent titers of ICS antibodies of nine

patients collected throughout the course of their illness and used to monitor their disease activity and their therapeutic response.

COMMENT

Oral mucous membrane involvement is a common manifestation that affects two of three patients with pemphigus vulgaris.[1] As previously mentioned, it is the area of initial involvement of the disease in over half of the cases.[1,2] Similarly, the oral mucosa is often the site of recalcitrant lesions persisting when otherwise successful control of generalized cutaneous pemphigus is achieved by steroid or immunosuppressive therapy.[13] One common explanation for this phenomenon is the constant exposure of the oral cavity to repeated trauma. Hashimoto and Lever[14] suggested that the relative abundance of ICS in the oral mucosa as compared to the skin may enhance the binding of circulating antibodies to the ICS of this tissue. Also, specific junctions, such as gap junctions and desmosomes, are inferior in development and number in mucous membranes when compared with normal skin. Cellular adhesion in the mucosal area, therefore, may be more dependent on nonspecific junctions and more susceptible to the acantholytic process.[15]

Pemphigus of the oral mucosa and/or mucous membranes without associated or subsequent cutaneous involvement is rare.[16,17] It is unlikely that the ten patients described here comprise such a subgroup of pemphigus vulgaris. It is more probable that the absence of cutaneous lesions in these patients represents an induced dormancy in the usual relentless progression of this disease due to early diagnosis and prompt initiation of treatment. It is possible that many cases of pemphigus are not recognized by the physician in the early, mucosal stage.

The rare limitation of pemphigus vulgaris to the site of its most common initial involvement may reflect the inadequacy of the usual diagnostic tools at such an early stage of the disease. The difficulties of histologic evaluation due to secondary alterations of the histologic lesions has been mentioned.[18] The Nikolsky sign is often not present,[16] as was the case in our patients, and the cytologic examination is of rather limited value due to the transient nature of intact bullae on mucosal surfaces.

Although the clinical picture of persistent, painful erosions, ulcerations, and sometimes blisters in the oral cavity, associated with a histologic picture of intraepidermal, acantholytic clefting, certainly suggests oral pemphigus vulgaris, confirmation of this diagnosis by direct and/or indirect IF provides strong support for an aggressive therapeutic approach necessary to bring the disease under control before generalized cutaneous lesions develop.

Biopsy specimens for direct IF from perilesional mucosa were positive in all patients tested. In vivo bound C3 was present in all specimens including those from patients already treated with systemic corticosteroids as well as from lesions of untreated patients that had been present for up to 15 months.

The predominant immunoglobulin found on direct IF was IgG, once alone, three times in conjunction with IgM, and four times with IgA.

Two additional patients with oral pemphigus vulgaris not included in the study because of subsequent cutaneous involvement also demonstrated oral mucosal IgA deposition on direct IF. The much higher frequency of IgA bound to the ICS in oral mucosa in contrast to the skin might be explained by the high concentrations of locally synthesized IgA in this tissue.[19] Whether the IgA observed in oral pemphigus lesions represents ICS antibodies of the IgA type or not remains to be determined.

Indirect IF has also proved to be a valuable adjunct in the diagnosis of pemphigus vulgaris. Nine of our ten patients demonstrated positive titers on initial evaluation, seven of which remained positive on subsequent examinations. In contrast with the findings of Bean et al,[8] Tuffanelli,[20] Ryan,[21] and Nisengard et al,[22] who suggested that ICS antibodies are often not detectable in the sera of patients with early disease or minimal involvement such as oral lesions, the indirect IF data on our patients indicate that this frequency of positive values is much higher.

Several authors[20,22,23] have demonstrated the importance of serial indirect IF studies in monitoring the disease activity of pemphigus vulgaris. In our cases of pemphigus vulgaris a pronounced correlation between disease activity and indirect IF titer was noted only in those patients who were examined monthly for prolonged periods of time.

This investigation was supported in part by research grant AI 12049 from the National Institutes of Health and by a grant from the Dermatology Foundation.

Treatment of Psoriasis With Long-Wave Ultraviolet Light

John A. Parrish, MD

• Repeated exposures of 4 by 5-cm sites to erythemogenic doses (20 to 300 joules/sq cm) of long-wave ultraviolet light (UV-A; 320 to 400 nm) led to improvement of the psoriasis vulgaris condition in nine of ten patients treated. Comparison studies showed the therapeutic responses to be similar to that of daily sunburn spectrum (UV-B; 290 to 320 nm) radiation. This finding suggests that the therapeutic response spectrum for psoriasis may parallel the action spectrum for delayed erythema of all portions of the ultraviolet spectrum that pass through psoriatic scale.

(*Arch Dermatol* 113:1525-1528, 1977)

For decades, clinicians have recognized that sun exposure often leads to improvement of psoriasis. Although the therapeutic action spectrum of sunlight was not known, it was thought to be within the ultraviolet spectrum. In order that "the response to light should be more prompt and the involution (of psoriasis) more rapid," Goeckerman[1] in 1925 tried adding various photosensitizers before deciding on crude coal tar. Since that time, the combined use of coal tar and its derivatives with ultraviolet light has been a standard treatment for psoriasis. The action spectrum for augmented delayed erythema caused by the photosensitizing tar products is within long-wave ultraviolet light (UV-A; 320 to 400 nm).[2,3] However, the spectral power distribution of most light sources used in Goeckerman's treatment[4,5] is such that the sunburn spectrum (UV-B; 290 to 320 nm) component delivers sufficient radiation to cause delayed erythema long before UV-A radiation could reach erythema-producing doses in the presence of the relatively weak photosensitizers in tar.[2] Clinical trials[6] and bilateral comparison studies[7,8] have confirmed that exposure to UV-B (290 to 320 nm) alone leads to improvement of psoriasis.

UV-A is therapeutic in treating psoriasis when given in quantities sufficient to cause erythema in skin that is previously sensitized with topical[9-11] or oral[7,8] psoralens. Preliminary observations in our laboratory suggested that much higher doses of UV-A (doses high enough to cause erythema from UV-A alone) might also improve the condition of patients with psoriasis.[12] To further test this hypothesis, we irradiated plaques of psoriasis vulgaris with large doses of UV-A alone. It is known that UV-A can cause delayed (8 to 20 hours after exposure) erythema in normal skin when given in exposure doses 1,000 times greater than erythemogenic doses of UV-B. Exposure doses of this magnitude and greater were used to treat small areas of psoriasis in ten patients.

MATERIALS AND METHODS

Five informed white adult patients with stable psoriasis vulgaris volunteered for the initial phase of this study. In each patient, each of three adjacent 4 by 5-cm areas within a single large psoriatic plaque were treated with either UV-B, UV-A, or psoralen and UV-A (PUVA). A fourth site within the plaque was identified as a control area. No other treatment was given during the study or for ten days before the onset of the study.

UV-B and UV-A exposures were given daily. Opaque tape was used to outline the exposure sites that were radiated at a distance of 4 inches from the source. Initial exposures of 20 millijoules/sq cm and 20 joules/sq cm, respectively, were increased by 40% each day as tolerated. PUVA treatments were given on alternate days. After completion of both UV-B and UV-A exposures, patients ingested 40 mg of methoxsalen (8-methoxypsoralen). Two hours after ingestion, the PUVA site was exposed to UV-A. Initial exposure was 2 joules/sq cm, which was increased by 1 joule/sq cm each day, as tolerated. Exposure doses were increased as just outlined as often as necessary to maintain a minimal to modest increase in delayed erythema in the treated sites when compared with the remainder of the lesions. High irradiance UV-A exposure can cause a prominent immediate erythema as well as the usually delayed (12 to 24 hours postexposure) "sunburn" response seen after UV-B exposure. The immediate erythema is transient (minutes to hours); it was the delayed erythema response that was used as a guide to determine subsequent UV-A and UV-B exposure doses. If tender erythema or edema was present, treatment was discontinued until these symptoms faded. When therapy was discontinued at the end of 17 days, patients had received 13 to 17 UV-B and UV-A exposures and seven to nine PUVA treatments. Final UV-B doses were 100 to 300 millijoules/sq cm and final UV-A doses were from 100 to 300 joules/sq cm. No UV-A treatments greater than 300 joules/sq cm were given because a single such exposure required 76 minutes. Four-millimeter punch biopsy specimens obtained from the control and UV-A treated sites were fixed with hematoxylin-eosin. Patient No. 5 refused biopsy.

To determine if a greater number of UV-A exposures would eventually lead to further improvement, an additional five patients were exposed daily to UV-A alone for 17 to 32 days using the same exposure doses as just outlined.

Light Sources

UV-B.—A bank of eight FS40 Westinghouse fluorescent bulbs was used; irradiance at 4 inches was 1 mW/sq cm of 320 to 380 nm, peaking at 312 nm (40% of irradiance was at wavelengths shorter than 320 nm).

UV-A.—A xenon-mercury arc, 1,000 W, was used with distilled water and a WG 335 Schott filter (2 mm). Irradiance at 4 inches was 65 mW/sq cm; the spectrum obtained was 320 to 380 nm. All measurable radiation of wavelengths shorter than 320 nm was less than 0.0001% of the UV-A radiation.

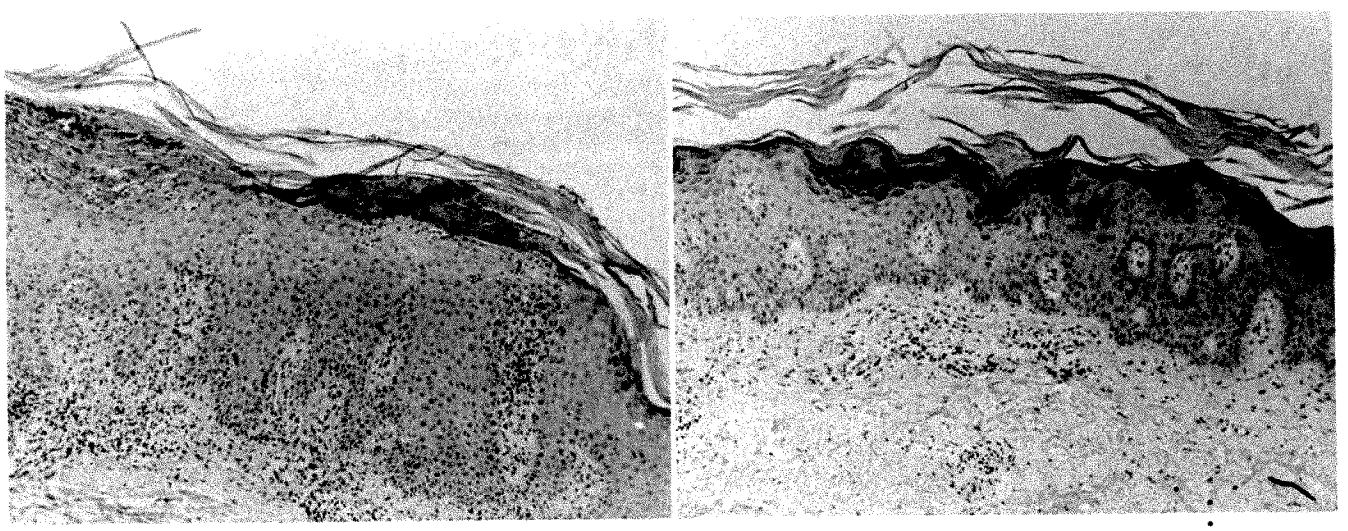
Table 2.—Therapeutic Response to Daily UV-A Treatments

Patient No.	Improvement		No. of UV-A Treatments	Cumulative UV-A Treatments (Joules/sq cm)	Comments
	Control Site	UV-A-Treated Sites			
1	0	50	14	2,180	. . .
2	0	75	14	2,250	Striking response after third treatment, but no further improvement
3	0	50	13	1,930	. . .
4	0	95	13	1,870	History of clearing completely each summer without other therapy
5	0	75	13	1,800	Missed 4 days of therapy after eighth treatment
6	0	95	17	2,137	. . .
7	0	75	18	2,357	. . .
8	25	75	19	2,464	. . .
9	0	0	26	4,174	Generalized flare during treatment
10	0	50	32	6,980	Essentially clear at 10 treatments, then worsened



Left, Untreated site with striking parakeratosis, Monro microabscesses, and absent granular layer (hematoxylin-eosin). Right, Adjacent UV-A-treated site shows orthokeratosis, hyperkeratosis, and uniform epidermal thickening (hematoxylin-eosin).

PUVA.—A bank of eight specially designed Sylvania fluorescent PUVA lamps were used.[13] Irradiance at 4 inches was 10 mW/sq cm from 320 to 380 nm.

Instrumentation

A calibrated IL 700 research radiometer with UV-A and UV-B detectors was used to monitor the output of all ultraviolet light sources. SEE 240 (190 to 300 nm) and SEE 400 (250 to 780 nm) detectors were used with additional filters to limit spectral sensitivity. The detectors and radiometers were calibrated in mW per square centimeter traceable to the National Bureau of Standards in Washington, DC.

Improvement was graded as follows: 0 indicated not significantly improved; 50, 50% improved; moderate decrease in scaling and palpability of lesions; 75, 75% improved; significant and obvious decrease of psoriasis (the treated area has much less induration than the surrounding untreated sites); 95, only scattered 1 to 2-mm papules remain within the plaque, otherwise, the skin appears normal; 100, no clinical evidence of psoriasis.

RESULTS

Nine of ten UV-A-treated sites improved. Six sites showed 75% or greater improvement and two of these were 95% improved.

Comparison Study

The improvement noted at each treatment site is given in Table 1. In four of five patients, the sites treated with PUVA cleared completely. All of the sites treated with erythemogenic exposure doses of UV-A or UV-B improved. None cleared completely and there was no significant difference between UV-B and UV-A treatment. One patient (No. 4) was nearly clear (greater than 95% improved) in all treatment sites.

UV-A induces pigmentation within psoriatic plaques. Some of the UV-A-treated sites did not improve further after they became very tan, possibly because of the considerable screening effect of the increased melanin. As treatment progressed, UV-A-treated sites became more pigmented than PUVA-treated sites that seemed to darken only after lesions were considerably improved. UV-B-treated sites pigmented less than the other treated sites.

Continuation of Therapy

Table 2 gives the total number of treatments and final improvement grading for all patients treated with UV-A. One patient (No. 9) did not improve despite 26 treatments. He had been receiving large doses of topical steroids up until ten days before this experiment was initiated and experienced a generalized flare of his psoriasis during this experiment. The UV-A-treated site did not improve. The remaining patients improved, but the UV-A-treated sites in patients No. 6 through 10 did not improve further after the 14th treatment. In fact, the UV-A-treated site of patient 10 was nearly completely clear at ten treatments but gradually worsened during the next ten treatments and then remained unchanged. The cumulative UV-A dose for all of the patients is given in Table 2.

Histology

The histologic findings in the untreated sites were compatible with psoriasis vulgaris. Regularly elongated rete ridges separated edematous elongated papillae that bulged beneath thin suprapapular epidermis. There was loss of granular layer beneath the parakeratotic scale, and polymorphonuclear cells were seen individually and in microabscesses in the epidermis. None of the UV-A-treated sites were completely normal, but they were all substantially different from the untreated sites. In the treated sites, a prominent granular layer was present beneath a thickened orthokeratotic stratum corneum. Scattered individual cell dyskeratosis was noted. The entire epidermis was thickened but less so than in the control site and the thickening was more uniform and less psoriasiform than control sites (Figure).

COMMENT

In treating psoriasis, the beneficial effect of ultraviolet radiation is not confined to any specific portion of the ultraviolet spectrum. Ultraviolet treatment of psoriasis, with or without photosensitizers, requires exposure doses that approximate delayed erythema-producing doses. Provided adequate photons penetrate through the scale, the therapeutic response has an action spectrum similar to that of delayed erythema.

Within the range of 250 to 400 nm, the shorter wavelength end of the spectrum is more efficient at causing threshold erythema of normal, nonscaling, unpigmented skin. The higher energy associated with these photons is appropriate for absorption, photochemical alterations, and a poorly understood cascade of events resulting in altered cell metabolism and delayed erythema. Because less energy is required, light sources may be less intense, exposures of shorter duration, and less heating of skin results.

Electromagnetic radiation of wavelengths shorter than 290 nm (UV-C), however, do not sufficiently penetrate through scale, and radiation at wavelengths longer than 320 nm (UV-A) requires long exposure to high-intensity sources because much larger exposure doses are required to cause delayed erythema of normal skin. Longer wavelengths, however, penetrate more deeply through scale, pigment, and thickened epidermis. Because UV-A penetrates more deeply into the skin than does UV-B, the longer wavelengths could have more effect on blood vessels or dermal chromophores. Conventional UV-B sources offer a reasonable compromise of erythemal efficiency and penetration (absorption at depths well into the skin).

Radiation of any portion of the ultraviolet spectrum in doses well below the erythemogenic range would not be expected to have substantial, easily demonstrable cytotoxic effect on normal skin cells or to benefit patients with psoriasis. At any wavelength region, adequate exposure doses seem to be necessary. This may explain why some investigators[14,15] have found UV-B to be ineffective in treating psoriasis whereas others using larger exposure doses[6-8] have found UV-B to be beneficial. Using exposure doses of 7 to 14 joules/sq cm of UV-A, Young and van der Leun[16] found UV-A to have no effect on psoriasis in ten patients. Fischer[17] treated small areas of psoriasis with ultraviolet sources of 334- and 365-nm bands in repeated doses as high as 30 joules/sq cm without success. Using repeated doses up to 300 joules/sq cm of UV-A, we found that the psoriatic condition was improved. In our laboratory, the minimum erythema dose of the skin of white subjects to UV-A is 10 to 100 joules/sq cm.[2,18,19] Because of prolonged exposure times, the highest exposure dose of UV-A given in this study was 300 joules/sq cm. Most patients had reached this dose by the tenth to 15th treatment and were then held at this dose. It is possible that continued increase in UV-A exposure dose may have led to further improvement in the conditions of patients 6 to 10.

Most of the known cytotoxic effects of ultraviolet radiation have been documented using wavelengths shorter than 320 nm. Erythemogenic ultraviolet radiation causes a temporary reduction in the number of mitoses in epidermal basal cells and prolongation of the turnover time of the epidermis. Depression of DNA

synthesis persists for several hours after UV-B radiation in hairless mouse skin,[20] human skin,[21] microorganisms,[22,23] and cultured mammalian cells.[24,25] Inhibition of RNA and protein synthesis are also early postultraviolet irradiation effects,[20,26,27] and several enzyme activities are decreased.[28] These alterations may be related to the effect of ultraviolet irradiation on the hyperproliferative state of psoriasis.

UV-A, however, cannot be considered innocuous to cells. Relatively large exposure doses of UV-A lead to erythema and melanogenesis of normal human skin and also lead to improvement of the psoriatic condition. Many UV-A-induced cutaneous phenomena require about 1,000 times more energy than the comparable reactions by shorter ultraviolet wavelengths. At first glance this may make UV-A reactions seem less important, but it must be remembered that noonday sun on earth contains ten to 100 times more UV-A than all shorter wavelengths and this ratio may reach 1,000:1 in the early and late hours of the day. Moreover, human skin response to UV-A and UV-B may be additive[18,19] or synergistic.[29] The therapeutic effects of UV-A may also be additive or augmentative to other forms of phototherapy.

The use of UV-A alone to treat psoriasis is not presently practical. Not enough information exists about the long-term effects of repeated large exposure doses of UV-A on psoriasis or normal skin, and light sources capable of delivering total body radiation of several hundred joules per square centimeter in short time periods are not available. Thermal effects may also result from high exposure doses or high rates of delivery of ultraviolet energy given over large body areas.

Approaches that take optimum advantage of the optical properties of the more erythemogenic (and more therapeutic) shorter wavelengths and the more deeply penetrating longer wavelengths would be as follows: (1) the addition of photosensitizers that enhance the erythemogenesis and therapeutic effect of longwave ultraviolet light; (2) the development of ultraviolet treatment systems with peak emission between 310 and 330 nm as a "compromise zone;" and (3) the development of light sources that have erythemogenically balanced amounts of all wavelengths greater than 280 nm. This would require, for example, 1,000 times more energy at 365 nm than at 297 nm.

Loretta Caruso, Brian Fitzpatrick, and Timothy Kingsbury provided technical assistance.

Photochemotherapy of Psoriasis Using Methoxsalen and Sunlight

A Controlled Study

John A. Parrish, MD; H. Anthony D. White, MB, BS, FRACP; Timothy Kingsbury; Mahmoud Zahar, MD; Thomas B. Fitzpatrick, MD

• Fifty-one patients with psoriasis were treated with oral methoxsalen and sunlight exposure. Twelve of these patients received either methoxsalen or placebo prior to whole-body exposure. The remainder were treated with methoxsalen and sunlight to one side of the body and sunlight alone to the other. The conventional dose of methoxsalen (0.6 mg/kg) was compared with a low dose (0.3 mg/kg). Oral methoxsalen when used in the higher dose followed by sun exposure is an effective treatment for psoriasis. Accurate ultraviolet dosimetry is essential to avoid phototoxic burns. The advantages and disadvantages of solar photochemotherpy are discussed.

(*Arch Dermatol* 113:1529-1532, 1977)

Photochemotherapy using orally administered psoralens and subsequent exposure to longwave ultraviolet light (UV-A, 320 to 400 nm) has been shown to be effective in the treatment of psoriasis vulgaris.[1] This drug and light combination has been termed PUVA (psoralen and UV-A).[2] Using methoxsalen (8-methoxypsoralen) and specially designed artificial sources of UV-A,[3] comparison studies have shown PUVA to be more effective in the treatment of psoriasis than ultraviolet light alone.[1-4] This study explores the potential of using sun as the source of ultraviolet radiation for oral psoralen photochemotherapy. Because sun exposure itself is often beneficial to psoriasis, psoralen + UV-A from the sun (which we have termed PUVASOL) was compared to sun exposure alone in a placebo study and in a bilateral comparison study.

MATERIALS AND METHODS

Patient Selection

Fifty-one white volunteers with chronic, stable, or flaring psoriasis covering 10% to 75% of their body were treated. No patients with erythrodermic or pustular psoriasis were included in the trial. No pregnant patients or persons with known photosensitivity were permitted in the study. Although several patients had been receiving methotrexate or steroids for systemic effect in the past, patients were not permitted to use antipsoriatic medications for systemic effect, topical or oral steroids, or known photosensitizing medications during the course of this study. No topical medications except for emollients and conventional scalp applications were permitted throughout this study. When lubricants were permitted, they were used on both sides of the body in the bilateral comparison studies. Laboratory evaluation was carried out before, during, and after the study, and included hematocrit readings, hemoglobin levels, WBC count, antinuclear antibody reactions, SGOT levels, alkaline phosphatase values, bilirubin levels, and microscopic examination of urine. Informed consent was obtained.

Treatment Groups

Group 1 was a double-blind psoralen-placebo study (12 patients). Group 2 was a bilateral comparison study; a higher dose of methoxsalen was used (approximately 0.6 mg/kg). There were two subgroups within group 2: A, alternate-day PUVASOL vs alternate-day sun treatment for six patients; B, alternate-day PUVASOL vs daily sun treatment for 11 patients. Group 3 was a bilateral comparison study; a lower dose of methoxsalen was used (approximately 0.3 mg/kg). Within this group there were three subgroups: A, alternate-day PUVASOL vs alternate-day sun treatment for four patients; B, alternate-day PUVASOL vs daily sun treatment for three patients; C, daily PUVASOL vs daily sun treatment for ten patients.

Patients in the double-blind study were randomly assigned to receive methoxsalen or a placebo capsule. In this group, ingestion of medication was followed by sun exposure of the whole body every other day (or three times each week). In the bilateral comparison studies, while one side of the body was being treated, the other side was shielded with folded sheets or black cloth taped at the midline. The front and back of the same side were treated identically by having the patient first lie in a supine position and then in a prone position. On days when both PUVASOL treatment and sun treatment were to be given, the latter was given first, the exposure ending about one hour before zenith. After completion of the sun treatment, patients ingested psoralen and were kept out of the sun for two hours before they began their PUVASOL exposure about one hour after zenith. Because of the danger of cumulative phototoxic reactions, PUVASOL was never used at the higher methoxsalen dose more frequently than every alternate day. At the lower drug dose, daily PUVASOL treatments were compared to daily sun treatments (group 3, C).

Drug Dose

Ten-milligram capsules of methoxsalen were given according to the patient's weight. In groups 1 and 2, patients weighing up to 50 kg body weight received 20 mg; those weighing from 51 to 65 kg body weight received 30 mg; those weighing from 66 to 80 kg body weight received 40 mg; and those heavier than 80 kg body weight received 50 mg. In group 3, patients weighing up to 66 kg body weight received 10 mg, and those heavier than 66 kg body weight received 20 mg.

Solar Exposure Doses

The time between ingestion of methoxsalen and the initiation of sun exposure was two hours. All exposures took place under controlled, observed conditions between 10 AM and 3 PM, standard time,

during the summer months. Twenty-eight patients were treated in Boston (latitude 42° 21'N) between June and August, and 23 patients in Sydney, Australia (latitude 33° 5'S), between January and April. The duration of sun exposure was estimated for each patient according to their individual characteristics and according to the ultraviolet flux prevailing at the time of exposure. Initial exposure times were based on complexion, degree of pigmentation, individual sunburn and suntan histories, and in some patients, on actual minimal erythema dose and minimal phototoxic dose testing. At the outset, identical exposure times (based on the highest predicted safe dose of UV-A) were given for sun alone and for PUVASOL treatments. All subsequent treatments to each side of the patient were increased independently to maintain a trace erythema. The delayed erythema response was assessed 24 hours after exposure to sunlight alone and at 48 hours after PUVASOL. Exposure doses were based on clinical judgment, and ultraviolet light meters were used to determine the duration of exposures. However, the meters used in the two centers differed in principle and calibration. The radiometer (IL700 research radiometer with PT 171C detector, UV-A filter, and cosine-corrected optics full hemispheric measurement) used in the Boston study was calibrated in milliwatts per square centimeter traceable to the National Bureau of Standards, Washington, DC. It consisted of an ultraviolet-sensitive vacuum photodiode and digital read-out amplifier. The filter-detector combination was designed to pass radiation in the 320-nm to 400-nm spectral band. The response was a bell-shaped curve peaking at 365 nm. In Sydney, the Robertson meter was used, which employs a pulse-counting technique to measure UV-A and UV-B irradiance. The meter reads in relative terms, and doses were therefore calculated from day to day as the product of time of exposure and average meter reading. Dosimetry in this combined study is therefore expressed in terms of the number of treatments rather than in absolute terms (total joules per square centimeter) and this is the basis for comparing treatment groups.

Grading of Responses

Improvement was graded by an observer who did not know the patients' treatment program, but the exaggerated melanogenic response of the PUVASOL-treated sites made blind grading impossible. At the time of each treatment, patients were evaluated and responses were graded as follows. *Essentially clear* was 95% to 100% improved. Psoriatic lesions are less than 5% of original distribution (excluding scalp, nails, or unexposed areas). *Improved* was significantly (50% to 95%) improved. In this grade, definite and obvious improvement are seen but clearing is not complete. Lesions remain minimally palpable or scaly. *Not significantly improved* was minimally (0% to 50%) improved.

In addition to this grading, one side of the body was compared with the other in the paired-comparison studies. In the double-blind placebo study, patients who were not significantly improved after three to four weeks were then treated with capsules known to contain methoxsalen. Patients in groups 2 and 3 were treated until one side had been clear for three treatments, until both sides were clear, or until 40 days were reached, whichever came first.

Results

Of the 51 patients who volunteered for this experimental treatment, five patients did not finish the study. Two patients, although initially highly motivated and showing some signs of improvement, found the treatments too inconvenient. The heat, insects, long exposure times, daily travel to the medical center, and miscellaneous difficulties with being available at midday caused them to discontinue treatment. One patient broke a bone in an unrelated accident and discontinued treatment. Two patients (Australian) discontinued therapy because of single incidents of painful phototoxic erythema. Forty-six patients completed the study and summaries of their data are given in Table 1 and 2. Owing to the uncertainties of weather, the protocol schedule of treatments (daily or second-daily) was seldom attained. Treatment times ranged from four minutes per side initially to more than 60 minutes per side as tan increased and solar ultraviolet radiation decreased.

Group 1

All of the patients in the PUVASOL group (six patients) attained the "improved" grade within four to seven treatments, whereas none of the placebo group reached this grade in five to nine treatments. The difference at this stage was sufficiently clear-cut that persistence with placebo was considered unwarranted, and a switch to PUVASOL was made in all but one patient. In the latter case, improvement with sun alone was deliberately sought by continuing to 12 treatments.

Four of the six initial PUVASOL patients had complete clearing in an average of 11.5 ± 2 treatments. The two in whom clearing failed received only seven and six treatments, respectively, because of waning summer sun and declining ultraviolet intensity. After three to four weeks (7 ± 2 treatments) of placebo therapy, the five unimproved patients were changed to PUVASOL and all subsequently improved, with three patients having complete clearing in four to 16 additional treatments.

Group 2, A

In five of six patients in subgroup A of group 2, the PUVASOL-treated side cleared completely in an average of seven treatments. The sun-treated side of five of six patients improved in an average of six treatments, but no sun-treated side cleared despite continuous therapy for more than one month. After completing the bilateral comparison study, four of these patients were eventually cleared with additional total body treatments with methoxsalen and sunlight. The remaining two patients were cleared with PUVA using artificial light sources (Table 2).

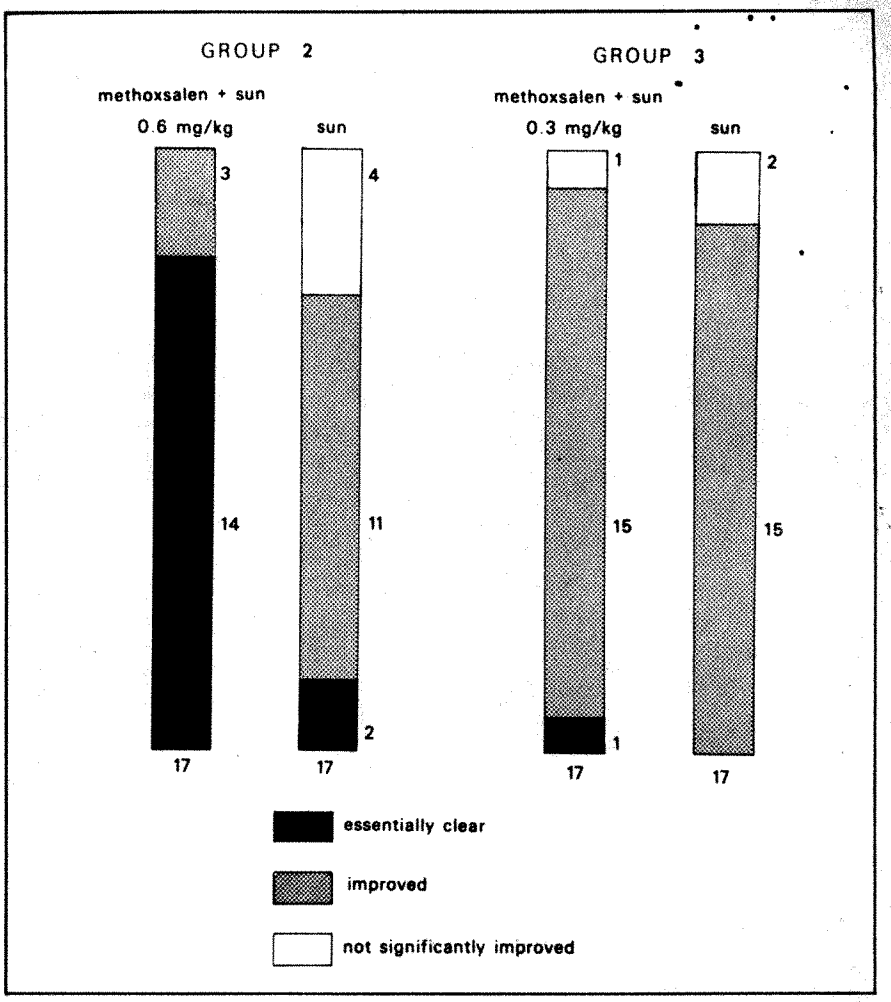
Group 2, B

Nine of the 11 patients in the B subgroup in group 2 were considered essentially clear (8.5 ± 3.0 treatments) on their PUVASOL-treated sides. Two of these nine patients were also essentially clear on the sun-treated side (13 treatments). However, in the remaining seven patients, three to ten additional sun treatments given after the PUVASOL side was clear failed to clear the sun-treated side. Subsequent to the bilateral comparison study, all 11 patients were made free of psoriasis bilaterally by treating with methoxsalen and total body exposure. Sunlight was used as the source of UV-A in nine patients, and artificial UV-A light sources were used in two patients (Boston).

Group 3

Three of four patients in the A subgroup in group 3 improved significantly on both sides in eight to ten treatments and the PUVASOL-treated side was considered clear in one patient (ten treatments). No patient cleared on the sun-treated side. Although no patient in the B subgroup in group 3 cleared, all PUVASOL sides and two of three sun-treated sides showed significant improvement. In each case, improvement was judged to be more marked on the PUVASOL side. All of the ten patients in the C subgroup (daily exposure) in group 3 improved. In eight of ten patients, the PUVASOL-treated side was judged to be more improved than the sun-treated side, but no patients improved enough to be judged as essentially clear (Table 2).

When lower doses of psoralens were used, the beneficial effects appeared to be similar to that seen with sun alone. Fifteen of 17 patients improved on both sides. In addition, one patient cleared on the PUVASOL side. Because no continuing improvement was observed in any patient, the group 3 bilateral comparison experiment was discontinued after 14 to 20 PUVASOL treatments. Sixteen of the 17 patients in group 3 were subsequently treated with 0.6 mg/kg of methoxsalen and artificial light and 15 had complete clearing. A total of 32 of the patients who were not clear on at least one side at the termination of the bilateral comparison (groups 2 and 3) experiment were subsequently treated with full doses of psoralen and either sun or artificial light, and 30 were thereafter judged essentially clear.



Bilateral comparison studies. Two bars on left side represent group 2 (conventional-dose (methoxsalen) patients; two bars on right represent group 3 (low-dose methoxsalen) patients. All patients, whether receiving daily or alternate-day treatments, are included in each group. Numbers refer to number of patient sides.

AD	0	3	1
D	0	2	1
D	0	10	0

Side Effects

Because all of the patients in the placebo study were eventually treated with methoxsalen, all 51 patients took methoxsalen at some time. Eight

patients ingesting 0.6 mg/kg of methoxsalen complained of mild nausea on at least one occasion at some point during their treatment. Severe nausea or vomiting occurred occasionally in only one patient, but this did not interrupt therapy. No patient ingesting the lower doses of methoxsalen experienced nausea. Moderate itching occurred on at least one occasion in two patients during placebo and sun therapy and in two patients receiving the lower dose of methoxsalen. Although itching occurred in five of 23 patients ingesting the higher dose of psoralen, severe itching was not a problem and never caused cessation of therapy. No ultraviolet burns occurred in the placebo group, the sun-treated sides, or the low-dose methoxsalen-treated sides. In the high-dose methoxsalen-treated sides, there were three occasions of local tender erythema and three more extensive painful erythematous responses, two of which led to patients dropping out of the study. Laboratory factors remained unchanged in all of the patients during the study.

Summary of Results

Sunlight alone is moderately good therapy for psoriasis. More than 80% of the patients' sides in the bilateral comparison studies (groups 2 and 3) improved considerably with sun therapy (Figure). Patients in group 1 (Table 1) treated with placebo and sun did not do as well as the sun-alone sides of patients in the bilateral comparison study. This difference cannot be explained by different frequencies or the total number of treatments and remains unexplained. In the bilateral study (Table 2), daily sun (83% of sides improved) was only slightly better than alternate-day sun (80% of sides improved), but two sides were considered essentially clear with daily sun therapy and no persons had complete clearing with alternate-day sun.

Low doses of methoxsalen (0.2 to 0.3 mg/kg) and subsequent sun exposure led to improvement in 94% of the patients' sides treated, with little difference in daily or alternate-day methoxsalen-sun treatment. The higher dose of methoxsalen (0.5 to 0.8 mg/kg) clearly leads to a better response to sun exposure. All of the patients treated improved substantially and 82% of the sides treated in the bilateral comparison study were judged to be essentially clear.

COMMENT

This report documents that under controlled conditions, using accurate dosimetry and adequate doses of methoxsalen, solar photochemotherapy is an effective treatment for psoriasis. The therapeutic dose of PUVA is close to the phototoxic dose. Because of this fact and because of the impossibility of accurately estimating global UV-A flux, correct dosimetry is essential. In Boston where an integrating dosimeter was used, burns were less frequent and severe than in Sydney where this type of meter was not available and where two severe burns resulted.

PUVASOL differs from artificial PUVA in that UV-B, visible light, and infrared radiation accompany the UV-A. These fractions of the electromagnetic spectrum may make a significant contribution to the erythemogenic or therapeutic effect of PUVASOL. In the present study, PUVASOL cleared four of the six (group 1) patients (whole body treated with PUVASOL placebo) in an average of 11.5 ± 2 treatments. In group 2 (split comparison, high-dose methoxsalen), 14 of the 17 patients cleared on the PUVASOL side in less than 12 treatments. These rates of clearing compare favorably with those published for artificial PUVA.

A direct comparison of PUVASOL and artificial PUVA is, however, not possible in this study in the absence of absolute ultraviolet dosimetry on all of the patients. Neither can treatment groups be compared in terms of length of exposures since solar UV-A flux varied from hour to hour. Because in all cases in the criterion for judging exposure times was the biologic response (erythema) of the subject after the previous treatment, the number of treatments remains a valid basis for comparison.

The principles of photochemotherapy are now well established.[1,2,4,5] When determining exposure doses one must consider (1) the spectral distribution of the source and how this relates to the erythema action spectrum of the skin of persons sensitized with psoralens, and (2) the intensity of the source within the erythema spectrum. This determines the duration of treatment.

In some geographic locations, the sun provides a UV-A source that requires no extra floor space, no travel to treatment centers, and no cost. However, the disadvantages are considerable and include the variability of the source due to season, or local weather factors, and time of day. In Sydney, on 26 of the 94 days, no exposures were possible due to rain or cloud. At many latitudes, exposures are feasible only during the summer. Excessive heat or cold, insects, and lack of privacy may seem to be trivial considerations, but they may result in loss of treatment days. Exposure times in the sun may be much longer than in high-intensity artificial systems. For instance, the Sylvania Phototherapy System[1,3] has more than twice the UV-A intensity of sunlight at noon in June at the equator and treats the whole body at once. Sun treatment requires that the patient receives treatments while in both prone and supine positions. Thus, the shortest possible PUVASOL treatments will be four times that of artificial sources. Exposures that are given other than at peak summer, zenith, or at the equator are lengthened further. Long treatment times extend exposures beyond the time when orally administered psoralens are most active in the skin.

Because of frequent and prolonged interruptions to the treatment schedule by weather, the investigators had opportunities of observing the response to single doses of PUVASOL. It was apparent that in many cases psoriasis would continue to clear for up to one week after one exposure. In this way, some patients had clearing in as few as five treatments. This observation has obvious therapeutic implications, and a PUVASOL trial using prolonged treatment intervals is envisioned.

Dr D. F. Robertson of the University of Queensland supplied the dosimetry equipment. Diedrich Waterman, Michael Latessa, Doffy White, Pat Lane-Brown, Beth Levin, Brian Fitzpatrick, and Loretta Caruso provided technical assistance on this project; Mr Charles Comeau, of International Light, Inc, Newburyport, Mass provided expertise; and Dr Robert Stern provided critical review and comments in the preparation of this manuscript.

Smokers' Melanosis

Occurrence and Localization in the Attached Gingiva

C. Anders Hedin, DDS

• The aim was to clinically study the frequency and extension of the melanin pigmentation in the attached gingiva and its relation to tobacco smoking. The population examined consisted of patients and dental nurse students at the School of Dentistry in Umeå, Sweden. All of the patients with pigmentation proved to be tobacco smokers. The pigmentation was given the name "smokers' melanosis." Between 12.9% and 14.9% of those examined and between 25.5% and 31.0% of those who smoked had smokers' melanosis. Patients with smokers' melanosis had a significantly higher tobacco consumption than smokers without pigmentation. In 95.2%, smokers' melanosis was found in the mandible and was most common in the attached gingiva on the labial side of the canines and incisors.

Smokers' melanosis is thus considered to be caused by tobacco smoking and is expected to be found in other parts of the oral mucosa.

(*Arch Dermatol* 113:1533-1538, 1977)

Melanosis gingivae is often found in members of dark-skinned ethnic groups,[1-4] but is seldom found among white Europeans.[3,5,6] Besides melanosis gingivae caused by genetic factors, melanin pigmentation is observed in other parts of the oral mucosa. The cause can be medical drugs such as antimalarials and certain tricyclic thymoleptics.[7,8]

Several diseases are characterized by melanosis in the oral mucosa. Among them are Addison's disease, Albright's syndrome, Peutz-Jeghers syndrome, and von Recklinghausen's disease.[5] Patients suffering from periodontitis are having their oral mucosa carefully examined in connection with their periodontal treatment. To obtain a clinically correct picture of the gingival inflammation, the color differences appearing in different parts of the attached gingiva are registered. During such examinations, a brown discoloration of parts of the interdental papillae and the attached gingiva was observed in patients visiting the Department of Periodontology at the School of Dentistry in Umeå, Sweden.

Histological studies showed that the pigmentation consisted of melanin. Literature states that a maximum of 6% of the population among white Europeans have some kind of pigmentation in the oral mucosa.[4,9,10] There seemed to be a difference in frequency between the literature reports and the Umeå patient group. There also seemed to be a connection between smoking and melanosis in the attached gingiva.

AIM OF INVESTIGATION

The aim of the investigation was to clinically study the frequency and extension of the melanin pigmentation that was found to be localized to the attached gingiva and to study its relation to smoking.

MATERIALS AND METHODS
Part 1

To study the frequency of melanin pigmentation in the attached gingiva, 121 patients (53 men and 68 women) were randomly picked from the patients referred to the Department of Periodontology in 1974 (Fig 1). The periodontal diagnosis of these patients varied between gingivitis and periodontitis complicata. To study the frequency of melanin pigmentation in the attached gingiva in persons with good gingival conditions, 93 female dental nurse students were examined. They were all the students in three subsequent courses of dental nurse education in Umeå. Their average age was 21.1 years (SD = 3.5) and as a rule, the conditions of their gingivae were excellent, although minor areas of erythema and edema corresponding to the diagnosis gingivitis, were observed.

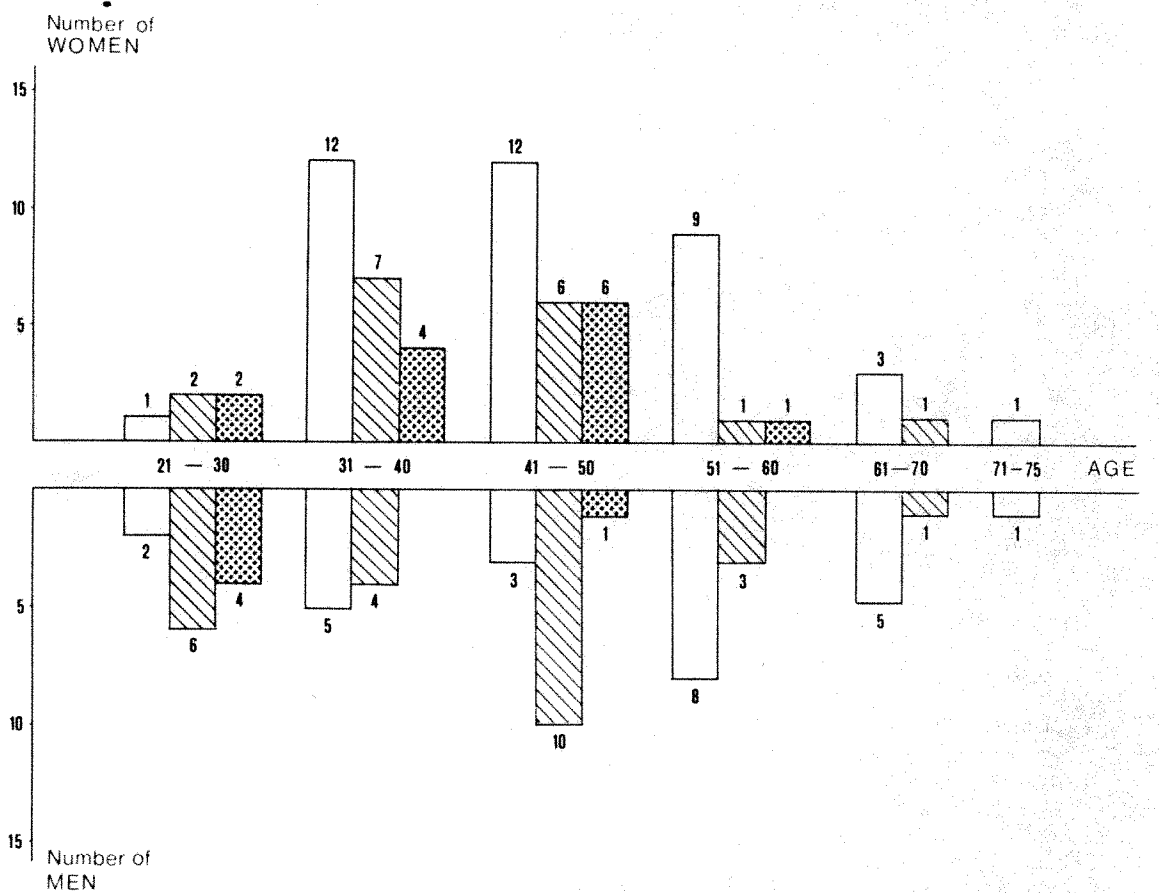

Fig 1.—Age and sex distribution among 121 patients randomly picked out from patients visiting Department of Periodontology, School of Dentistry, Umeå, Sweden. Nonsmokers without smokers' melanosis consisted of 38 women, 24 men. Smokers without smokers' melanosis consisted of 17 women, 24 men. Smokers with smokers' melanosis consisted of 13 women, 5 men. Clear bar indicates nonsmokers without pigmentation; bar with diagonal lines, smokers without pigmentation, dotted bar, smokers with pigmentation.

Part 2

To study the localization of the pigmentation and the connection with smoking in a greater number of patients with pigmentation, 71 patients (48 women and 23 men) with melanosis in the attached gingiva were picked from the patients visiting the Department of Periodontology during a one-year period (Fig 2).

State of health, medicine consumption, and smoking were noted in the case history of the patient. Color of eyes and hair was noted for the students in part 1 and for the patients in part 2. Frequency and extension of pigmentation of the attached gingiva were clinically registered in diagrams and in color photographs. Amalgam tattoos could be ruled out through their gray blue color, their position near amalgam restorations, and the fact that radiopaque substances could often be observed in the pigmentation area.[11] In connection with periodontal surgery, biopsy specimens from the attached gingiva were obtained from the patients in part 1 of the investigation.

Statistical calculations of cigarette consumption were carried out with Student's t test. The clinical extension of the pigmentation was calculated with the aid of the Sign test. The generally accepted significance levels were used.

RESULTS

Frequency of Pigmentation

Part 1.—Among the 121 patients in part 1, 18 patients (five men and 13 women [14.9%]) had melanin pigmentation in the gingiva (Fig 1). Among the 93 female students, there were 12 students (12.9%) with melanin pigmentation in the gingiva.

All of the patients and students declared that they were healthy. Their medicine consumption is given in Table 1.

Histology

The histological study of the pigmentation was performed on tissue taken from the 18 patients with pigmentation in part 1 of the investigation. In histological stains, it was evident that in the pigmented gingiva heavy silver stain (Masson-Fontana) was deposited in the basal layer of the epithelium (Fig 3) as well as in the higher cell layers (Fig 4). DOPA staining showed a high number of enzymatically active melanocytes in the basal layer (Fig 5). Electron microscopy showed premelanosomes and melanosomes in the melanocytes and compound melanosomes distributed to the keratinocytes (Fig 6). It was concluded that the clinically registered brown discoloration of the attached gingiva consisted of melanin. Studies of tissue from nonpigmented parts of the gingiva or from patients without clinical pigmentation showed minor traces of melanin in the basal cell layer.

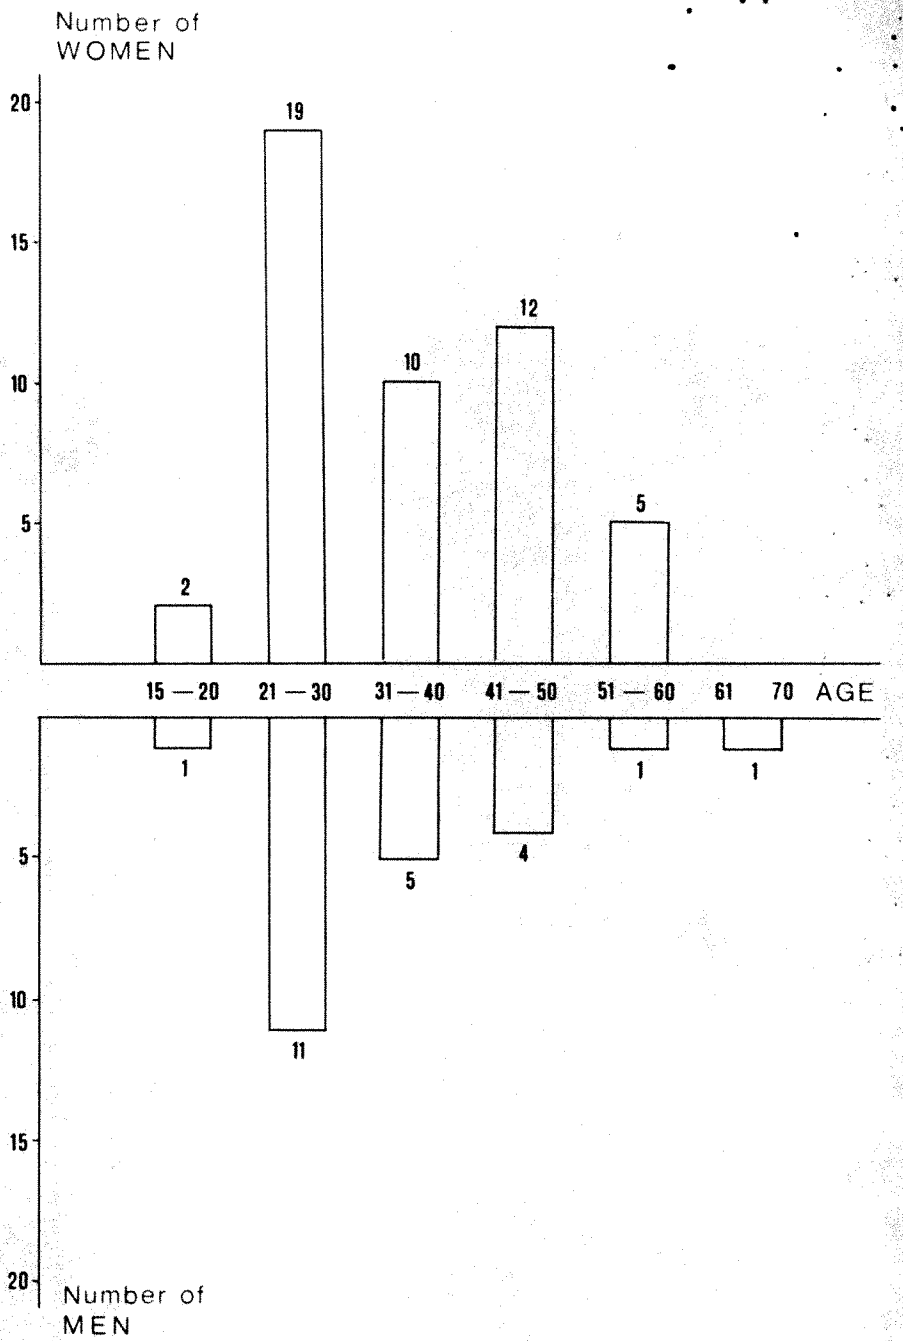

Fig 2.—Age and sex distribution among 71 patients (48 women and 23 men) with smokers' melanosis. During one year, all patients with smokers' melanosis were selected from patients visiting Department for Periodontology, School of Dentistry, Umeå, Sweden.

Localization

The least-extended pigmentation was localized to the central part of one or two solitary interdental papillae (degree I). Often it was the papillae between the canines and the nearest incisors that showed this degree of pigmentation (Fig 7). When the pigmentation was somewhat more extended, pigmentation of more numerous solitary interdental papillae was observed (degree II). At a more comprehensive extension, isolated pigmented areas had converged into short continuous ribbons (degree III) or into one long continuous ribbon that included the greater part of the gingiva in front of the canines and incisors (degree IV, Fig 8). The different degrees of pigmentation are shown graphically in Fig 9. Among 83 persons with pigmentation who were in parts 1 and 2 of the investigation, degree I was found among 21 (25.3%). Degree II was found among 25 (30.1%), degree III among 20 (24.1%), and degree IV among 17 (20.5%). The pigmentation was always localized to the attached gingiva and thus, the apical extension did not exceed the mucogingival junction (Fig 10). The free gingiva did not show pigmentation and pigmentation was not observed in the lingual or palatal part of the gingiva.

In 42 (50.6%) of the students and patients in part 2 of the investigation, pigmentation was found only in the mandible, whereas in 39 (47.0%) pigmentation was found both in the mandible and in the maxilla. In two (2.4%) pigmentation was found only in the maxilla. Thus, melanin pigmentation in the attached gingiva is most common in the mandible ($P < .001$). In 33 (84.6%) students and patients with pigmentation, the pigmentation in the maxilla was found within a sector of the attached gingiva, laterally confined by the gingiva on the labial side of the maxillary canines. In six (15.4%) of those with pigmentation, the pigmentation was also found in the premolar areas. In 68 (84.0%) of those with pigmentation in the mandible, the pigmentation was localized to the sector of the attached gingiva that is laterally confined by the gingiva on the labial side of the mandibular canines. In 12 (14.8%), the

UNIVERSITY OF MEDICINE LIBRARY

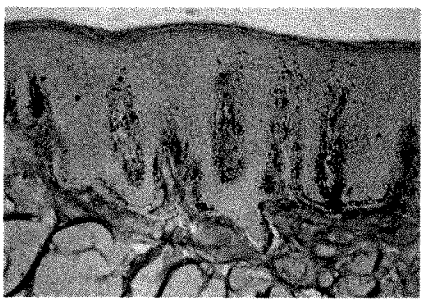

Fig 3.—Pigmented gingival tissue from patient with smokers' melanosis. Heavy accumulation of silver stain in basal cell layer of epithelium points to melanin (Masson-Fontana, van Gieson, original magnification ×175).

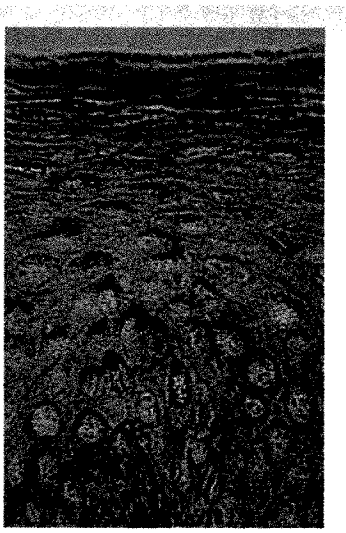

Fig 4.—Pigmented gingival tissue from patient with smokers' melanosis. Silver stain has deposited in keratinocytes through prickle cell layer, granular layer, and cornified layer, pointing to melanin (Masson-Fontana, van Gieson, original magnification ×450).

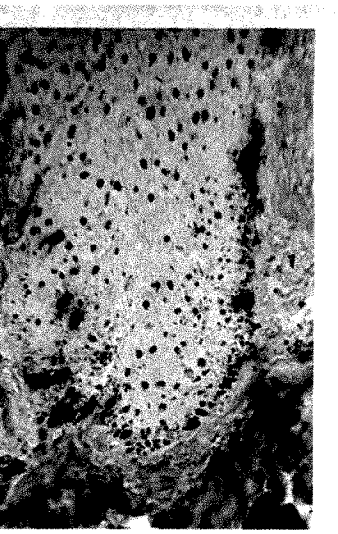

Fig 5.—Pigmented gingival tissue from patient with smokers' melanosis. DOPA stain shows enzymatically active melanocytes in basal layer of epithelial ridge (DOPA, eosin, original magnification ×250).

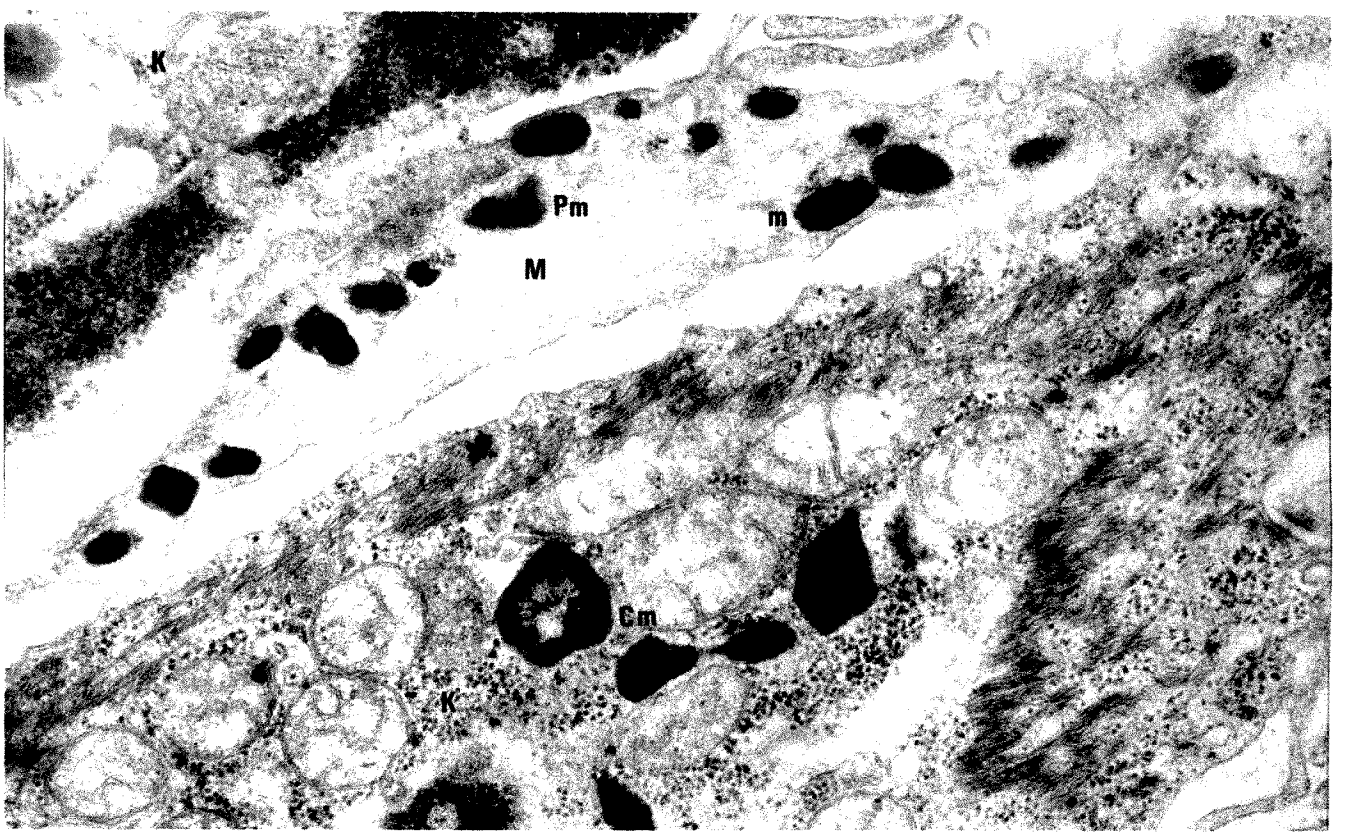

Fig 6.—Pigmented gingival tissue from patient with smokers' melanosis. Dendrite of melanocyte (M) is extending between two keratinocytes (K). Dendrite contains premelanosomes (Pm) and melanosomes (m). One keratinocyte contains compound melanosomes (Cm) (original magnification ×35,200).

Fig 7.—Degree I of smokers' melanosis. Moderately brown pigmentation can be seen in papilla medial to canines. This picture shows most common localization of smokers' melanosis.

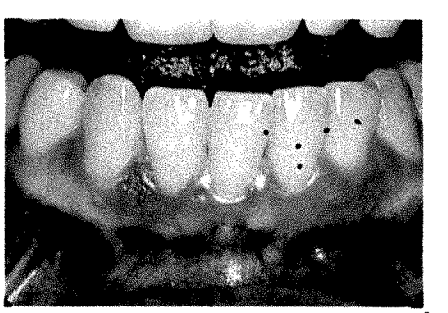

Fig 8.—Degree IV of smokers' melanosis. Moderately brown pigmentation including greater part of attached gingiva just in front of canines and incisors.

pigmentation was as well observed to the lateral side of this sector; in a single case it was also in the first molar area. Thus, melanosis in the attached gingiva is more often found in the labial part of the gingiva that is in the area of the canines and incisors than in the lingual and palatal part or in the premolar or molar areas ($P < .001$). There were no differences dependent on sex as to the localization of the melanosis.

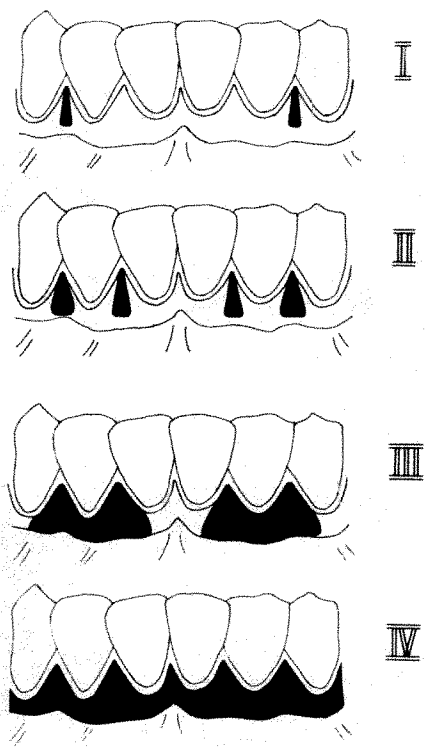

Fig 9.—Degrees of pigmentation in maxilla and mandible. Among persons with smokers' melanosis degree I occurred in 25.3%; degree II in 30.1%; degree III in 24.1%; and degree IV in 20.5%. (Black color shade in graphic does exceed in vivo brown color.)

Tobacco Consumption

All of the patients and students with melanin pigmentation in the gingiva were smokers. Patients with pigmentation had a higher cigarette consumption than smokers without pigmentation ($.01 > P > .001$). A tendency toward greater cigarette consumption among the men with melanin pigmentation than among the women could be observed in part 2 of the investigation ($.05 > P > .01$). Tobacco consumption data are given in Table 2.

Color of Eyes and Hair

No statistical correlation was found between any special iris or hair color and the occurrence of gingival melanin pigmentation.

COMMENT

The investigation shows that 18 (14.9%) of the patients and 12 (12.9%) of the students had melanin pigmentation in the gingiva. The small difference between the number of persons with pigmentation in these two groups shows that periodontitis does not increase the frequency of pigmentation significantly.

The magnitude of 18 (14.9%) and 12 (12.9%) of persons having gingival melanin pigmentation had not been reported earlier, to our knowledge, for light-skinned Europeans. This can be due either to the fact that in general, earlier investigations have had the whole oral cavity as the examination field or to the fact that the interest has been concentrated on discolorations that contrast strongly to the mucosa. At such examinations, it is probably easy to overlook a modestly pigmented interdental papilla.

The investigation shows a very strong correlation between melanin pigmentation in the gingiva and smoking, as all the persons having melanin pigmentation were smokers. No earlier investigations show this connection. Van Wyk,[3] however, suspects that smoking could be the cause for the variations in gingival pigmentation of the Bantus.

Cigarette smoking was dominant compared to pipe smoking and therefore it is not possible to show, in this investigation, any difference between cigarette smokers and pipe smokers as to pigmentation.

It has been known for a long time that melanosis gingivae is controlled by genetic factors among people with a dark complexion.[1,3] This investigation shows, however, that for a number of persons from northern Sweden where brown iris and dark hair are not predominant in frequency, it is possible to isolate tobacco smoking as a cause for melanin pigmentation of the gingiva. To distinguish the normal, genetically caused melanosis gingivae from the melanin pigmentation caused by tobacco smoking, the latter has been given the name "smokers' melanosis." Since smokers' melanosis probably can be found in all parts of the oral mucosa, the respective localization could be added. Besides the attached gingiva, other sectors of the oral mucosa are also exposed to high concentrations of tobacco smoke. At the inhalation of tobacco smoke, the mucosa in the region of the oropharynx is probably exposed. Merchant et al[12,13] have found melanin pigmentation in the soft palate in patients with serious lung diseases. They connect this with a long-time production of adrenocorticotropic hormone (ACTH) from the abnormality in the lung. All of the patients, however, are reported to be excessive smokers, and therefore it is highly probable that these changes in pigmentation are not caused by ACTH production from the lungs. They are probably smokers' melanosis in the soft palate. The connection between smoking and lung diseases has been known for a long time.

Lindquist and Ullberg[14] have shown that nicotine as a polycyclic compound has great affinity to the melanin in the inner ear. They showed that polycyclic compounds disturb the melanin-containing cells and cause a higher melanization through the development of more melanosomes and the migration of the melanosomes. The reason why smokers' melanosis arises in the oral mucosa can be due to similar disturbances in the normal

Cigarette smokers without pigmentation		36 (38.7%)	9.2 cigarettes/day, SD = 3.4
Cigarette smokers with pigmentation		12 (12.9%)	10.7 cigarettes/day, SD = 8.9
71 patients with pigmentation, part 2			
Cigarette smokers	21 (29.6%)	48 (67.6%)	Males†: 16.7 cigarettes/day, SD = 8.1* Females†: 12.6 cigarettes/day, SD = 4.6*
Pipe smokers	2 (2.8%)	...	50.0 gm/wk, SD = 0

*Patients with pigmentation had a higher cigarette consumption than patients without pigmentation who smoked ($.01 > P > .001$).
†A tendency toward greater cigarette consumption among men with pigmentation than among women with pigmentation could be observed in part 2 of the investigation ($.05 > P > .01$).

metabolism of melanosomes in the melanocytes and in the keratinocytes in the oral mucosa of smokers.

Among the patients with smokers' melanosis in part 1 of the investigation, 13 (72.2%) were women. It should then be noted that 68 of the 121 patients were women. However, the tendency is interesting when seen against the background of an almost significantly lower cigarette consumption by the women with pigmentation compared with the men with pigmentation. The cause for this could be the periodic increase in the amount of estrogen in the blood in connection with menstruation, gravidity, and/or consumption of hormonal contraceptives. Several investigations have shown an increased pigmentation tendency in women on these occasions.[15-17]

Further lines of investigation include the mechanism behind the development of smokers' melanosis and the connection with periodontitis.

Topically Applied Antifungal Agents

Percutaneous Penetration and Prophylactic Activity Against *Trichophyton mentagrophytes* Infection

Sylvia M. Wallace, PhD; Vinod P. Shah, PhD; William L. Epstein, MD; Joseph Greenberg, MD; Sidney Riegelman, PhD

• **Penetration and prophylactic activity against *Trichophyton mentagrophytes* infection of topically applied antifungal agents were studied in human volunteers. The concentration and persistence of drug in the stratum corneum was determined after different treatment schedules and from different vehicles. Measurable levels of griseofulvin, clotrimazole, miconazole nitrate, and thiabendazole remained in the skin four days after discontinuation of topical applications. Griseofulvin, miconazole, and clotrimazole exhibited prophylactic activity against infection by *T mentagrophytes* spores in a standardized test. Griseofulvin was a significantly better prophylactic agent than either miconazole or clotrimazole.**

(*Arch Dermatol* 113:1539-1542, 1977)

In preliminary studies,[1] topically applied griseofulvin was shown to protect against experimental infection by *Trichophyton mentagrophytes* spores. The present study further investigates the prophylactic activity of topically applied griseofulvin and other therapeutically active antifungal agents. The drugs—thiabendazole, miconazole nitrate, and clotrimazole—were chosen from commercially available therapeutic agents used to treat superficial fungal infections.

Topical thiabendazole has been suggested[2] as a useful agent for the treatment of superficial *T mentagrophytes* infections. Miconazole is claimed[3] to be effective in the topical treatment of dermatomycosis. Studies suggest[4] that penetration of clotrimazole from topical application is sufficient to provide minimum inhibitory concentrations against most fungi.

The effect of vehicle formulation on the epidermal reservoir of the drug was also studied.

Accepted for publication May 11, 1977.

SUBJECTS AND METHODS

Subject Selection

Healthy adults between the ages of 18 and 50 were considered as suitable subjects. Medical examinations prior to initiating the study substantiated a history free of notable past illnesses and allergy to griseofulvin, clinically normal, healthy skin, and absence of chronic superficial fungal infections. Subjects who were to receive application of fungal spores were tested on the forearm with an intradermal infection of *Trichophyton* antigen. Subjects who gave an immediate response or no response after two days were excluded.

Skin Samples.—Skin samples were obtained from the palm and forearm by light scraping of the skin surface with a large, open dermal curette (level 1). In some cases a second, deeper sample (level 2) was obtained by more vigorous scraping with a curette until the glistening layer was reached.[5]

Samples were weighed and homogenized in distilled water. The homogenate was extracted with 10 ml of ether and analyzed for drug content by the appropriate method.

Assay Procedures

Griseofulvin.—Griseofulvin was determined in skin samples by the electron capture gas chromatographic procedure or fluorescence assay previously reported.[5]

Thiabendazole.—Thiabendazole was quantitated by fluorescence spectrometry. The ether extract of skin was evaporated to dryness and the residue dissolved in 0.5 ml of methyl alcohol. The solution was acidified with 1 drop of concentrated sulfuric acid. Fluorescence was measured in a spectrophotofluorometer (excitation wavelength, 300 nm; emission wavelength, 350 nm). Standard curves of fluorescence vs thiabendazole concentration were linear from 0.1 to 1 μg/0.5 ml.

Clotrimazole and Miconazole.—Both were quantitated by electron capture gas chromatography. Ether-extracted samples were chromatographed on a glass column packed with 3% phenylmethylsilicone (50% phenyl substituents) coated on a dimethyl dichlorosilane-treated diatomaceous earth (3% OV-17 on Gas Chrom Q). Griseofulvin served as the internal standard for clotrimazole assays and 8-chlorotheophylline for miconazole assays. Analytical methods were sensitive to 5 ng of drug. Details of analytical procedures are to be published.[6]

Penetration of Topically Applied Antifungals

Experiment 1 involved the following drug formulations: placebo of 95% ethyl alcohol, 0.45% griseofulvin solution in ethyl alcohol, 1% thiabendazole solution in ethyl alcohol, 1% clotrimazole solution in polyethylene glycol 400, and 2% miconazole nitrate cream. These formulations were applied to the forearm twice daily for ten days. Skin scrapings were collected 24 and 96 hours after discontinuation of topical applications.

Experiment 2 involved three formulations each of griseofulvin and clotrimazole: a 1% solution in polyethylene glycol 400, a 1% solution in propylene glycol, and a 1% suspension in 2.5% sodium carboxymethylcellulose. Subjects applied one formulation twice daily for five days on both palms. Approximately six hours after the last application, epidermal scrapings were obtained from the left palm at two levels (1 and 2) by consecutive curettage. Approximately 24 hours later, similar scrapings were obtained from the right palm.

Experiment 3 involved the following formulations: 1% griseofulvin solution in 85% polyethylene glycol 400-15% ethyl alcohol and 1% griseofulvin solution in 75% polyethylene glycol 400-25% ethyl alcohol. A formulation was applied twice daily to one arm for five days and to the other arm for 13 days. Epidermal skin scrapings were obtained from the forearm 6 and 24 hours after discontinuation of topical applications.

Prophylaxis of *T mentagrophytes* Infection

Experiment 4 involved the following formulations: placebo of 95% ethyl alcohol, 0.45% griseofulvin solution in ethyl alcohol, 1% thiabendazole solution in alcohol, 1% clotrimazole solution in polyethylene glycol 400, and 2% miconazole nitrate cream. A drug formulation was applied twice daily for ten days to one forearm. A placebo was similarly applied to the other arm. On the 11th day, 300 spores of *T mentagrophytes* were applied to a 6-sq-cm area of each forearm. The areas were covered with an occlusive plastic dressing for four days. After the patches were removed, the sites were examined weekly (for 30 days) for evidence of fungal infection.

Experiment 5 involved the following formulations: 1% griseofulvin solution in 85% polyethylene glycol 400-15% ethyl alcohol, 1% clotrimazole in polyethylene glycol 400, 2% miconazole nitrate cream, and 85% polyethylene glycol 400-15% ethyl alcohol. To maintain a double-blind study, drug formulations were letter-coded, and appli-

cation sites (on the forearms) for the four formulations were allocated according to a Latin square design. A different drug formulation was applied twice daily for ten days to each of the four areas. Each 6-sq-cm area was infected with 300 spores to *T mentagrophytes*, and the sites were occluded for four days. After removal of the dressing, gauze patches were cultured for evidence of viable fungi. Areas on the forearm were examined weekly (for 30 days) and lesions scored according to established criteria. A score of 0 represented normal skin with only slight scaling and erythema; +1, six to ten small erythematous follicular papules or small pustules with no more than one or two larger (2 to 3 mm) erythematous papules or pustules; +2, a greater number of papules or pustules, a colony formation, or coalescence of lesions. A +2 response was considered unacceptable for a prophylactic antifungal agent. For collection of data, one week was chosen (on an individual basis) when the greatest degree of response occurred. The dermatologist (W.L.E.), scoring the infections, was not aware of the treatments received. The treatment code was assigned and maintained by participants not involved in assessing the infection. Since the scoring of infections produced discontinuous data, ie, the response could only assume discrete values of 0, 1, and 2, results were analyzed by χ^2 contingency tables. Heterogeneity of treatments was further examined by multiple comparisons. For three scoring categories and two treatments, expected frequencies for the +1 response category were less than 2.5, and greater than 20% of cells were less than five. Cochran[7] suggested that in such circumstances the χ^2 calculated would be baised. Therefore, to make individual comparisons statistically valid, tables were collapsed by combining 0 and +1 responses to produce two categories—acceptable (0 and +1) and unacceptable (+2). A priori, a +1 category of infections was established as acceptable for a prophylactic agent while +2 was unacceptable. Probabilities for these individual 2 × 2 tables were calculated by the Fisher exact test.[8]

RESULTS AND COMMENT

Measurable levels of clotrimazole, miconazole, griseofulvin, and thiabendazole remain in skin four days after discontinuing topical application of formulations (experiment 1). Average epidermal concentrations of thiabendazole after ten days' topical application are significantly greater than miconazole, clotrimazole, or griseofulvin (Table). However, the rate of disappearance of thiabendazole and miconazole from the skin is greater than that for griseofulvin and clotrimazole. The 96-hour level is 20% of the 24-hour level for clotrimazole and 17% for griseofulvin, but only 6% for miconazole and 8% for thiabendazole. The rate of removal of drug from the skin influences the length of time the minimum inhibitory concentration against fungi is maintained and thus the efficacy of the medication.

Although the ethyl alcohol solution of griseofulvin delivered high concentration of drug to the stratum corneum, the vehicle is too irritating to be used chronically or over a widespread area. Thus, alternative vehicles were investigated. Stratum corneum concentrations six hours after discontinuation of application of griseofulvin in polyethylene glycol 400, propylene glycol and 2.5% carboxymethylcellulose (experiment 2) were not significantly different (analysis of variance, $P = .05$) (Table 2). However, the epidermal reservoir of griseofulvin 24 hours after discontinuation of topical applications was significantly larger with the polyethylene glycol 400 vehicle. Drug levels were much lower than achieved with an ethyl alcohol vehicle.

None of the three formulations of clotrimazole (experiment 2) exhibited any distinct advantage. Stratum corneum concentrations of clotrimazole were not significantly different after application in polyethylene glycol 400, propylene glycol and 2.5% carboxymethylcellulose (Table 3). Twenty-four hours after a five-day application (Table 3), clotrimazole levels in the stratum corneum were significantly less than after a ten-day application (Table 1). The difference could be due to prolonged application and/or the different permeability of palm and forearm skin.

*Probability of the observed table occurring by random chance as calculated from the following formula:

$$\frac{(a+b)!\,(c+d)!\,(a+c)!\,(b+d)!}{N!\,a!\,b!\,c!\,d!}$$

†Probability of obtaining the observed table or one even more extreme if the null hypothesis were true. The null hypothesis (there is no significant difference between treatments) is tested by examining the sum of the probabilities (as calculated from the aforementioned formula) for the observed and all more extreme tables.[9]

Multiple irritation studies of polyethylene glycol-ethyl alcohol combinations gave negative results, thus indicating a low degree of potential irritation for mixtures containing up to 50% ethyl alcohol. Mixtures of polyethylene glycol 400 and ethyl alcohol (experiment 3) were effective delivery agents for griseofulvin, but the drug did not accumulate to the extent noted when pure ethyl alcohol was used as the solvent. There was no significant difference (t-test, $P = .05$) in the epidermal concentrations of griseofulvin achieved after application in a 75% polyethylene glycol 400-25% ethyl alcohol vehicle and an 85% polyethylene glycol −15% ethyl alcohol vehicle (Table 2). Concentration of griseofulvin in epidermal skin samples obtained from the forearm was significantly greater (paired t-test, $P = .05$) after 13 days' repetitive application than after five days' application. Concentrations 24 hours after discontinuation of applications were significantly less than six hours after discontinuation.

A preliminary experiment (experiment 4) validated the infection procedure and screened topical antifungal agents for prophylactic activity. Eighteen of 22 subjects developed infections on the control forearm (ie, untreated). None of the subjects in the griseofulvin-treated group developed infections. Two of five clotrimazole, one of three miconazole, three of four thiabendazole, and five of five placebo-treated subjects developed infections on the treated arm. Results as analyzed by the Fisher exact test were statistically significant ($P < .05$) only for the placebo-griseofulvin comparison. Because of poor response, thiabendazole was not included in subsequent experiments.

Promising results of the preliminary experiment prompted further tests (experiment 5) on the prophylactic activity of griseofulvin, clotrimazole, and miconazole. Four treatments—griseofulvin, clotrimazole, miconazole, and placebo—were randomly assigned to sites on the forearms of 24 subjects according to 4 × 4 Latin squares. Two subjects did not complete the study, and one subject was excluded from statistical analysis because of departure from protocol (Table 4). The details of the statistical treatment are discussed in the Methods section. For three scoring categories (0, +1, +2) and four treatments, a χ^2 of 41.7 (Table 5) indicated a significant difference between treatments ($P < .05$, 6 df). Although the expected frequency in some cells of the χ^2 table was less than five, the significance level was still considered valid since all cells contained expected frequencies greater than 2.5.[9] Statistical comparisons between individual treatments after pooling responses into two groups (unacceptable and acceptable) are summarized in Table 6. Griseofulvin, clotrimazole and miconazole were significantly better than placebo ($P < .05$). While 91% of subjects developed +2 infections in the placebo-treated sites, 38% and 43% developed +2 infections in the clotrimazole- and miconazole-treated sites, respectively. None of the subjects developed +2 infections at the griseofulvin-treated site. Based on the above statistical analysis, it is concluded that griseofulvin showed a significantly higher prophylactic activity than either clotrimazole or miconazole. Miconazole was not significantly better ($P < .05$) than clotrimazole.

This investigation was supported by US Army contract DAMD 17-75-C-5003.

Design of the microbiological experiments and statistical analysis of the data were developed in cooperation with Lt Col A. Allen, Letterman Army Institute of Research, Presidio of California.

Clotrimazole solutions were provided by Delby Pharmaceuticals, and miconazole cream by Johnson and Johnson, Ltd.

Cell Populations in Experimental Contact Dermatitis

Nicole Hunziker, MD, Richard K. Winkelmann, MD, PhD

• Sequential biopsy specimens from contact dermatitis induced in the guinea pig by the application of dinitrochlorobenzene were studied by histologic, histochemical, and electron microscopical methods. At 12 hours, mononuclear cells and polymorphonuclear cells reached their peak numbers. Increasing numbers of basophils were observed, and at 24 and 48 hours, the basophils reached their maximal numbers. The basophils were observed not only in the dermis but also in the epidermis, and they may have had an active role in inflammation or repair. A close relationship was noted between the macrophage and all of the successive cell populations in the dermis.

(*Arch Dermatol* 113:1543-1549, 1977)

Experiments on transfer of delayed cutaneous hypersensitivity by Landsteiner and Chase[1] in 1942 proved, for the first time, the role of the lymphocyte in allergic contact dermatitis in guinea pigs. Since then, there has been universal acceptance of the lymphocyte as the principal cell of this reaction. More recently, other authors have emphasized the presence of lymphocytes, monocytes, and macrophages.[2-5] Wolf-Jürgensen,[6] using the skin window technique, demonstrated the role of the basophil in cutaneous delayed hypersensitivity. By histologic examination, he found that the occurrence of basophil leukocytes coincided with the capacity for delayed hypersensitivity. In 1965, Hunziker and others[7] showed that the basophil count of the peripheral blood increases after primary cutaneous sensitization. Since 1970, Dvorak et al[8] have observed basophils in the Jones-Mote tissue reaction and proposed the term "cutaneous basophil hypersensitivity." Askenase et al[9] concluded that antibody cutaneous basophil reactions may be distinctive hypersensitivity responses distinguishable from classic anaphylactic Arthus and delayed hypersensitivity. Additional studies showed that basophils occur in various delayed hypersensitivity reactions, and Chase[10] questioned whether a reaction type should be characterized solely by its basophil content. In 1974, Katz et al[11] observed that, in cyclophosphamide-pretreated, sensitized guinea pigs, the cutaneous reaction is notably increased, and almost no basophils are detected. Thus, these authors stated that basophils are not necessary for the delayed hypersensitivity reaction and that they probably modulate the severity of the reaction.

We followed the time course of the basophils and other inflammatory cells in light microscopy, fluorescence, electron microscopy, and histochemistry in the cutaneous delayed hypersensitivity reaction in guinea pig skin and observed the associations of cells in the dermis and epidermis with the evolution of the inflammatory response.

MATERIALS AND METHODS

Six male albino guinea pigs, each weighing about 400 gm, were sensitized by the daily applications of 1% dinitrochlorobenzene (DNCB) dissolved in acetone to a 3-cm area on the back of the neck. Ten or more days later, the DNCB (0.1%) was applied to a 2-sq cm area of the flank skin. The degree of inflammatory activity was recorded at 2, 6, 12, 24, and 48 hours, according to a conventional scale (0 to + + +): 0, no reaction; +, mild erythema; + +, substantial erythema with induration; + + +, massive erythema with vesiculation, oozing, or crusting. Two nonsensitized guinea pigs were used as controls, with and without the application of DNCB to skin.

Biopsies were performed at each period of observation; a total of 30 biopsies were done in the sensitized guinea pig. Each biopsy specimen was immediately cut into pieces for subsequent handling.

Histology

After buffered formaldehyde fixation and paraffin embedding, sections were cut for staining with hematoxylin-eosin, Giemsa, toluidine blue, and polychrome methylene blue. Sections stained with acridine orange were examined by fluorescent microscopy with a xenon light source and an objective filter (K 530).

Histochemistry

Portions of the biopsy specimens were frozen in liquid nitrogen and were stored at −70 C until use within one week. Alkaline phosphatase,[12] acid phosphatase, and naphthol-AS-D-chloroacetate esterase (NASDCAE)[13] techniques were performed on each biopsy specimen.

Electron Microscopy

Small (1 mm) biopsy specimens were fixed in Chick's solution and were embedded in plastic.[14] Thick sections were stained with toluidine blue and Giemsa.[8] Thin sections (500 to 900 A) were triple stained with lead citrate, 3% uranyl acetate, and

lead citrate. The tissue sections (copper grids 150 to 200 mesh) were examined with an electron microscope at 60 kV. Six to nine grids from each of two blocks selected by thick-section examination from those available for each guinea pig for each time of observation were used for the sensitized and for the two nonsensitized guinea pigs.

Blood Cell Counts

Total WBC counts, basophils, and differential cell counts of blood smears in 107 normal albino guinea pigs and in the six DNCB-sensitized guinea pigs were done at 1, 6, 12, 24, and 48 hours after the DNCB-challenge test.

RESULTS

Clinical and Histologic Response

The macroscopic reaction after challenge with 0.1% DNCB in saline in the skin of the sensitized guinea pigs was positive after two hours, with the redness increasing until 12 to 24 hours. The reaction was still present at 48 hours, but exudation and crust formation was apparent at this time (Tables 1 and 2 and Fig 1 and 2). The histologic results of our study of sequential skin specimens parallel those from previous classic studies of this model.[15,16]

Blood Leukocyte and Basophil Studies

The normal guinea pigs had an average of 0.6% basophils in the blood. No substantial changes in basophil numbers were noted in the six sensitized guinea pigs at the time of the biopsies 2, 6, 12, 24, and 48 hours after the challenging application of 0.1% DNCB. However, the total leukocyte count consistently increased in both the sensitized and the control guinea pigs after the test, presumably from the stress of handling and testing.

Routine Tissue Basophil Study

The Giemsa, toluidine blue, and polychrome methylene blue stains were not routinely helpful, although these have been used for confirmation of data concerning the nature of the cells in the inflammatory infiltrates. We found it necessary to individually stain sections with Giemsa to obtain good results.

Fluorescent Basophil Study

The acridine orange method using fluorescent light demonstrated an increase in the number of orange fluorescent, discrete cells in the dermis at six hours. The number of fluorescent cells increased up to the end of observation at 48 hours. At 24 and 48 hours, some discrete, yellowish, granular cells, which may have been degranulated cells, were observed.

Histochemical Basophil Study

The histochemical procedure for NASDCAE demonstrated basophil and mast cells, showing bright red-stained granules filling the cytoplasm. NASDCAE-positive cells were easily found in the dermis at two and six hours in only two of the six guinea pigs. The number of cells in the dermis increased up to 24 hours and then seemed to stabilize or to be slightly increased at 48 hours. Some scattered granules were found free in the dermis at 24 and 48 hours. Positive cells were first observed in the epidermis at 12 hours, but they were more frequently seen at 24 and 48 hours. At that time, some isolated granules also were found in the epidermis.

Electron Microscopy

The thick sections stained with toluidine blue or Giemsa for electron microscopy also showed both mast cells and basophils. The Giemsa stain showed the granules more brightly and distinctly. The number of single or grouped basophils was increased in

the dermis at 12, 24, and 48 hours, and these were also observed in the epidermis. Three to four basophils were frequently seen clustered in the epidermis of the 48-hour specimens.

Cell Populations

Two Hours.—At two hours (Table 1 and Fig 1), mononuclear cells were present between the collagen fibers and about the vessels in the reticular dermis. These mononuclear cells varied from the typical monocyte that had a round, oval, or kidney-shaped nucleus with clear cytoplasm and normal organelles to the activated macrophage, which was large and had many pseudopodia, a large irregularly shaped nucleus, and a cytoplasm rich in organelles, lysosomes, and multivesicular bodies. Observed in the dermis were lymphocytes (each with a large nucleus), peripheral chromatin, and a clear cytoplasm containing few organelles, such as mitochondria and only rare lysosomes. Most of the lymphocytes probably were activated because their cytoplasm contained many cell membrane processes. Most of the lymphocytes also were closely associated with macrophages. A few lymphocytes were observed that were elongated between the keratinocytes in the intercellular space of the epidermis. These cells contained vacuoles and multivesicular bodies in their elongated cytoplasmic processes. Indeterminate cells (Langerhans' cells without granules) or macrophages were also observed in the intercellular spaces of the epidermis. These were clear cells that had large convoluted nuclei with clear cytoplasm and no defining cytoplasmic granules. Langerhans' cells were observed in the lower epidermis, with their dendrites extending in all directions between the keratinocytes, even between the basal lamina and the keratinocytes in some instances.

In the dermis, we observed a few basophils and eosinophils with activated membrane processes that were in striking apposition to macrophages. The basophil granules were oval and electron-dense, with a crystalline structure. Scattered neutrophils were found in the dermis alone or in association with macrophages. Free leukocyte granules were observed in the dermis.

Six Hours.—At six hours, the collagen fibers were partly dissociated with fibrin deposits, RBCs, and greater numbers of infiltrating cells. Fewer typical monocytes were found, and activated macrophages were readily observed. These activated macrophages were frequently associated with other cells, such as activated lymphocytes, and occasionally with basophils or eosinophils. The basophils were active, with a vacuolated cytoplasm that showed membrane activity. The vacuoles connected with the membrane-bound basophil granules and at times with the external surface of the cell. There were some free membrane-bound granules in the dermis. The neutrophilic leukocytes were principally found associated with the macrophages.

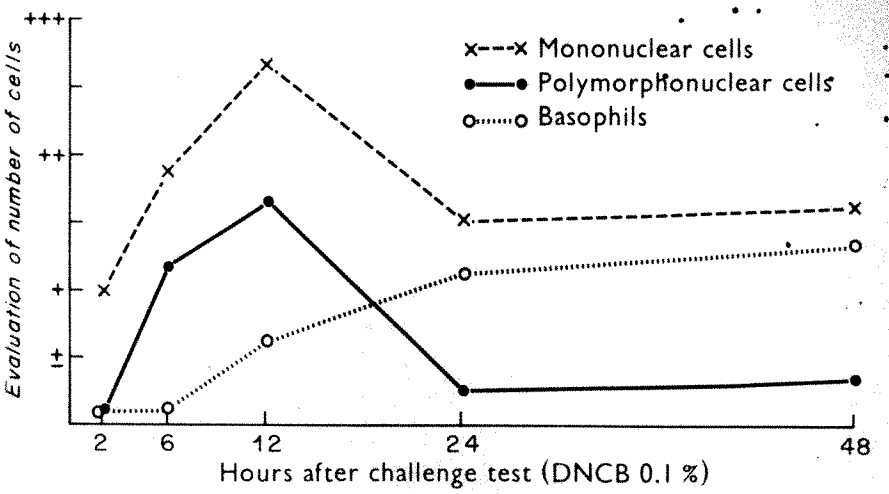

Fig 1.—Cells in dermis in experimental contact dermatitis.

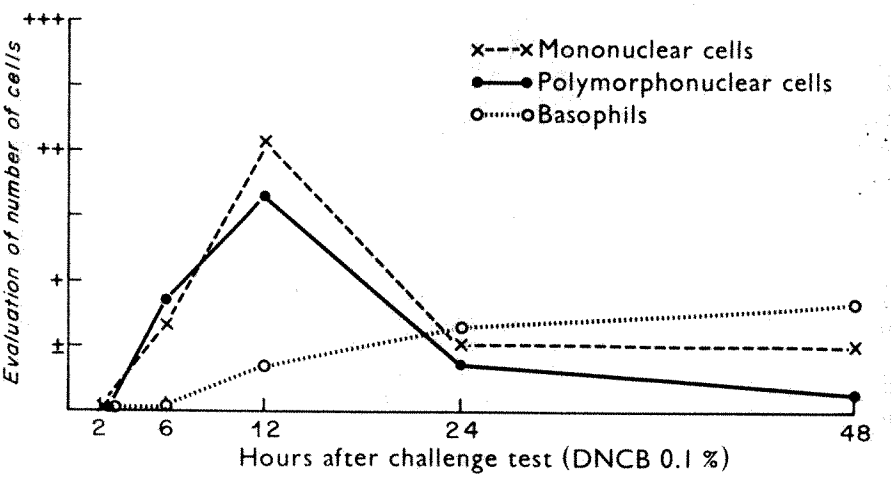

Fig 2.—Cells in epidermis in experimental contact dermatitis.

Lymphocytes were observed in the epidermis between the keratinocytes alone or in association with Langerhans' cells, as previously described by Silberberg et al[17] and by us (unpublished data). In the specimen of one guinea pig, three lymphocytes were seen closely related to a Langerhans' cell. Additional cells, each with highly indented nucleus and clear cytoplasm, were observed where the specific determination between an indeterminate cell and a mononuclear cell was difficult.

Twelve Hours.—At 12 hours, masses of infiltrating cells and RBCs separated the substantially altered collagen and fibrin masses. Most of the dermal cells were macrophages with many vacuoles, lysosomes, and myelin figures. A notable pinocytotic activity was observed, with regular dense bodies on the membrane and free in the cytoplasm. Activated lymphocytes also were observed. Neutrophil and basophil leukocytes were easily found, but eosinophils were rare. Most of the infiltrating cells occurred in closely related groups of two, three, or more cells. There were free neutrophil granules in the dermis.

While some basophils appeared to be normal, with crystalline or lamellar granules, most of the basophils contained glycogen granules, myelin structures, and dense but smudged or homogeneous granules, having lost their ordered structure but still being surrounded by a membrane. Occasionally, the cytoplasm was clear, having partly lost its granules or containing empty membrane-bound vesicles.

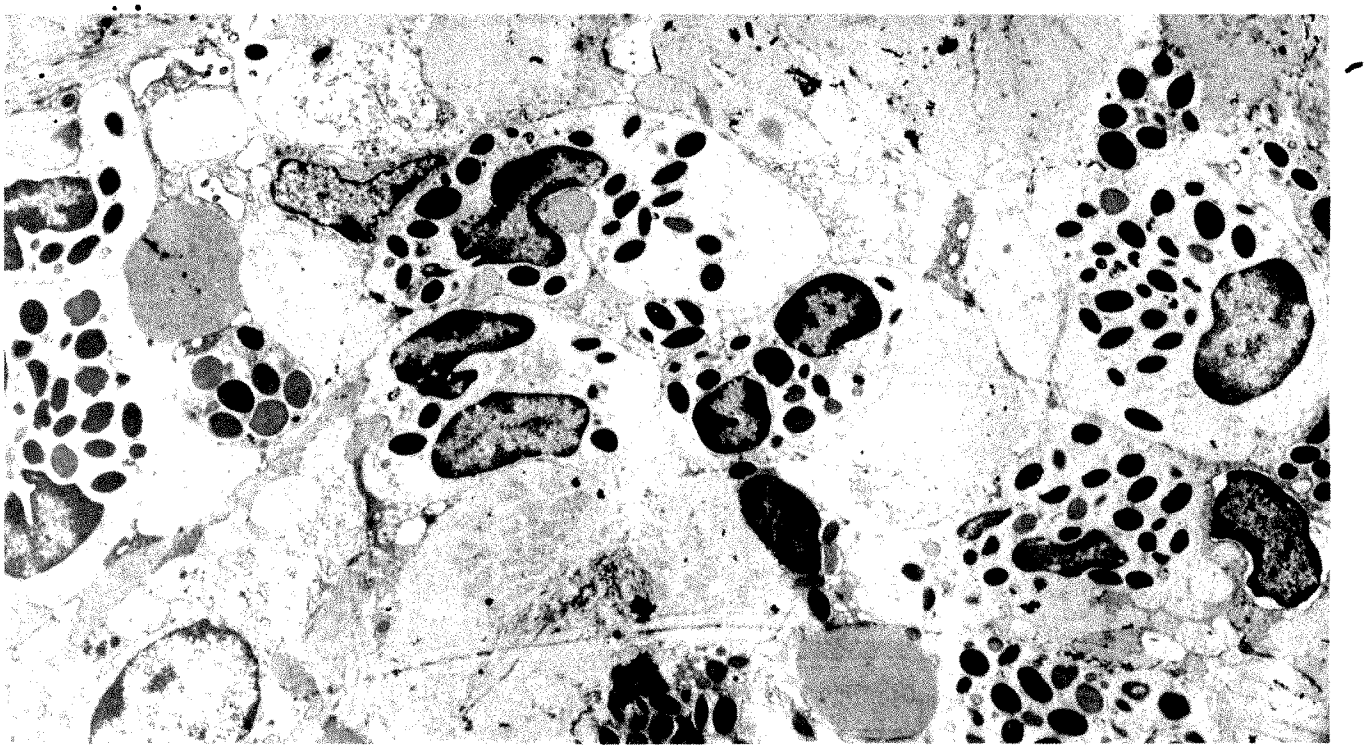

Fig 3.—Skin of sensitized guinea pig 48 hours after application of 0.1% dinitrochlorobenzene. Numerous basophils in dermis (original magnification ×7,000).

The intercellular spaces were enlarged in many areas of the epidermis, and desmosomal contacts were partially lost. Some of the intercellular space was clear and contained a uniform finely granular substance. Occasionally, free neutrophil granules were observed between the keratinocytes. The activated lymphocytes, some basophils, and a rare macrophage composed the intraepidermal cellular infiltrate.

Twenty-Four to 48 Hours.—At this time, the number of macrophages and activated lymphocytes in the tissue seemed to be reduced, particularly in comparison with the number of basophils, which was substantially increased (Fig 3). Some macrophages contained membrane-bound basophil granules. Macrophages also contained nuclei of degenerated cells. Almost all the macrophages with pinocytic activity were associated with activated lymphocytes, basophils (Fig 4), and occasionally eosinophils. Some basophil granules were observed in the interstitial space. Some basophils seemed to be nearly normal, and others contained principally clear vacuoles, myelin figures, and glycogen granules. Some basophil granules were membrane-bound, and others were partially membrane-bound, with an irregular peripheral border. Many granules did not have the consistent parallel arrangement of their lamellae, partly or wholly lacking periodicity. In other granules, the electron density was not homogeneous, and electron-lucent membrane-bound vesicles also were observed, giving a honeycomb appearance to the cells.

The epidermis in some areas was normal, and in other areas, it showed intercellular and intracellular edema, with decrease in tonofilaments in the keratinocytes. Some dark cells with dense, degenerate cytoplasm were found (dark keratinocytes). Langerhans' cells were observed in the upper epidermis, and no association with inflammatory cells could be documented. While some activated macrophages and lymphocytes could still be found in the epidermis, the number of basophils was much more striking (Fig 5). Many epidermal basophils were observed alone or in clusters. When observed in groups in the epidermis, these basophils often were associated with macrophages. Their location was in the lower epidermis near the basal lamina and in the middle and upper epidermis near the stratum corneum (Table 2 and Fig 2).

Cellular Histochemistry.—The acid phosphatase method in normal and in sensitized nontested guinea pig skin showed rare dermal round cells with a positive cytoplasm. After the challenge test, there was an infiltrate of mononuclear cells in the dermis at two hours, which was positive for acid phosphatase. The number of these cells increased until 12 hours and then diminished. At 24 and 48 hours, scattered or grouped positive cells were found. Acid phosphatase-positive cells were not found in normal epidermis or at two hours after the test, but some were observed at six hours, and many epidermal acid phosphatase-positive cells were observed at 12 hours. Subsequently, their number decreased.

Alkaline phosphatase is not found in normal guinea pig skin, except associated with hair follicle papilla and with the tactile hair disk of Pinkus. At two hours after DNCB challenge, two of six guinea pigs showed a few scattered dermal-positive cells recognized as polymorphonuclear leukocytes. The unstained polylobed appearance of the nucleus could be easily discerned in enzyme-positive cytoplasm. The number of positive cells increased until 12 hours. At 24 and 48 hours, only a few positive cells were observed in the dermis. In the epidermis, the number of positive cells reached a peak at 12 hours, and thereafter only foci of epidermal enzyme activity related to desquamated crust formation were observed. Several of the guinea pigs developed microscopic pustules of leukocytes in the upper

follicles, and these foci also were positive for alkaline phosphatase.

COMMENT

The primary role of the lymphocyte in allergic contact dermatitis is unquestioned and is confirmed again in this study. The passive transfer by lymphocytic cells and the inhibition of the reaction by antilymphocytic serum[18] indicate that the lymphocyte is the necessary cell for the reaction. Similarly, the macrophage-lymphocyte and the Langerhans' cell-lymphocyte interactions in the dermis and epidermis are an accepted part of the reaction. Although basophils may occur routinely in the dermis and epidermis as part of the reaction, in 1974, Katz et al[13] showed that, in the almost complete absence of basophils, allergic contact dermatitis occurred in cyclophosphamide-pretreated guinea pigs, with an enhanced cutaneous macroscopic reaction. In 1976, Askenase,[19] using guinea pigs sensitized with oxazolone in complete Freund's adjuvant, showed that the challenge reaction was strong, long-lasting, and devoid of basophils. Furthermore, he transferred a basophil-rich reaction to nonsensitized guinea pigs, using cells of these strongly sensitized guinea pigs. The absence of basophils may be related to such strong, long-lasting reactions. Eosinophils may occur in large numbers in special types of delayed hypersensitivity, as that induced by citraconic anhydride, but their usual few numbers is unrelated to the standard pattern of reaction.

One major finding in the present study was the close cell-to-cell contact in the dermis of the macrophage-Langerhans' cell population with the other cells of the infiltrate. Beginning with the lymphocytes, the activated macrophage formed cell-to-cell contact. Endocytosis from cell to cell was observed. Later, similar relationships were established with polymorphonuclear leukocytes and rarely with eosinophils. Most important for this study was the developing relationship of macrophages and basophils. At first, a clustering of basophils with macrophages was observed; later, with partial degranulation, the granules or portions of the cytoplasm were engulfed by macrophages. If we had used dermal injection and Freund's adjuvant for sensitization, the macrophage activity might have been greater, because this would have induced a nonspecific macrophage activation.[20]

While the basophil is not necessary to experimental epicutaneous delayed hypersensitivity reaction, it is a frequent and important part of the reaction. The marked dermal infiltration with basophils at 24 and 48 hours demonstrated the potential role of mast-cell mediators in the delayed hypersensitivity reaction. Dvorak et al[8,21] even while emphasizing the special features of cutaneous basophil hypersensitivity that was produced by soluble protein antigens in the Jones-Mote reaction, stated that basophils are an expected part of the cellular reaction of delayed hypersensitivity in animals and man. However, the basophil leukocytes may accumulate locally, so that their number in relation to other cells may become more than 20 to 30 times larger than that seen in the blood. Although the number of peripheral blood basophils increases after initial sensitization with DNCB,[7] no correlation was found in this study between peripheral WBC counts and basophil counts at the times of observation. The peripheral basophil count in the guinea pig was 0.6%/cu mm (mean of 107 normal guinea pigs); generally only a few basophils or mast cells are observed in normal guinea pig skin. Ward et al[22] have shown that the chemotactic factors for basophils include a substance (lymphokine) in culture fluid from antigen-stimulated lymphocytes and that monocytes can adsorb basophil chemotactic activity. A specific antigen also can suppress basophil chemotaxis. The mechanism is still unclear, but this could explain the behavior of basophils in delayed

hypersensitivity: (1) their large number in dermis and epidermis in the late reaction when the monocytes are less in number and the Langerhans' cells have disappeared in the epidermis, at the moment when the macroscopic reaction is fading, and (2) their absence in strong, long-lasting reactions, where antigen presumably persists.[11,19]

The basophils observed during the early phases of the reaction of guinea pig contact sensitivity do not have the dramatic features of degranulation found in anaphylaxis. The changes in the granules indicate that metabolic activity or a release of some substances may have occurred, but these changes are so different from those in anaphylaxis that a role other than anaphylaxis must be considered for the basophil. Because of the late appearance of the basophil in the tissues, we wonder whether a growth factor, such as histamine or a mediator from the basophil, might not have a role in resolving the inflammation. Also important may be the presence of mast cells or basophils in the epidermis of normal gingiva (which is rapidly dividing and renewing itself) or in chronically damaged epidermis (such as in prurigo nodularis [J. A. Doyle, S. Connolly, R. K. Winkelmann, unpublished observation], lichenification with massive IgE blood levels,[23] tuberculosis verrucosa cutis, and bromoderma).[24] In these conditions, the presence of basophils or mast cells in the epidermis might be related to the repair stimulus rather than to the primary reaction.

Our study indicates that one method of tissue examination for basophils in inflammation is not sufficient. The data could only have been obtained and checked by the use of the fluorescent acridine orange method, the histochemical NASDCAE method, and thick- and thin-section examination by electron microscopy; each technique has its individual virtues, and together they provide needed confirmation during the course of the progressive inflammation seen in experimental contact dermatitis.

Topical Treatment of Herpes Labialis With Chloroform

Cynthia A. Taylor, MD; J. Owen Hendley, MD; Kenneth E. Greer, MD; Jack M. Gwaltney, Jr, MD

• **The efficacy of topical chloroform treatment of herpes labialis (HL) was evaluated in 50 patients with culture-verified HL. Treatment was begun within 48 hours of lesion onset, with either chloroform or camphor-in-oil placebo applied locally once a day for three days. Patients were observed daily by one investigator who also cultured and photographed the lesions. The photographs were evaluated by two other investigators. By direct observation, the time for scab formation was significantly less in the group treated with chloroform ($P < .01$). No difference in time to healing was noted. Blind evaluation of the serial photographs showed a trend for more rapid scab formation and healing in patients treated with chloroform, but the differences were not significant. The minimal benefit derived from topical chloroform therapy of HL does not appear sufficient to recommend its routine use.**

(*Arch Dermatol* 113:1550-1552, 1977)

A safe and effective treatment for herpes simplex labialis (HSL) is not available, although many remedies have been tried. Lipid solvents, specifically chloroform or ether, have been suggested for topical treatment of HSL and have been thought to be effective in uncontrolled observations.[1-3] As recently recommended by Sabin,[3] a controlled trial of this form of therapy is needed. This report describes such a study in which chloroform was used as the treatment compound because it is not explosive, as is ether.

Accepted for publication June 1, 1977.

PATIENTS AND METHODS

Patients

Volunteers, both male and female, with recurrent HSL were recruited from the general population of Charlottesville, Va, during April and May 1975. They ranged in age from 19 to 60 years, with the majority being 20 to 30 years old. All volunteers were ambulatory, otherwise in good health, and gave informed consent to participate in the study.

Participants contacted an investigator at the first premonitory sign of eruption of the herpetic lesion. Seventy volunteers were seen with lesions less than 48 hours old; 45 of the 70 had lesions that were positive for herpes simplex virus (HSV) by culture. Four of the 45 virus-positive cases were lost to follow-up. The analysis of efficacy of the test compound was based on evaluation of the 41 virus-positive patients who completed the study.

Compounds

Undiluted chloroform was the test substance, and 10% camphor in mineral oil was the placebo. Previous in vitro studies verified the virucidal effect of chloroform and the absence of any measurable virucidal activity of the camphor-in-oil, with use of a standard test for virus inactivation[4] with 10^5 tissue culture ineffective dose ($TCID_{50}$) per milliliter of virus. Both compounds were in identical, coded bottles; volunteers were randomly assigned to receive chloroform or the placebo. Although it was possible to distinguish between the two compounds, participants were not told what compounds were being used and were not thought to be prejudiced in favor of either compound as being the test substance or placebo. Indeed, a few volunteers recognized the odor of the camphor-in-oil and, associating it with Camphophenique, thought it was the treatment substance. The compound was applied directly to the lesions with a cotton-tipped swab for ten minutes once a day for three consecutive days.

Clinical Observations

The lesions were cultured and photographed prior to each treatment. After the three treatment days, each patient returned on alternate days to have the lesion cultured and photographed either until it had healed or for a total of nine days. Four methods of evaluating response to treatment were utilized.

1. Direct observation: Five factors were measured daily by the investigator (C.A.T.) who applied the compounds: subjective burning, tenderness, vesicle rupture, scab formation, and healing. Although all factors were analyzed, the two that were most helpful in comparing the patients' courses were the length of time to drying or scab formation and the length of time to healing of the lesion.

2. Analysis of photographs: Two investigators who were unaware of which compound was applied reviewed serial photographs of the lesions of each patient with a lesion less than 24 hours old when first treated. One investigator was a

dermatologist, the other an internist specializing in infectious diseases. Factors for evaluation included lesion "active" (with subcategories, "same," "better," or "worse"), lesion "inactive" (that is, scab formation), and lesion "healed."

3. Subjective impression of efficacy by treated patient: At the end of the nine study days, each participant was asked to judge whether the treatment had facilitated healing of the lesion. Volunteers answered "yes," "no," or "unable to determine" in response to the question: "Do you feel this treatment has helped your fever blister heal?"

4. Viral shedding: Each day the patient was seen the lesion was swabbed with a dry cotton-tipped applicator, prior to application of the compound. The swab was immediately placed in 2 ml of beef heart infusion broth with 1% bovine serum albumin. Within six hours, 0.2 ml of the broth was inoculated into each of two tubes of human embryonic lung cells (WI-38). Identification of HSV was made by a standard neutralization test.[4] No attempt was made to distinguish between type 1 and type 2 HSV.

RESULTS

Direct Observation

For analysis, the patients were divided into those with a lesion that was less than 24 hours old when treatment was begun and those who were first treated when the lesion was between 24 and 48 hours old (Table 1). In the less-than-24-hour group, the mean time from initiation of treatment to scab formation on direct observation was 1.1 days in the 15 patients treated with chloroform and 2.3 days in the 11 patients treated with placebo ($P = .004$, Student's t test). The mean time for healing was 5.7 days with chloroform treatment and 6.1 days with placebo ($P = .6$, Student's t test). In the group of patients with lesions between 24 and 48 hours old, the time to scab formation was 1.3 days in nine patients

treated with chloroform vs 1.7 days in the six receiving the placebo. Mean times for healing were 5.8 and 6.2 days for the chloroform and placebo groups, respectively. These differences were not statistically significant.

Analysis of Photographs

Observer 1 noted a consistent trend on days 2 through 9 for more rapid scab formation in the patients who received chloroform (Fig 1). Observer 2 interpreted the same photographs as showing a higher proportion of patients receiving chloroform with scab formation on days 3, 5, 6, and 7, but a clear trend was not evident. Statistical analysis of the results from both observers showed no significant differences (Fisher exact test).

The time to healing of the lesion was determined from review of the same group of photographs (Fig 2). Observer 1 read the photographs as showing a trend for faster healing in the chloroform group (days 3 through 7 and 9), while interpretation by observer 2 showed no trend. Again, there were no statistically significant differences in percent of lesions healed with chloroform vs placebo treatment on any day.

Subjective Evaluation of Efficacy

Of those treated within 24 hours of onset of the lesion, 12/15 (80%) treated with chloroform vs 7/15 (47%) treated with placebo thought that the treatment was effective ($P = .06$, Fisher exact test) (Table 2). The proportion who thought treatment was ineffective or who could not tell were similar in the two groups. Patients treated more than 24 hours after the appearance of the lesions noted no difference in efficacy.

Viral Shedding

There was no difference in recovery of virus from lesions treated with chloroform compared to the camphor-in-oil placebo (Table 3). Of interest is the fact that HSV was not recovered from any lesions after three days, regardless of which compound was applied.

COMMENT

A preliminary evaluation of chloroform therapy for HSL was conducted by this laboratory in 1974, with use of a volunteer population similar to that in the current study. The time to scab formation was shortened significantly in patients treated with chloroform vs placebo as determined by the direct observations of one observer who was aware of which compound each patient was receiving.

In the current study, chloroform treatment again hastened scabbing as determined by direct observation. The experimental design of this trial was improved by including evaluation of serial photographs by two observers who were unaware of the treatment status of the volunteers. A consistent trend for more rapid scab formation and healing of the lesions of patients treated with chloroform compared to those treated with placebo was noted by one observer. However, the differences in the rate of healing and scabbing were neither very impressive nor statistically different. The second observer did not detect any appreciable difference in scabbing and healing times of the two groups from the photographs.

Each patient was questioned about the length of time HSL lesions usually lasted. Their responses correlated well with healing time observed in previous studies[5-9] with a mean of 5 to 12 days and a range of 1 to 42 days. However, the average time to scabbing noted in the current study was markedly different from that reported by Myers et al.[10] In this study scabbing times were 1.1 and 2.3 days with chloroform or placebo, respectively (values determined by direct observation). Myers et al found that the mean time to scabbing was 5.5 days in both neutral red- and placebo-treated patients. The intervals before healing were similar in the two studies. The average healing time in the current study was 5.7 and 6.1 days, chloroform and placebo treatment, respectively, and 7.5 and 7.1 days for neutral red and placebo, respectively, in the study of Myers et al. Differences in the method of evaluation and between the observer judging day-to-day changes in the lesion may explain the observed differences between the two studies.

Cultures were positive for HSV in 45 (64%) of 70 suspected HSL lesions. No virus shedding occurred after three days with lesions cultured serially, a finding also reported by Daniels and LeGoff.[11] Sixteen patients with lesions exclusively on the oral mucosa were cultured and none were positive for HSV. These latter patients were thought to have aphthosis, a condition unrelated to HSV infection.

The findings of the current study suggest that the daily topical application of chloroform may be of minimal benefit in the treatment of HSL. Efficacy might be improved by variation in the treatment regimen, such as more frequent application. Similarly, other solvents active against the lipid envelope of HSV might be more effective, though the explosive potential of ether makes that compound unsafe for casual use.

Since this study was conducted, chloroform has been implicated as a cause of liver cancer in mice and kidney cancer in rats (National Cancer Institute, March 1976). Subsequently, the Food and Drug Administration has banned the use of chloroform in any drug or domestic product, although products currently on the market will not be recalled.[12] Because of the limited treatment efficacy of topical chloroform for herpes labialis, and because of the theoretical concerns of chloroform carcinogenesis, the treatment should not be used around the mouth where oral ingestion is likely. Topical chloroform may be of some use in the treatment of herpes genitalis; however, verification would be contingent on appropriate controlled clinical trials.

The University of Virginia Student Health Service cooperated in this study; Anne Calhoun and laboratory staff provided technical assistance; and Jacqueline Grubbs and Linda Lynch provided secretarial assistance.

Erythropoietic Porphyria

Two Cases and the Results of Metabolic Alkalinization

George S. Stretcher, MD

• **Two previously unreported cases of erythropoietic porphyria are presented. Therapeutic modalities are discussed along with the results of both short- and long-term metabolic alkalinization. Although there was a substantial increase in urinary coproporphyrin excretion during a six- to 8-day period of alkalinization, three months of alkalinization therapy resulted in no substantial depletion of porphyrin stores and both patients continued to have new skin lesions develop, indicating no clinical improvement.**

(*Arch Dermatol* 113:1553-1557, 1977)

Erythropoietic porphyria (Günther's disease), a congenital disorder of porphyrin metabolism, is quite rare, with slightly more than 70 cases reported in the literature.[1] Affected patients seem to have a relative deficiency of uroporphyrin III cosynthetase (isomerase)[2] that results in preferred production of the type I isomer of uroporphyrinogen rather than the usual synthesis of the type III porphyrin isomers. Excessive production of porphyrin, taking place mainly in the bone marrow, results in increased levels of blood, urinary, and fecal porphyrins. Recurrent vesiculobullous eruptions on sun-exposed areas of the skin eventually result in mutilating ulceration and scarring. Hypertrichosis, hyperpigmentation, brown-stained teeth that fluoresce, brownish red urine, and hemolytic anemia are the other usual clinical features.

Accepted for publication April 28, 1976.

It is hypothesized that in erythropoietic porphyria, and also in porphyria cutanea tarda, the manifestations of increased fragility and susceptibility to blister formation in light-exposed areas of the skin are due to excessive accumulations of porphyrin (especially uroporphyrin) molecules that, when activated by radiant energy penetrating the skin, cause tissue damage. A depletion of tissue stores of porphyrin in either of these two types of porphyria could perhaps ameliorate the skin manifestations.

Wiegand et al[3] and Perry et al[4] have reported that patients with porphyria cutanea tarda will benefit from metabolic alkalinization, presumably by depletion of porphyrin tissue stores, through increased excretion of coproporphyrin. Rational for this treatment is based on the work by Bourke et al[5] that established that urinary coproporphyrin excretion is increased in the presence of an alkaline urine. This is apparently due to the pK of coproporphyrin that dictates that coproporphyrin, filtered or secreted into the alkaline media of the renal tubule, converts from an unionized, lipid-soluble, weakly acidic molecule to an ionized, relatively lipid-insoluble form that cannot back diffuse and hence is excreted.

Uroporphyrin excretion is not affected by alkalinization. Depletion of uroporphyrin by alkalinization would require a stepwise depletion of coproporphyrin, coproporphyrinogen, and through increased activity of the uroporphyrinogen decarboxylase system depletion of its immediate precursor, uroporphyrinogen. If, during the period of metabolic alkalinization, there is increased excretion of coproporphyrin (secondary to alkalinization of the urine), indirect depletion of uroporphyrin through stepwise depletion of coproporphyrin precursors, and no compensatory production of uroporphyrin and coproporphyrin, one would hope to obtain a favorable clinical improvement.

Two new cases of erythropoietic porphyria are reported with the results of a therapeutic trial of metabolic alkalinization. The effects of metabolic alkalinization were studied in two phases. To document the immediate effect on porphyrin urinary excretion, there was an initial short-term period of alkalinization during which continuous 24-hour urinary porphyrin levels were monitored. This was followed by an extended period of alkalinization to determine if there were any depletions of porphyrin stores, as reflected by lowered 24-hour urinary porphyrin levels.

REPORT OF CASES

CASE 1.—A 54-year-old woman of Irish ancestry was first admitted to Eugene Talmadge Memorial (Augusta, Ga) Hospital on Nov 11, 1968. She gave a history of blister formation on sun-exposed areas and red urine since 4 years of age. The blisters originally occurred more frequently during the summer, but in the past decade there had been no seasonal variation. Bullae, occurring spontaneously and also at sites of trauma, generally became infected and ulcerated leaving residual fibrosis and scarring. Although the patient was edentulous, both she and her relatives confirmed that her teeth had had a brownish stain. There was no history of severe anemia, abdominal pain, or neurological disorder.

On admission, the patient had multiple infected ulcerated lesions on the upper and lower extremities. No vesicles were present. There was facial hypertrichosis (Fig 1), generalized hyperpigmentation, bilateral scleral erosions, and a palpable spleen tip. The hands were considerably deformed with scarring, contractures, partial resorption of the terminal phalanges, and loss of nails (Fig 2). The diagnosis of congenital

erythropoietic porphyria was made on the basis of negative urinary porphobilinogen, elevated urinary uroporphyrin and coproporphyrin levels, and the presence of 4% to 5% "fluorocytes" with fluorescence of a peripheral blood preparation. Results of liver function studies were within normal limits. Hematologic studies included the following values: hematocrit, 38%; hemoglobin, 11.6 gm/100 ml; reticulocytes, 9.8%; WBCs, 11,400/cu mm; platelets 457,500/cu mm; serum iron, 27 μg/100 ml; total iron binding capacity, 210 μg/100 ml. Examination of the peripheral smear showed a mildly hypochromic, microcytic pattern with no normoblasts or bizarre RBC morphology. Roentgenologic studies revealed generalized demineralization of osseous structures, resorption of the terminal phalanges of both hands, a congenital hip dislocation on the left, and a radiodensity in the right upper abdominal quadrant interpreted as probably representing a gallstone.

After discharge, the patient continued to have intermittent development of infected ulcers on the extremities from both sites of blisters and in areas of no previous blister formation, despite avoidance of direct sunlight and conditions predisposing toward trauma to the skin. These responded to debridement and oral administration of antibiotics although healing was slow and there was residual scarring.

The patient was readmitted on Feb 19, 1970, for the purpose of evaluating the short-term effects of alkalinization for systemic effect. Physical findings were essentially unchanged except for new purulent ulcers on the right hand and both forearms. Laboratory data included the following values: WBCs, 6,600/cu mm; hematocrit, 45%; hemoglobin, 14.2 gm/100 ml; reticulocytes, 4.4%; platelets, 217,500/cu mm; and a negative direct Coombs test. Again, examination of the peripheral blood smear showed no normoblasts or bizarre morphology. Table 1 gives porphyrin determinations during the hospitalization. Stool protoporphyrin level was 422 μg/100 gm wet weight (normal range, 200 to 2,350 μg/100 gm wet weight). Red blood cell protoporphyrin levels were elevated, ranging from 139 to 201 μg/100 ml.

CASE 2.—March 9, 1970, was the first Eugene Talmadge Memorial Hospital admission for this patient, a 14-year-old boy of Irish ancestry and a distant cousin of patient 1. He also gave a history of blistering and recurrent infected ulcers on sun-exposed areas since 1 year of age. Freshly voided urine had been noted to be of a reddish brown color since infancy and the permanent teeth had always had a brownish discoloration. There was no history of anemia, abdominal pain, or neurological disorders.

Physical examination on admission showed several crusted, purulent, superficial ulcers on both lower legs. Focal areas of scar formation were present on the sun-exposed areas of the body (Fig 3). Hypertrichosis was remarkable but mainly confined to the face and areas of scar formation (Fig 4). All of his teeth had a brown discoloration and exhibited a red fluorescence with Wood's light examination. Additional physical findings were blepharitis of the right eyelid and palpable spleen on inspiration.

Laboratory data included elevated urinary, blood, and stool uroporphyrin and coproporphyrin levels (Table 1). Stool protoporphyrin level was 1,600 μg/100 gm wet weight. Red blood cell protoporphyrin levels were elevated ranging from 103 to 166 μg/100 ml. A test for urine porphobilinogen was negative. Fluorescence of a peripheral blood preparation revealed the presence of several "fluorocytes." Hematologic studies during this admission included a WBC count of 11,400/cu mm; a hematocrit reading of 41.4%; a hemoglobin value of 13.6 gm/100 ml; a platelet count of 177,500/cu mm; a reticulocyte count of 3.0%; a serum iron value of 45 μg/100 ml; a total iron binding capacity of 189 μg/100 ml; and a negative direct Coombs test. A peripheral blood smear showed no normoblasts or bizarre morphology; however, there was a slight hypochromia. *Staphylococcus aureus* coagulase-positive and group A β-hemolytic *Streptococcus* grew from cultures of the purulent ulcers. A flat plate roentgenogram of the abdomen confirmed the physical finding of splenomegaly. Immunofluorescence studies on a biopsy specimen from the dorsum of the hand obtained during an outpatient visit on Dec 21, 1973, revealed no deposition of immunoglobulin about the blood vessel walls or at the basement membrane.

METHODS

Initial Short-Term Alkalinization Therapy

For initial evaluation of systemic alkalinization, each patient was hospitalized for approximately 18 days in which there were three separate periods of study: before, during, and after alkalinization. An ad lib

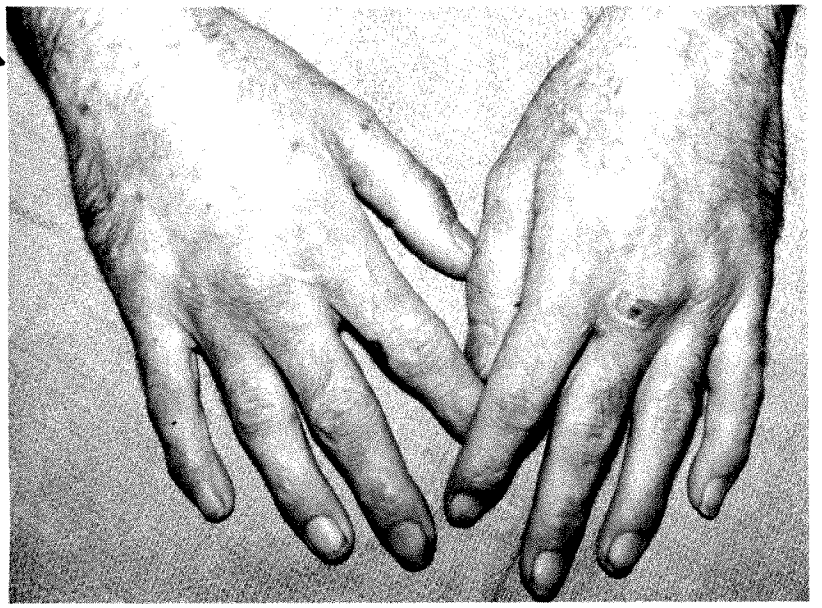

Fig 3.—Patient 2, Superficial scar formation on dorsum of hands.

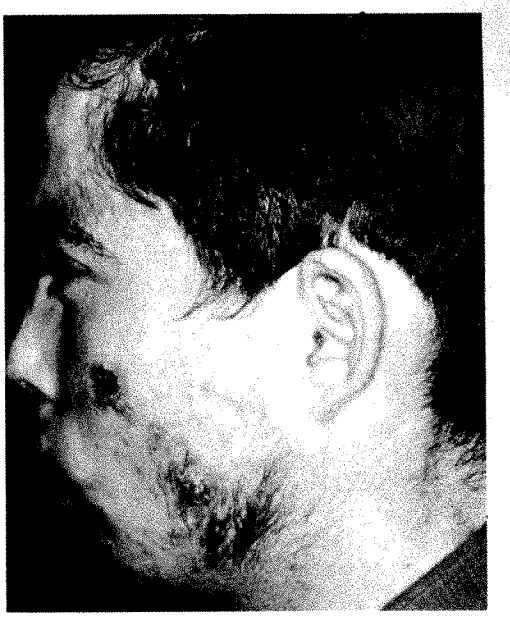

Fig 4.—Patient 2, Focal areas of superficial ulcerations, scar formation, and hypertrichosis on face.

diet and fluid intake were allowed. Approximately 40 ml of blood was drawn biweekly for routine hematologic studies and RBC porphyrins. Alkalinization for systemic effect designed to maintain a urinary pH of between 7 and 8 for the majority of each day was accomplished by daily oral doses of sodium bicarbonate amounting to 4.2 gm for patient 1 and 4.8 gm for patient 2. Continuous 24-hour urines were collected for porphyrin determinations and each 24-hour specimen was analyzed with 12 hours of collection. Sodium bicarbonate was not added to the collection bottles since coproporphyrin and uroporphyrin determinations on paired collections of acidic porphyric urines with and without added sodium bicarbonate showed no significant difference when analyses was performed on the same day of urine collection. Total creatine level was determined on each 24-hour urine specimen to ensure completeness of collection.

Porphyrin analyses were carried out by the method of Schwartz et al[6] except for the "split batch" method of uroporphyrin analysis as described by Talman.[7] Determinations were performed on the Amico spectrophotofluorometer with the Corning 7-51 and Wratten 2C as primary filters and a Wratten 23A as a secondary filter. The coproporphyrin standard was obtained from Harleco.

Long-Term Alkalinization Therapy

The second phase of the study evaluated the effects of long-term alkalinization in which both patients received systemic alkalinization therapy on an outpatient basis for a period of approximately 3½ months. Patient 1 started therapy on Nov 9, 1972, and patient 2 began therapy on Nov 19, 1972, receiving 4.2 gm and 4.8 gm of sodium bicarbonate, respectively. Porphyrin determinations on 24-hour urine collections were performed using the same methods described previously for short-term alkalinization therapy.

RESULTS

Table 2 gives a summary of the data for the 24-hour urinary porphyrin determinations done during the initial phase of the study. Group 1 represents the baseline collections during which there was no alkalinization. Urinary pH during this period obtained on each freshly voided specimen ranged from 4.5 to 6.5. Group 2 includes the days of sodium bicarbonate administration plus one additional day since urinary pHs remained alkaline for the majority of the 24 hours after discontinuation of medication. Group 3 includes the postalkalinization collections during the period in which there was an acidic urine. The first 24-hour urine collection in group 2 (patient 2) was deleted since urinary creatine levels indicated incomplete collection.

Table 3 gives an analysis of the results statistically. There is a consid-

Table 3.—Statistical Analysis (Student's *t*-test) of Urinary Porphyrin Levels During Initial Short-Term Alkalinization*

	1 vs 3	$P < .1$	NS

*URO indicates uroporphyrin; COPRO, coproporphyrin; and NS, not significant.

erable and statistically significant difference between the coproporphyrin values obtained before (group 1) and during (group 2) alkalinization. The difference between the values obtained during (group 2) and after alkalinization (group 3) are not as marked because of an increase in coproporphyrin levels from the period before alkalinization (group 1) to the period after alkalinization (group 3). This finding of increased levels of both coproporphyrin and uroporphyrin in the period immediately following alkalinization as compared with the baseline levels before alkalinization may represent residual effects of alkalinization or perhaps a natural variation in the disease; however, the most likely explanation is that by obtaining rather sizable biweekly blood samples, we stimulated erythropoiesis, which in turn, can cause increased blood and urinary porphyrin levels.[6-8] Evidence for erythropoiesis was noted in patient 2 in that the reticulocyte count increased from 3.0% to 8.0% during the period of initial alkalinization.

The results of the second phase of the study in which there was long-term alkalinization therapy are seen in Fig 5 and 6. Patient 1 showed an increase in urinary porphyrins during the course of alkalinization and patient 2 showed a slight, but nonsignificant decrease at the end of alkalinization. The lack of a substantial decrease in the urinary excretion of porphyrins during this period indicates that alkalinization therapy was unsuccessful in depleting porphyrin stores. In addition, in both patients new skin lesions continued to develop during and at the end of the study, thus reflecting no clinical improvement.

COMMENT

The following are several explanations as to the lack of effectiveness of metabolic alkalinization in congenital erythropoietic porphyria. One is porphyria cutanea tarda (PCT), which although having certain similarities to congenital erythropoietic porphyria is a different disease entity with differing metabolic defects. Therapy that proves effective for PCT is not necessarily guaranteed to also be effective for erythropoietic porphyria. That the period of alkalinization may be too short is a second explanation. The period of alkalinization used in this study was essentially the same as that used in cases of PCT.[1] Allowing for possible differences in total body stores or production rates of porphyrins, successful therapy with alkalinization in erythropoietic porphyria may require longer periods of therapy than that recommended for PCT.

Third, there are natural variations in disease activity and levels of porphyrin excretion in all of the porphyrias. There is a possibility that both patients may have been in an "up swing" of disease activity during the study, thus masking the benefits of alkalinization therapy. Finally, metabolic alkalinization may not be effective therapy for porphyria. Many of the patients with PCT were also instructed to discontinue their intake of alcohol; thus, one may question whether the improvement in disease was the result of alkalinization or the abstinence from alcohol. Of those patients with PCT who did not discontinue alcohol consumption during alkalinization, three of a total of five showed clinical and chemical improvement.[4] These numbers would not seem sufficient for any definite conclusions on the efficacy of metabolic alkalinization for porphyria cutanea tarda and certainly there was no dramatic improvement in the patients in our two cases of erythropoietic porphyria.

OTHER THERAPEUTIC MODALITIES

Attempts to prevent repeated hemolytic crises and the mutilating long-term effect of recurrent bullae followed by infected ulcerations, dramatically illustrated by patient 1, have led to the investigation of several modes of therapy for erythropoietic porphyria. Splenectomy has been performed in several patients and although there have been reports of clinical improvement,[9-11] other studies have shown only a transient or lack of response.[12-14] Chloroquine, an antimalarial, and desferrioxamine, an agent for reducing serum iron levels, were given to one patient who showed no improvement of the anemia or levels of porphyrin excretion with either form of therapy.[14] Chatterjea[15] has reported four cases, three of which showed considerable improvement of the anemia with the administration of prednisolone. In the fourth case, in which there was no anemia, there was a decrease in the urinary excretion of porphyrins. The value of prednisolone in reversing anemia was confirmed by Kramer et al[16]; however, Kaufman et al[14] obtained no clinical improvement after giving prednisolone. An initial report of beneficial effects from the administration of purines[17] led to its investigation in three other patients in whom there was no biochemical or clinical improvement.[18,19] Induced polycythemia by means of transfusions of packed RBCs does seem to inhibit erythropoiesis and to reduce the levels of excreted porphyrins,[20] but, this mode of therapy in chronic disease would seem impractical.

Recently, there have been encouraging reports of the use of beta carotene for the photoprotection in erythropoietic protoporphyria.[21] Beta carotene may also prove to be effective in cases of erythropoietic porphyria; however, this is not a foregone conclusion since the clinical and biochemical features of the two diseases are different.

There is a preliminary report suggesting the efficacy of beta carotene therapy in one case of congenital erythropoietic porphyria.[22] However, short-term therapeutic studies are difficult to evaluate due to few objective measurements of clinical response. The induction of skin lesions using monochromatic light sources is useful in evaluating therapy in cases of congenital protoporphyria; however, skin lesions in congenital erythropoietic porphyria can generally not be reproduced by this method. There have been attempts to monitor disease activity in the various porphyrias through the use of induced suction blisters[23]; unfortunately, this method was not satisfactory in our two patients because of the unreproducibility of control suction blister times (range: from 30 to 84 minutes when tested on the forearm using a 2.2-cm glass cup with continuous suction of 120 mm of Hg).

CONCLUSION

At the present, there does not seem to be a satisfactory therapy for congenital erythropoietic porphyria. The incidence of scarring from skin lesions may be reduced by minimal sun exposure to sunlight, avoidance of minor trauma to the skin, and the prompt treatment of bacterial infections occurring in ulcerated blister sites. Three months of metabolic alkalinization did not result in any substantial improvement. The effects of beta carotene administration await a critical long-term study.

Ulcers of the Leg in Thalassemia

Dwight M. Stevens, MD; Jerome L. Shupack, MD; Jamshid Javid, MD; Robert Silber, MD

• Four patients had thalassemia and leg ulcers. In three patients the hematologic diagnosis of thalassemia had not been previously made; the presenting symptom was the leg ulcer. The diagnosis of thalassemia should be considered in patients who have unexplained chronic leg ulcers; the incidence of this complication of thalassemia may be higher than previously reported.

(*Arch Dermatol* 113:1558-1560, 1977)

Leg ulcers have long been known to occur with certain blood dyscrasias. The incidence of this complication has been estimated at 5%[1] to 75%[2] in sickle cell anemia, 0[3] to 27%[4] in sickle cell-β thalassemia, and 6%[5] in hereditary spherocytosis. Only 13 cases[6-15] of leg ulcers have previously been reported in patients with thalassemia.

Over a two-year period the diagnosis of thalassemia was made in four patients referred to the New York University Medical Center for treatment of leg ulcers. This cutaneous finding, which was the presenting symptom of the disease in three of the patients, led to the hematologic diagnosis.

REPORT OF CASES

CASE 1.—A 33-year-old black woman came to the outpatient clinic with a painless ulcer overlying the right medial malleolus. The ulcer had been present for four months and had slowly increased in size without evidence of healing.

The patient had three previous leg ulcers. The first of these occurred at age 10 on the lateral side of the left leg and lasted six years before healing completely. At the age of 24, another ulcer occurred over the right pretibial area. It healed spontaneously after two years. A third ulcer appeared at age 31 on the left medial malleolus and healed after six months.

The patient had known of anemia since age 15 and had required blood transfusions on three different occasions because of severe symptoms. She had tired easily and had experienced dyspnea on exertion since the age of 16.

On physical examination the patient had pallor of the conjunctivas and mucous membranes. There was no scleral icterus. A grade 3/6 systolic murmur was heard along the left sternal border. The spleen extended to the pelvic brim. Slight pitting edema was noted over the ankles. A 2.5 × 3-cm, punched-out ulcer was present overlying the right medial malleolus (Fig 1).

Laboratory data (Table) indicated the diagnosis of thalassemia. The ulcer healed in four months with daily application of gentian violet and absorbable gelatin sponge (Gelfoam) powder.

CASE 2.—The 36-year-old brother of the first patient came to the clinic with ulcers on the medial sides of both legs. These ulcers had been present for seven years and had decreased in size on different occasions without healing completely. Skin grafts had been unsuccessful. There had been no notable improvement after the patient underwent splenectomy five months prior to our examination.

Physical examination was unremarkable except for the shallow ulcers above both medial malleoli, each measuring 5 × 9 cm (Fig 2).

Laboratory data are summarized in the Table. The leg ulcers were treated with daily application of gentian violet and absorbable gelatin sponge powder with marked improvement. The patient moved from the area and was lost to further follow-up.

The family of these first two patients had been previously studied,[16] and both parents were found to have elevated hemoglobin A_2 levels and normal fetal hemoglobin (Hb F). Another brother also had a history of leg ulcers, and he was found to have a markedly elevated Hb F value of 26%.

CASE 3.—A 37-year-old Chinese man had a leg ulcer that had gradually enlarged over 14 months. The patient had known of anemia since age 12. A splenectomy had been performed in 1957 in Hong Kong. At that time he was told he had "Cooley's anemia." He subsequently has been in good health.

On physical examination the patient was found to have icteric scleras. A grade 3/6 systolic ejection murmur was heard along the lower left sternal border. A well-healed splenectomy scar was noted. The liver was palpated 7 cm below the right costal margin. A 6 × 6-cm necrotic ulcer was noted over the right medial malleolus.

Laboratory data are shown in the Table. The patient was treated with complete bed rest, soaks, and topical antibiotics, but the ulcer showed no evidence of healing. Skin grafts were then successfully performed.

The patient had two children, aged 3 and 5. Both were healthy without notable medical problems, and both had Hb F values of 5%.

CASE 4.—A 24-year-old man of Iranian parentage was referred for evaluation of indolent leg ulcers. The patient had been anemic since childhood but had not required blood transfusions or hospitalization.

Three years before admission he sustained minor trauma to the skin over his left medial malleolus. The abrasions failed to heal, and a gradually enlarging ulcer developed that did not respond to conservative treatment.

On physical examination, a grade 2/6 systolic murmur was heard at the apex. The spleen was palpated 6 cm below the left costal margin. Darkly pigmented skin was noted over both ankles, and a 2.5 × 6-cm ulcer was present over the left medial malleolus.

Laboratory findings are given in the Table. The patient's older brother was clinically well; he had a hemoglobin level of 13.9 gm/100 ml with mean corpuscular volume (MCV), 73 cu μ; mean corpuscular hemoglobin (MCHb), 23 pg; Hb A_2, 5.2%; and Hb F, 5.1%. On the basis of the clinical and laboratory findings, it is likely that our patient is homozygous for the variety of thalassemia described by Schokker et al.[17]

On a regimen of complete bed rest, soaks, and topically applied antibiotics, the ulcer diminished in size to 1 × 5 cm, but it failed to heal completely. After discharge, it again increased in size. Multiple skin grafts were attempted but were unsuccessful.

COMMENT

A number of similarities between our patients and the 13 previously reported patients should alert the physician to the diagnosis of thalassemia. Most of the patients are young adults with few other symptoms when they first develop their leg ulcers, which are usually recurrent, bilateral, and tend to be located over the malleoli. In half of the cases, other members of the family have had ulcers and presumably had thalassemia. The racial background of the patient (Mediterranean, African, Middle Eastern, or Eastern Asiatic) should also alert the physician to this possibility.

Three different hemoglobins may be detected within the RBC of the normal child and adult. Each one is composed of one pair of identical α chains and a second pair that is unique to each hemoglobin. Hemoglobin A (α_2

β_2) accounts for 96.5% to 98% of the total; Hb A_2 (α_2 δ_2) is present in small amounts (2% to 3.5% of total hemoglobin); and Hb F (fetal hemoglobin, α_2 γ_2) accounts for less than 1% of the total. The level of fetal hemoglobin at birth is 60% to 70%, but declines to the adult level by the first year of life.

Normally, the sum of β, δ, and γ chain synthesis is equal to α chain production. The thalassemia syndromes may be defined as conditions in which the synthesis of a specific hemoglobin polypeptide chain is reduced, which results in an unbalanced amount of polypeptide chains. The excess subunits are unstable and precipitate in the normoblasts as Heinz bodies; these in turn contribute to the hemolysis and ineffective erythropoiesis that characterize this disease.

The most common variety in the United States is β thalassemia, in which β chain synthesis is deficient. There are at least two, and probably more, varieties of β thalassemia genes. The one encountered more commonly among the people of Mediterranean origin is associated with total or nearly total lack of synthesis of the β chain, designated β^0. The variety encountered among the black population, β^+, allows the synthesis of reduced but measurable amounts of β chain. The wide range of clinical severity represents the occurrence of the β^0, β^+, and the normal β gene in various combinations.

The homozygotes for β^0 have severe limitation in β chain synthesis. These are the cases first described by Cooley and Lee in 1925.[18] They manifest a chronic anemia from early childhood, hepatosplenomegaly, and bone changes secondary to extramedullary hematopoiesis. Frequent transfusions are the rule, and most affected patients die before reaching adulthood. These patients have very high Hb F values, and are considered to

have thalassemia major.

A number of individuals with intermediate symptomatology of the disease fall somewhere between the clinical extremes. These patients have a notable but not severe anemia and elevated Hb F values. Their genotype is usually β^0 combined with β^+, or another less common type of thalassemia gene. These are termed thalassemia intermedia, and three of our patients (cases 1, 2, and 3) fall into this clinical category. The presentation in this group is quite variable. One manifestation that has not been often reported is ulceration of the leg. This is a well-known complication of sickle cell anemia,[19-31] most commonly in homozygous sickle cell disease (SS disease) and least commonly in the heterozygous variants (SC disease).[32] However, an awareness of leg ulcers as a manifestation of thalassemia is important since the diagnosis of thalassemia may not be initially suspected. Such was the case in three of our four patients where the leg ulcer was the initial manifestation of the disease.

Whereas the sickle cell anemia vaso-occlusive phenomena play a considerable role in the pathogenesis of leg ulcers, its cause in thalassemia is not clear. Several factors may be involved. The tissue over the bony prominences of the malleoli is subject to repeated physical trauma, and clinical experience has shown that injuries in this area have a tendency to heal poorly. Superimposed on this anatomic feature, some abnormalities in thalassemia may contribute toward the development of ulcers. Two possible factors may be the rheologic properties of the RBCs and their high content of fetal hemoglobin as observed in our four patients. The abnormal shape of the RBCs and the presence in them of inclusions[33] may limit their deformability and thus hinder the normal flow of blood in the capillaries. In patients with increased levels of Hb F the high affinity of this hemoglobin for oxygen[34] may also contribute to tissue hypoxia. It may be a combination of these factors that makes the skin of the ankles susceptible to ulceration in thalassemic patients.

Stamatoyannopoulos et al[35] and Braverman et al[16] have shown that there are many thalassemic patients with very high fetal hemoglobin levels and only mild symptoms of their disease. This has been especially noted in American blacks of no apparent Greek or Italian heritage. If the elevated fetal hemoglobin does play a notable role in the pathogenesis of the leg ulcers, more such cases of leg ulcers in relatively asymptomatic patients may be expected.

There is a remarkable similarity in the clinical presentation of the leg ulcers in patients with thalassemia or sickle cell anemia. The ulcers in both diseases occur in young adults, most commonly are bilateral, appear punched-out with a well-defined margin, heal slowly with scarring, and tend to overlie or be near the malleoli.

When the diagnosis of a hemoglobinopathy is suspected in a patient who has leg ulcers, a routine blood cell count with RBC indices and a reticulocyte count should be performed. The finding of a microcytic and hypochromic anemia, in the absence of iron deficiency, suggests the diagnosis of thalassemia. The finding of sickled cells on the blood smear should prompt further studies. These include a sickle cell preparation and hemoglobin electrophoresis. Further tests to characterize the qualitative and quantitative defect in hemoglobin synthesis, as indicated in the Table, should then be performed to make a diagnosis of thalassemia, sickle cell anemia, or sickle cell-β thalassemia disease. In doubtful cases, family study is indicated.

Conservative therapy with absorbable gelatin sponge and gentian violet resulted in healing of the ulcer in one patient and in marked improvement in another until he was lost to follow-up. One patient was successfully treated with a skin graft, while in another patient grafting was unsuccessful. Splenectomy or blood transfusions did not appear to be of any benefit in the healing of the ulcers.

DeSanctis-Cacchione Syndrome

A Case Report With Autopsy Findings

William B. Reed, MD†; Gerald I. Sugarman, MD; Reed A. Mathis

• One of the first patients studied by Cleaver on the DNA repair defect to ultraviolet light damage in xeroderma pigmentosum has been subjected to autopsy examination. This patient had the DeSanctis-Cacchione syndrome (microcephaly, dwarfism, mental deficiency, and choreoathetosis). Her autopsy findings were similar to those of the other three patients with this syndrome, emphasizing olivopontocerebellar atrophy, who underwent autopsy. The patient apparently could not tolerate psoralens because of increased incidence of carcinoma formation.

(*Arch Dermatol* 113:1561-1563, 1977)

The subject of this report and her brother were among the original patients with the DeSanctis-Cacchione variant of xeroderma pigmentosum (XP) studied by Cleaver[1] and later by Epstein and associates.[2]

Xeroderma pigmentosum is characterized by freckle-like lesions in areas exposed to sunlight with the subsequent development of carcinomas. These symptoms usually have their onset at an early age. The DeSanctis-Cacchione syndrome is the most severe form of XP. In addition to the skin lesions, the syndrome includes microcephaly with mental deficiency, premature closure of the sutures, retarded growth and sexual development, choreoathetosis, cerebellar ataxia, eventual quadriparesis with shortening of the achilles tendons, and sometimes sensorineural deafness.

This patient has been pictured many times in various medical texts and films[3-8] (Fig 1). Her epidermal cells have been kept alive in liquid nitrogen for further studies of XP.[4-11] Her brother died of lymphatic leukemia and has been described elsewhere.[4] We describe the fifth reported autopsy findings in a patient with DeSanctis-Cacchione syndrome.

REPORT OF A CASE

A girl was one of two severely affected siblings.[3] Her gestation was uneventful, and at birth she weighed 2,524 gm. There were no abnormalities apparent at birth, but mental retardation was evident at 8 months of age. Inspection of the skin revealed no pigmentary disturbances.

Pneumoencephalographic studies showed closure of the cranial sutures before 3 years of age. The ventricles and the basal cisterns all appeared somewhat dilated and larger than usual. These radiographic findings were consistent with cerebral atrophy. The occipital area of the skull was asymmetrical, with the left side slightly flattened and the left petrous bone projecting lower than the right. Posteroanterior films of both hands and wrists at 3½ years of age showed the bony development to be consistent with the age level of 4 years 2 months, according to the Greulich-Pyle standard.

At 3 years of age the patient could walk only short distances with a spastic gait and athetoid movements of her head and arms.

At 5 years of age she had frequent infections: adenotonsillitis, otitis media, mastoiditis, sinusitis, pneumonitis, multi-

Accepted for publication April 12, 1976.

Fig 1.—Patient, age 7, and her brother, age 3, who died of lymphatic leukemia. Both underwent autopsies.

Fig 2.—Patient at age 14 years, one month before death, showing early signs of puberty.

ple carious teeth, and numerous bleeding episodes from her nose and ears.

She suffered three severe sunburn reactions when 9 months of age, and then developed freckling of the sun-exposed skin when 1 year of age. Thereafter, the skin condition grew progressively worse for the next five years. She was seen almost on a monthly basis for removal of skin lesions. These usually were histopathologically confirmed keratoacanthomas, much less frequently basal cell carcinomas, usually pigmented, and only rarely squamous cell carcinomas. At 6 years of age she was treated with 1% to 5% fluorouracil in a propylene glycol base for application to her skin. For 1½ years the skin lesions improved, but later resistance to this therapy developed and more lesions appeared. She was treated with trioxsalen with very poor results, apparently leading to a greater number of skin lesions. This therapy was stopped after a month because of this apparent adverse effect. Sun screens were ineffectual in preventing new carcinomas.

In January 1970, she was studied by a team of immunologists under the supervision of Robert Good, MD. She had normal IgA, IgM, and IgG levels but an extremely elevated IgE level (1,685 units; normal, less than 300 units). Associated with her increasingly frequent infections, she became severely deficient in IgA, so much so (119 mg/100 ml at 14 years of age) that she developed a secondary immunologic deficiency.

Two weeks before death she had the onset of seizures, vomiting, and anorexia, with increasing loss of ambulation; she became bedridden. She developed severe dyspnea and was hospitalized at Children's Hospital of Los Angeles and was given intensive pulmonary therapy, but died at home a few days later (Fig 2).

Autopsy Findings

Autopsy examination showed severe microcephaly (the brain size was that of a child 8 weeks of age, although the patient was 14 years old). There was diffuse loss of cortical neurons in the cerebrum with no evidence of a storage disease or injury, nor gliosis or perivascular inflammation. Neurons of the thalamus, putamen, and pallidum were sparse. Loss of Purkinje cells were noted in the cerebellum. The inferior olive and pons were also atrophic.

The thymus showed chronic involution, and Hassal's corpuscles were present with slight fibrosis. The thymus weighed 8 gm (normal weight, 30 gm).

In addition, the autopsy showed bilateral acute and subacute pneumonia with aspiration of food and superimposed abscesses. The midmesenteric, retroperitoneal, and paratracheal lymph nodes were hyperplastic. The ovaries were atrophied, with the outer cortex fibrotic and the follicle cells scanty. The tunica albuginea was thick and fibrotic.

COMMENT

Before Cleaver's discovery of the inability of fibroblasts from XP patients to repair ultraviolet (UV)-inflicted DNA damage, XP was considered first to have just two manifestations: XP alone or XP with neurologic complications (the DeSanctis-Cacchione syndrome). The fibroblasts initially given to Dr Cleaver came from three patients with the DeSanctis-Cacchione syndrome and one patient with XP.[1-4] The DNA repair rate was at only 20% normal efficiency in fibroblasts of the XP patient and was nonexistent in fibroblasts of the DeSanctis-Cacchione patients. Thereafter, Epstein and coworkers reported that epithelial cells from XP and DeSanctis-Cacchione patients showed defective DNA repair in vivo.[2]

A study in Holland in 1972 shed more light on the genetic heterogeneity of the XP clinical entities. De Weerd-Kastelein and others[12,13] devised an intergenic complementation test to study the complexity of the enzyme system involved in the repair of UV-damaged DNA. Xeroderma pigmentosum cell strains were caused to form binuclear fusions by the fibroblast membrane activity of UV-inactivated Sendai virus, after a technique by Harris and Watkins.[14] After this treatment, certain combinations of XP cell strains resulted in heterokaryons with increased repair levels as shown by higher incorporation of tritiated thymidine. Fusion of cells of the same strain or from the same patient produced heterokaryons with unchanged repair levels. In one study,[12] heterokaryons were produced by fusion of fibroblasts from one of two male patients with severe XP and from a female patient with severe XP combined with those of a male patient who had the DeSanctis-Cacchione variant. The three groups of heterokaryons all displayed higher repair levels following controlled UV exposure.

This result indicated that the DNA

repair system enzymes were defective in XP cells and were different from the DeSanctis-Cacchione variant. Hybrid cells containing genes from XP and DeSanctis-Cacchione cells may synthesize the full complement of normal enzymes, as evidenced by the enhanced repair levels. Further use of this technique has led to the discovery of five subclasses of XP, each caused by a mutation at a different locus, indicating the complexity of the enzyme system involved in the repair of UV-damaged DNA.[9]

Of the five types of XP, not all are clinically distinct entities. More types may be detected, since there is heterogeneity in genetic disorders. Our patient had genetic subtype A, which is one of the three subtypes with neurologic abnormalities.[10]

Cleaver et al,[15] studying the human diseases with altered DNA repair processes, found that the damage inflicted on fibroblasts by many "chemical carcinogens" could be classified as either x-ray-like (that is, damage that XP cells can repair) or UV-like (that is, damage that XP cells cannot repair). One of the substances causing UV-like damage is methoxypsoralen, which attaches to the DNA of the fibroblasts and to the epidermal cells in vivo after UV irradiation.[16,17] Such an injury might have been responsible for the apparent acceleration of tumor formation that was associated with tripsoralen therapy in our patient.

Olivopentocerebellar atrophy is a major part of the CNS in the DeSanctis-Cacchione syndrome, as noted in the autopsy findings of our three patients. In all but one patient (the brother) all organ weights examined have been small. The previous patients with small organ weights have all been Japanese (two described by Yano[11] and two by Reed and associates[4]). This is the first white to be described as having small organ weights. At death she was only 108 cm in length. This neuropathologic study was similar to the other cases reported. Three of the previously reported patients with this syndrome died of chronic infections of the respiratory tract, perhaps due to immunologic deficiencies as suggested by the immunological findings in our patient. The relationship of chronic infection to poor DNA repair, if any, is not clear at this time.

At the NIH conference on XP and its associated symptoms,[10] Festoff discussed the associated neurologic abnormalities. He stated that a relatively common finding was microcephaly, defined as a head circumference more than 2 SD below the mean. Mental deficiency is also a common neurologic abnormality. He also mentioned loss of neurons, since the number of large pyramidal cells of the cortex and the Purkinje cells of the cerebellum were greatly reduced in XP patients. Some of the NIH patients had some of the abnormalities of the DeSanctis-Cacchione syndrome, but all three of our DeSanctis-Cacchione patients showed the same neurologic, somatic, and sexual characteristics.[3,4] Festoff assumed that all presumably neurologically healthy individuals are losing neurons from the CNS at a given rate. Our autopsy reports on DeSanctis-Cacchione patients confirm that there is neuronal loss. Because the brain probably developed poorly before birth, the neurons may never have been formed. The subject of this report died at 14 years of age with a brain size equivalent to that of an 8-week-old child.

Benjamin Landing, MD, performed the autopsy at Children's Hospital of Los Angeles; Richard Breathnack, assisted with the preparation of the manuscript.

Acquired Periungual Fibrokeratoma

A Rare Benign Tumor Previously Described as the Garlic-Clove Fibroma

Ronald L. Cahn, MD

• A rare periungual tumor, clinically and histologically identical to the acquired digital fibrokeratoma, is discussed in association with the differential diagnosis of acral digital nodules. It is believed that this is the first report that conclusively links the previously described garlic-clove fibroma with the acquired digital fibrokeratoma.

(*Arch Dermatol* 113:1564-1568, 1977)

In 1965, Steel[1] described a previously unknown isolated periungual fibrous tumor surrounded by a hyperkeratotic epidermal capsule. Little attention was given to more precise nomenclature for this lesion until 1968, when Bart et al[2] described ten cases of an acral tumor that they termed acquired digital fibrokeratoma. It was suggested that Steel's three garlic-clove fibroma cases may actually have been acquired periungual fibrokeratomas, but this point remained mere speculation until the present patient was carefully studied. This report documents a tumor identical to the originally reported garlic-clove fibroma and further demonstrates its historical and histopathologic relationship to the acquired digital fibrokeratoma.

REPORT OF A CASE

A 44-year-old woman was seen in May 1975 because of an asymptomatic flesh-colored mass overlying the dorsal aspect of the nail on the left middle finger (Fig 1). The patient indicated that the distal interphalangeal joint of that digit had sustained moderate blunt trauma approximately seven years previously in which no laceration or fracture occurred. Within a year after the injury, she first noted a firm pink hyperkeratotic tongue of tissue protruding over the nail plate from beneath the cuticle of the proximal nail fold. The lesion progressively enlarged, deforming the proximal nail fold and eventually thinning and depressing the central portion of the nail plate ventral and distal to the lesion. Two prominent ridges on the nail plate paralleled the lateral margins of the tumor and extended to the free margin of the nail. There was no other history of notable concomitant cutaneous or systemic illness.

The lesion was approached surgically under digital block using 1% lidocaine with 1:200,000 epinephrine. On the dorsal distal phalanx two parallel longitudinal incisions were created to allow reflection of the entire proximal nail fold back to the distal interphalangeal joint with subsequent visualization of the tumor overlying the nail and matrix. Without appreciable difficulty or hemorrhage, the mass was bluntly dissected free from adjacent structures and its proximal attachment exposed and extirpated while care was exercised to avoid trauma to the nail matrix (Fig 2). Closure was effected by reapproximation of the nail fold margins to the surrounding skin with 5-0 nylon sutures. A nonadherent compression dressing was applied, and healing was uneventful with restoration of a normal nail configuration by the 12th postoperative week (Fig 3).

Histopathologic Findings

The surgical specimen was preserved in 10% formalin solution after which paraffin-embedded sections were prepared by standard techniques. An irregularly acanthotic hyperkeratotic epidermal envelope surrounded the entire tumor with the exception of the proximal basal attachment. The basal and Malpighian cell layers were normal with maturation to an exaggerated stratum granulosum. No parakeratosis was evident in any of the sections. The core of the tumor was composed of thickened interlacing sclerotic collagen bundles primarily oriented longitudinally (Fig 4). Fibroblasts were generally sparse throughout the tumor, and in none of the sections could stellate fibroblasts be observed. Occasional endothelial channels coursed through the collagenous matrix, their number being relatively greater in the superficial papillary dermis than deeper in the more sclerotic reticular dermis. Conspicuously absent was evidence of any inflammatory infiltrate.

Staining with the Verhoeff-van Geison technique demonstrated only widely scattered fragments of elastic tissue that could have been easily missed without careful scrutiny (Fig 5). The more specific aldehyde-fuchsin stain showed slightly greater quantities of elastic fibers that were thin and frequently clumped in granules deposited irregularly throughout the tumor (Fig 6). There was no predilection for increased elastic tissue in or near vessels.

Serial sections failed to demonstrate any evidence of foreign material. Polariscopic examination revealed no doubly refractory bodies. Appropriate stains for histochemically detectable glycogen, acid and neutral mucopolysaccharides, and fibrin were uniformly negative. Phosphotungstic acid-hematoxylin stains of multiple sections revealed no intracytoplasmic granules.

There was no evidence of cutaneous adnexal structures within the tumor, and no nerve fibers could be found in either the dermal core or at the basal point of attachment. Thus, this tumor is microscopically a hyperplastic fibroepithelial neoplasm devoid of neural elements and lacking any evidence of epidermal appendages.

COMMENT

The differential diagnosis of acral digital tumors includes a wide variety of lesions of diverse causation (Table). The majority are mesodermal in origin, thereby necessitating an extensive classification to facilitate their study. An attempt is made to bring some order to this multitude of lesions in general and the fibrous tumors in particular. Confused reporting has fostered inappropriate nomenclature of some of these tumors, a situation that may be clarified in part by the ensuing discussion. Basic to the diagnosis of many of these lesions is

the fact that not only are the histopathologic findings important, but the clinical history, gross appearance, and genetic background provide tangible clues to the correct diagnosis.

The neural tumors are readily differentiated histologically and in some cases by clinical inspection. Neurofibromas usually occur in association with other signs of von Recklinghausen's disease, ie, café-au-lait spots, axillary freckling, and multiple soft cutaneous tumors, the onset of which dates to childhood or early adolescence. A familial incidence with autosomal dominant inheritance further clarifies the diagnosis. Isolated neurilemomas are distinctly uncommon, may follow trauma, and frequently are painful on compression. They arise from the Schwann cell sheaths of peripheral nerves, usually situated within the subcutaneous layer. The neuroma is a tangled mass of neural tissue arising from the proximal end of a severed peripheral nerve. They usually are deep in the subcutaneous layer and cause considerable pain. The clinical history and histopathologic characteristics easily elucidate these diagnoses.

The tumors of vascular origin are clinically distinct from one another. Their histopathologic characteristics are definitive enough to obviate confusion with other mesodermal neoplasms. The situation is similar for cartilaginous and osseous lesions; the histopathologic findings are diagnostic, and in the case of exostoses, a routine roentgenogram substantiates the clinical impression.

The gross appearance, geographic location, and histologic characteristics of verrucas, mucous cysts, traumatic epidermal inclusion cysts, cutaneous horns, and foreign body granulomas facilitate these diagnoses, and little chance for error exists if adequate history and/or tissue is available for study. The eccrine poroma is the only cutaneous adnexal tumor that may be encountered on the hands or feet with any frequency. It appears as an erythematous nodule or pedunculated mass that has a distinctive microscopic appearance.

The remaining tumors in the classification are of fibroblastic origin and require greater effort for adequate differentiation. The frankly malignant fibrous neoplasms include the dermatofibrosarcoma protuberans and the fibrosarcoma, but these lesions are rare in acral locations. The former tumor is most frequently encountered on the trunk, but other locations have been reported. It is a slowly growing multinodular flesh-colored or red dermal mass that may eventuate with a bluish or brownish color as it enlarges, and secondary painful ulceration may follow. Dermatofibrosarcoma protuberans usually is a solitary lesion that may begin as early as the second or third decade and may be preceded by trauma. The histopathologic findings are sufficiently characteristic to be diagnostic. Fibrosarcomas are also readily identified by their microscopic appearance. They may arise at any age, but frequently the lesion develops many years after intense therapeutic radiation exposure thereby appearing on poikilodermatous skin. The most common location is the trunk where it appears as a slowly enlarging reddish or violaceous smooth nodule that eventually ulcerates. These two tumors are unlikely to be misinterpreted and therefore provide little confusion with regard to the other benign fibromatoses.

The recurring digital fibrous tumor of childhood is a histologically benign, but biologically aggressive lesion that frequently recurs after the most exhaustive attempts at local extirpation. The characteristic location of this smooth flesh-colored nodular dermal mass is on the distal phalanx; therefore the nail matrix and/or the nail plate may be secondarily involved resulting in dystrophy. The histopathologic hallmark of this tumor is the finding of intracytoplasmic inclusion bodies that stain positively with phosphotungstic acid-hematoxylin, or red with methylgreen pyronine.[3]

Keloids pose little difficulty in the differential diagnosis of acral digital lesions. A prior history of trauma is to be expected, and the keloid generally conforms to the area of cutaneous insult. The histologic appearance varies with the age of the lesion, but little chance of confusion exists once the clinical history is appreciated.

True benign fibromas occur uncommonly on the digits. Grossly they may resemble acquired digital fibrokeratomas, Koenen's tumors, or rudimentary supernumerary digits by virtue of their location, consistency, color, and contour. However, microscopically they are usually more cellular in terms of fibroblasts and endothelial elements, and a collarette of hyperplastic acanthotic epidermis distinctly separates the thickened collagen bundles of the neoplasm from the underlying normal dermis.[2] Additionally, elastic fibers are consistently lacking within the matrix of true fibromas.[4]

Koenen's tumors are the acral digital fibrous lesions associated with tuberous sclerosis. Generally, multiple, symptomless, subungual and periungual fibroepithelial excrescences develop on the fingers and toes at, or after, puberty. The other neurocutaneous signs of tuberous sclerosis are readily discernible, thereby narrowing the diagnostic possibilities. Histologically these tumors are angiofibromas that occasionally show stellate fibroblasts with the collagen matrix.

Rudimentary supernumerary digits and acquired digital fibrokeratomas are the most difficult of the fibrous lesions to separate histopathologically. Both appear as fibroepithelial nodules, but the rudimentary supernumerary digit is distinguished by the finding of multiple nerve bundles within the dermal core and especially at the proximal base of the nodule.[5] Such neuroid structures were not described in any of the 53 acquired digital fibrokeratomas examined by Bart et al[2] and Verallo.[5] Additionally, rudimentary polydactyly almost always occurs at the base of the metacarpophalangeal joint, tend to be familial, and are present at, or soon after, birth. The most important clinical feature of rudimentary polydactyly is its propensity to be bilaterally symmetric, a phenomenon never reported with acquired digital fibrokeratomas, although on two occasions the latter lesion has occurred multiply, but not simultaneously.[2,5]

In 1965, Steel described three cases of a peculiar periungual hyperkeratotic fibrous tumor that overgrew the dorsal nail plate from beneath the proximal nail fold and designated it the garlic-clove fibroma. There was no history of trauma, and the lesions were asymptomatic. No comment was made regarding the resultant nail dystrophy, but a clear illustration of a channel-like depression was provided in the original report. Steel indicated that the lesion arose from the nail bed. This seems unlikely in his cases, since the tumor would then have to herniate through the nail matrix or plate to reach the dorsal nail surface, the location described for each of the original lesions. This would necessarily produce a much greater nail dystrophy than the longitudinal depression herein described and illustrated in the original report. After careful dissection of the tumor in the present case, it was obvious that the lesion arose in the dermis proximal to the nail matrix and merely expanded distally, in the direction of least physical resistance. After resection, the matrix was depressed in the center, but intact distal to the basal attachment of the

tumor. The site of origin is further substantiated by the fact that a normal nail plate eventuated subsequent to successful surgery, an event unlikely to occur if the tumor primarily involved the matrix area. It is not inconceivable that this lesion actually could arise from the nail bed and protrude from beneath the nail plate. Such a lesion is pictured in one of the major dermatology texts,[7] albeit without further clinical or histopathologic explanation.

Steel indicated that the garlic-clove fibroma is composed of a core of dense interlacing collagen bundles with associated capillaries within a hyperkeratotic thickened epidermal capsule. He noted normal basal and prickle cell layers as well as a markedly thickened granular layer. As previously noted, there are the same general findings described for the acquired digital fibrokeratoma. The one notable histologic feature that has eluded firm definition is the quantitative and qualitative characterization of the elastic tissue within the tumor. Steel did not comment on the presence of elastin in his case. Bart et al examined two tumors for the presence of elastic fibers and found them to be very sparse in one specimen and thin straight fibers reduced in quantity in the second. Verallo found variable quantities of elastic fibers present in all lesions, some of which were noted to be coarse and others fragmented. In the present case, elastic tissue was almost undetectable with the Verhoeff-van Geison technique, but the more specific aldehyde-fuchsin stain demonstrated sparse abnormal clumped granules of elastin and less conspicuous, thin fragmented elastic fibers. It seems apparent, therefore, that this tumor is characterized by the presence of variable quantities of distinctly abnormal elastic tissue.

The tumor that is the subject of this report is histologically identical to the garlic-clove fibroma, but more importantly, such lesions appear congruent with the ten cases first described by Bart et al as acquired digital fibrokeratomas. Indeed, these authors speculated that the tumors described by Steel may have been acquired periungual fibrokeratomas, but at that time conclusive histopathologic proof was lacking. Current evidence now substantiates this association. Verallo reviewed 43 similar cases of acquired digital fibrokeratomas and generally corroborated the above clinical and pathologic findings. In doing so he noted that some lesions occurred on the dorsum of the hand, palm, sole, ankle, and patella, therefore agreeing with Bart et al that the broad designation, acquired digital fibrokeratoma, is less desirable than the specific term acquired fibrokeratoma, especially when the latter is further clarified by the exact anatomic location of the lesion.

The cause of this tumor is unclear. The initial report included three cases with no history of trauma. Bart et al reported one of ten cases that was preceded by trauma; Verallo noted direct predisposing major trauma or repeated minor insults in five of his 43 cases; and the present case followed within a year of direct blunt injury. These statistics suggest that trauma plays more than an incidental role in the genesis of this tumor, but the exact link remains elusive.

It now seems apparent that the term garlic-clove fibroma should be discarded and replaced by the more useful, and appropriate designation, acquired periungual fibrokeratoma, a term that encompasses both the salient clinical and histopathologic features of this unusual benign tumor.

Since the completion of this article, two additional cases of acquired periungual fibrokeratoma have been diagnosed and underwent operation.

A 16-year-old boy sustained moderate blunt trauma to the distal right hallux when he "stubbed" his toe on Dec 6, 1973. Pain was considerable, and roentgenograms taken then showed a chip fracture of the epiphyseal plate of the distal phalanx. The toe was splinted and healing was uneventful. Approximately one year later, the patient noted a bulging firm soft tissue mass emerging from beneath the proximal nail fold and lying dorsal to the nail plate. The lesion progressively enlarged until it deformed the nail plate, producing a shallow depressed groove. A tongue of thick keratin protruded from the distal margin to the tumor (Fig 7). Under local anesthesia, the lesion was resected in a fashion identical to that of case 1 (Fig 8). The site healed without incident, and a normal nail contour was restored.

A 17-year-old, severely retarded teenager sustained a direct dorsal blow to the distal right index finger in October 1974. This resulted in a laceration that necessitated the removal of the partially avulsed nail plate and suture reconstruction of the distal fingertip. Healing was uneventful, with the exception of slight radial deviation of the extreme distal fingertip. Approximately 11 months later the nail was noted to be deformed by a subungual hyperkeratotic mass that produced distal onycholysis (Fig 9). No attempt was made to rectify the deformity until the patient was seen in the dermatology clinic for an unrelated problem. Subsequently, the lesion was approached surgically by removing the nail plate (Fig 10) and bluntly dissecting free the tumor (Fig 11). Its point of origin was on the nail bed exactly at the previous suture line. Healing progressed without difficulty.

Histopathologic Findings

The histopathologic features of the latter two cases were very similar to those of the first lesion described in detail within the body of this article. The latter tumors had a very thick epidermis with an exaggerated granular cell layer. Massive orthokeratotic hyperkeratosis was uniformly present surrounding the lesions. The connective tissue core in both cases was composed of thick collagen bundles with little vasculature. What few vessels were encountered maintained an unusually straight course for extended lengths. These straight vessels were most prominent in case 2 where the lesion had been on the hallux. There did not appear to be any predisposition for their orientation either horizontal or vertical to the axis of anatomical tumor orientation.

The remaining features differed little from those presented previously. There were sparse fragments of abnormal elastic tissue widely scattered through the collagen bundles. The hallux lesion in case 2 showed the greatest total amount of elastin of any of the three cases. No inflammatory infiltrate was noted in any of the cases and, again, no neural elements were identified in any of the multiple sections examined from each tumor.

COMMENT

These three cases and those of Steele clearly indicate that the acquired periungual fibrokeratoma is induced by trauma. Their anatomic location and varying age of onset strongly favor a hyperplastic growth rather than any type of congenital malformation such as a supernumerary digit. The histologic picture also substantiates this differentiation. No evidence of neural elements was found in any of the present lesions, and elastic tissue was sparse and definitely abnormal. The latter findings would not be expected in congenital malformations, namely, supernumerary digits.

Ultimately, the cellular mechanisms responsible for the acquired periungual fibrokeratoma and the acquired digital fibrokeratoma may be elucidated. However, the present state of knowledge would indicate that these tumors are distinct clinical and histopathologic entities representing a reactive hyperplasia initiated by tissue trauma.

Fatal Cytomegalic Inclusion Disease

Associated Skin Manifestations in a Renal Transplant Patient

Norman Minars, MD; Jan F. Silverman, MD; Mario R. Escobar, PhD; A. Julio Martinez, MD

• A case of cytomegalovirus-induced vasculitis led to skin ulcerations in a renal transplant patient. Light and electron microscopy revealed inclusion bodies and viral particles, respectively, characteristic of cytomegalovirus. To our knowledge, this is the first report of cytomegalovirus-induced vasculitis producing skin ulcerations, and it illustrates another of the protean manifestations of cytomegalovirus inclusion disease that may have important clinical implications.

(*Arch Dermatol* 113:1569-1571, 1977)

Cytomegalovirus (CMV) is now considered as a member of the herpesvirus family that includes agents that are remarkable for their capacity to persist in a latent state, possibly from the time of conception to the time of death. In the general population, from 0.5% to 2.0% of newborn infants may be infected with CMV, depending on the socioeconomic level.[1] On the other hand, cytomegalic inclusion disease (CMID) in adults often becomes manifest in chronic debilitating conditions and frequently in immunosuppressed individuals, such as cancer patients and recipients of organ transplants. Of these, up to 91% may show evidence of CMV infection.[2]

The clinical manifestations of CMID in the adult are often nonspecific and vary depending on the organ involved. In the localized form of infection, the lungs (pneumonia) and the gastrointestinal tract (ulcers) are commonly affected, whereas in the disseminated form, most of the tissues may be compromised. Except for maculopapular or purpuric rash,[3] specific dermatological signs of CMID and the presence of the virus in the skin have not been documented in the literature. To our knowledge, this is the first report of CMV-induced vasculitis leading to skin ulcerations. This finding represents another manifestation of CMID that may have important clinical implications.

REPORT OF A CASE

A 24-year-old woman transplant patient was last admitted to the Medical College of Virginia with complaints of skin ulcers, fever of unknown origin, and decreased visual acuity. Her condition was first diagnosed as nephritis at the age of 7 years, which was well controlled by medical therapy. However, at the age of 21, she developed chronic uremia and renal tubular acidosis secondary to chronic pyelonephritis for which she was admitted to the Staten Island Hospital and treated by peritoneal dialysis. Subsequently, she had many hospital admissions there for hemodialysis. In August 1972, she was first admitted to the Medical College of Virginia, and in September of that year, she underwent renal transplantation two weeks after bilateral nephrectomy, ureterectomy, splenectomy, and appendectomy. Her mother served as a kidney donor. Subsequently, she underwent immunosuppressive therapy with azathioprine (Imuran) and prednisone. Hepatitis B surface (HB_s) antigen was first detected in her serum by complement fixation approximately a month after transplantation, but a peak titer of 1:2,000,000 was detected at 2½ months. The patient had two episodes of rejection at 37 and 104 days after the transplant for which alternate therapy with cyclophosphamide (Cytoxan), azathioprine, and prednisone, as well as irradiation was instituted. Her subsequent course was complicated by anemia; febrile urinary tract infections treated with gentamicin sulfate, nafcillin sodium, and sulfisoxazole (Gantrisin); and hypertension followed by a seizure and hemiplegia of unknown cause. She recovered from these problems and was discharged from the hospital 192 days after the transplant to remain under the care of her private physician.

The patient's condition was well under control until July 24, 1973, when she was readmitted to the Staten Island Hospital with a history of fever ranging from 38.3 to 41.1 C. At this time, she had a WBC count of 3,400/cu mm; platelets, 100,000/cu mm; hemoglobin level, 8 gm/100 ml; and hematocrit, 27%. *Escherichia coli* was isolated from a blood culture, and she was then treated with ampicillin sodium and chloromycetin. Two necrotic skin ulcers, one on her left elbow and the other on her right thigh, were noted for the first time but no biopsy was done. She was discharged on Sept 8, 1973, with continuation of immunosuppressive therapy and sutilains (Travase) ointment for her skin lesions.

Despite intensive therapy, the patient continued to have symptoms, and she was readmitted to the Medical College of Virginia Hospital on Sept 24, for the last time with complaints of necrotic skin ulcers (Fig 1), a chronic dry cough, fever of unknown origin, decreased visual acuity, and dysphagia. Physical findings on admission included oral candidiasis, skin ulcers, one on her left elbow and the other on her right thigh, Cushing's type of habitus, poor visualization of fundi with narrowed vessels and scarring with waxy exudates in the left eye and failure to see the discs. Punch biopsies from the skin ulcers were performed shortly after admission. She progressively deteriorated during her hospitalization that was complicated by gastrointestinal bleeding for which she received multiple transfusions. During this admission her condition was diagnosed as chorioidoretinitis of presumed viral origin, which progressed to blindness. Terminally, she developed diffuse pulmonary infiltrates bilaterally and her fever persisted despite broad-spectrum antibiotic therapy. She died approximately seven weeks following this admission.

MATERIALS AND METHODS

For light microscopy, punch biopsies from ulcers on the right elbow and the right leg and from nearby uninvolved skin

Fig 1.—Three-inch punched out ulcer of skin with a clear base and subcutaneous tissue with slight erythema of surrounding epidermis on anterior lateral upper thigh.

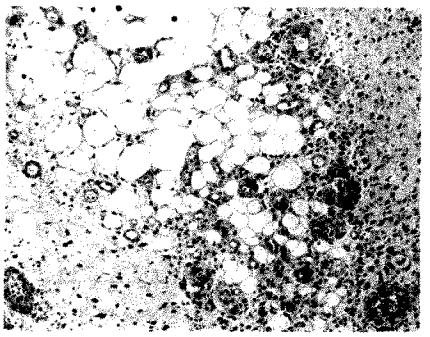

Fig 2.—Cytomegalic inclusion disease involving dermis and subcutaneous tissue. Dermal vessels markedly narrowed by the affected enlarged endothelial and perithelial cells with surrounding perivascular and interstitial inflammatory infiltrate (hematoxylin-eosin, original magnification ×120).

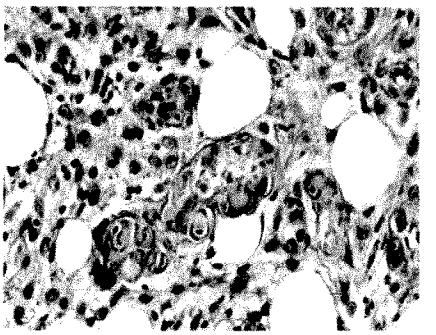

Fig 3.—Affected vessels revealing characteristically enlarged cells with large purplish intranuclear inclusion surrounded by clear halo and occasional eosinophilic intracytoplasmic inclusions (hematoxylin-eosin, original magnification ×375).

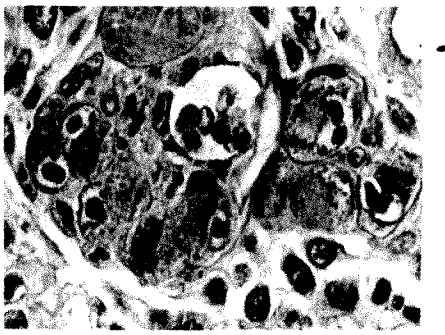

Fig 4.—Dermal arteriole markedly narrowed by swollen cells having characteristic large purplish intranuclear inclusion with surrounding halo (hematoxylin-eosin, original magnification ×920).

Fig 5.—Low power view of clinically uninvolved skin revealing no cytomegalic inclusion disease (hematoxylin-eosin, original magnification ×52).

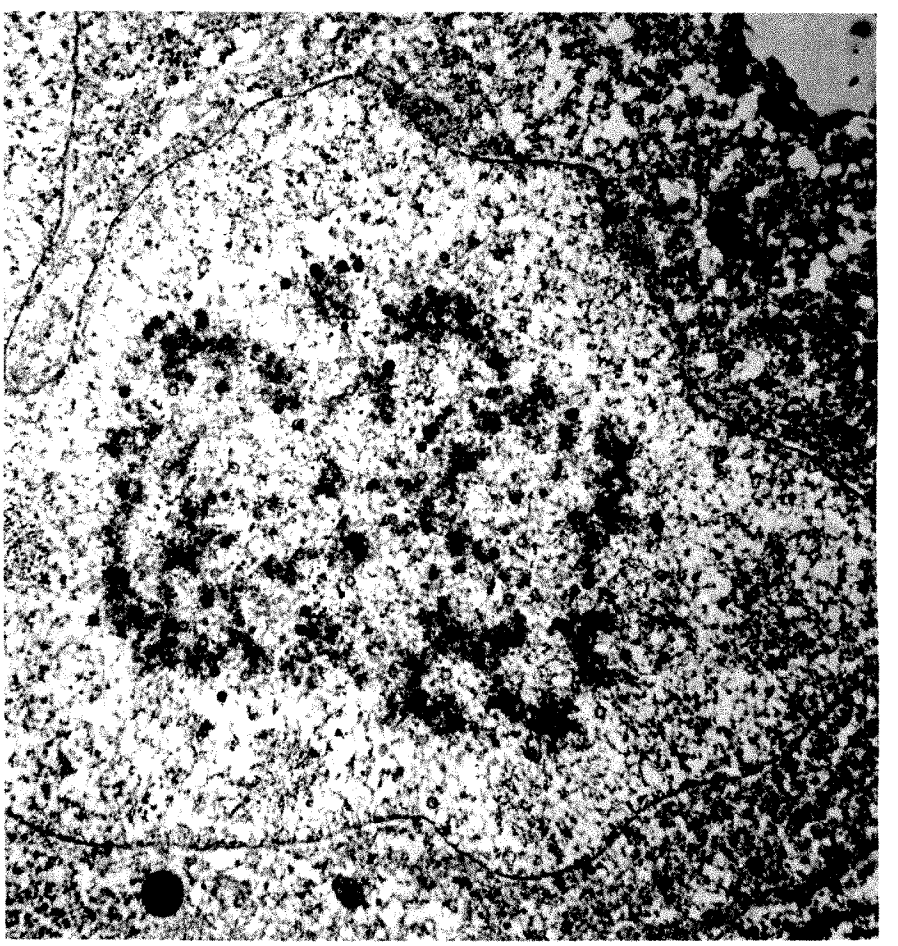

Fig 6.—Intranuclear spherical viral particles measuring 110 nm in average diameter containing either empty or dense cores (original magnification ×20,000).

were fixed in Zenker's solution and embedded in paraffin. Sections 6 μm in thickness were cut and stained with hematoxylin-eosin. At postmortem, specimens were submitted from the skin, lung, liver, kidney, breast, ovaries, adrenal, parathyroid, and eye tissues. Frozen sections from skin, kidney, liver, and lung tissues were prepared for indirect immunofluorescence, using isothiocyanate-conjugated rabbit antihuman γ-globulin and human antiserum to CMV (prepared at the Medical College of Virginia Virology Laboratory) free of antibody to herpes hominis and varicella-zoster viruses according to complement fixation and immunofluorescence tests. Cell cultures of human embryonic lung uninfected and infected with CMV were employed as negative and positive controls, respectively. Negative control serum (tested at the Medical College of Virginia Virology Laboratory) was also included. The technique used was originally described by Hanshaw.[1]

For electron microscopy, blocks of skin and subcutaneous tissue fixed in Zenker's solution and embedded in paraffin were used. Depending on previous histological examination, the blocks containing more inclusion bodies were selected. The paraffin was removed and the tissue rehydrated; then the cubes were placed in 4% glutaraldehyde in cacodylate buffer, postfixed in 2% osmium tetroxide dissolved in cacodylate buffer, dehydrated, and embedded in an epoxy resin. One-micron sections were cut with glass knives and stained with paragon PS-1301 for a general survey. Thin sections were cut with a diamond knife, double-stained with uranyl acetate and lead citrate, and observed with an electron microscope.

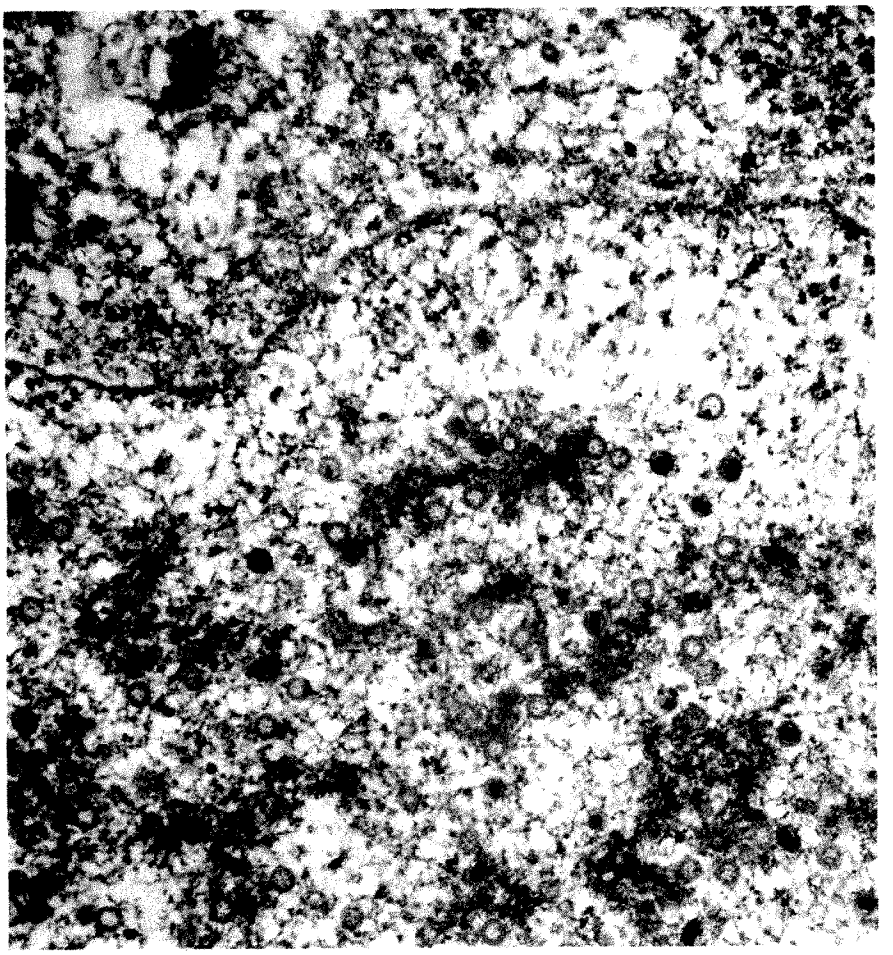

Fig 7.—Collection of mature and immature viral particles within nucleoplasm; some of them reveal dense cores while others are immature forms with single or double rings (original magnification ×45,000).

RESULTS

Microscopic examination from both skin ulcers demonstrated that the main pathologic change involved the small dermal vessels (Fig 2). The CMV inclusions were present in the endothelial and perithelial cells of the small arterioles, venules, and capillaries. The affected cells were characteristically enlarged and showed large purplish intranuclear inclusions surrounded by a clear halo. Occasional cells had circumscribed granular pale eosinophilic intracytoplasmic inclusions (Fig 3). Rarely, large cells with two nuclei containing inclusions were seen. The lumen of the involved vessels was markedly narrowed by the swollen cells (Fig 4). There was a severe perivascular and interstitial infiltrate composed of polymorphonuclear neutrophils, histiocytes, and lymphocytes. The biopsy specimen from the uninvolved skin revealed no CMID or inflammation (Fig 5).

At autopsy, disseminated CMID was present with involvement of the skin, lungs, liver, kidneys, breasts, ovaries, adrenal and parathyroid glands, and eyes. The kidney, liver, and lung sections showed areas of specific immunofluorescence with anti-CMV rabbit antiserum. The ulcerated skin sections were unsatisfactory for immunofluorescence.

Electron microscopic study revealed numerous degenerating cells within the dermis containing intranuclear viral particles approximately 110 nm in diameter. Some of these particles were devoid of dense cores while others represented immature intranuclear forms of the virus (Fig 6 and 7).

COMMENT

Cytomegalovirus inclusion disease may have protean clinical manifestations ranging from inapparent infection to widely disseminated disease with a fatal outcome, as in this case. The development of CMID in patients with underlying debilitating conditions is well documented, but whether CMV infection in organ-transplant or immunosuppressed individuals is primary or represents reactivation of a latent infection is unclear.[5] Approximately one year following renal transplantation and while she was receiving immunosuppressive therapy, this patient was readmitted to the hospital with complaints of skin ulcers, fever of unknown origin, and decreased visual acuity. To our knowledge, this is the first report of CMV-induced vasculitis presenting with skin ulcerations in a fatal case. The histologic changes in this case are similar to the ones described by Goodman and Porter[6] and Nakoneczna and Kay.[7] Both of these patients had gastrointestinal tract ulceration secondary to CMV-induced vasculitis. We believe that the striking CMID vasculitis in the dermal vessel caused the skin ulceration in our case.

The pathologic and histologic findings described in this case, as well as the demonstration by electron microscopy of intranuclear herpes-like viral particles in the ulcerated skin lesions of this patient, confirm that CMV was associated with the pathogenesis of the skin lesions in this patient. We suggest that biopsy should be done if immunosuppressed patients have skin ulcers. This case is another example of the protean manifestations of CMID and should alert the clinician of the possible occurrence of skin ulceration induced by CMV.

Halo Congenital Nevus

Martin H. Brownstein, MD; Bonnie B. Kazam, MD; Ken Hashimoto, MD

• A 24-year-old woman noted a depigmented halo around a pigmented lesion that had been present on her abdomen since birth. The halo and the central pigmented zone showed no change during the following year. Light and electron microscopic studies disclosed an uninflamed nevus extending to the deep reticular dermis; peripherally, the basal layer of the epidermis was depigmented. These findings indicate that a halo may develop about an *uninflamed* nevus that does not involute, and that the nevus may show the specific histopathology of *congenital* nevus.

(*Arch Dermatol* 113:1572-1575, 1977)

Depigmented zones may form about a variety of *acquired* melanocytic lesions,[1] including intradermal, compound, and blue nevi, and benign juvenile melanoma (spindle and epithelioid cell nevus), as well as primary and metastatic malignant melanoma. Histologic examination of the central lesion[1,2] classically shows a well-circumscribed, dense infiltrate of lymphoid cells and some melanophages admixed with nevus cells, enabling the pathologist to make the diagnosis of halo nevus without even examining the peripheral area of depigmentation. Our purpose here is to describe an example of a depigmented halo occurring around a *congenital* nevus in which inflammatory infiltrate was *absent* from the central area.

REPORT OF A CASE

A 24-year-old woman had had a 2.3 by 1.2-cm pigmented lesion on her abdomen since birth. The growth was dark brown and contained coarse black hairs. An irregularly shaped depigmented halo varying in width from 0.2 to 1.8 cm developed around it (Fig 1). Simultaneously, she noted several hypopigmented areas on her face, neck (Fig 2), and back. During the following year, there was no change in the central pigmented area or of the halo. Her general health was excellent.

One year after the appearance of the halo, a fusiform excision of the pigmented lesion, together with most of the halo and a small amount of normal skin, was performed under local anesthesia. A biopsy of a vitiliginous area on the neck was also carried out. Part of each specimen was fixed in 10% buffered formaldehyde and processed for light microscopy; another portion of each specimen was placed in 5% glutaraldehyde buffered to pH 7.2 with a 0.1M solution of cacodylate for electron microscopic examination.

Light microscopy showed benign nevus cells, with no inflammatory infiltrate, extending deeply into the reticular dermis (Fig 3). Staining with the Masson-Fontana silver technique disclosed heavy melanin pigmentation of the basal layer of the epidermis overlying the nevus (Fig 4, top left), a zone of depigmentation of the basal layer of the epidermis (Fig 4, top right), and an area of normally pigmented skin peripherally (Fig 4, bottom right). When examined by the silver technique, the hypopigmented macule on the neck showed a marked decrease, to absence of epidermal melanin.

When examined with the electron microscope, nevus cells in the dermis were slightly vacuolated (Fig 5); many of those in the upper cutis produced melanosomes. There was neither lymphocytic nor histiocytic infiltration into the lesion, except for occasional small monocytes; the nevus cell nests were practically free of inflammatory cells. In the epidermis overlying the intradermal lesion, melanocytes were shrunken but still produced melanosomes (Fig 6). Transfer of these melanosomes to the surrounding basal cells was accomplished normally. In the vitiliginous lesion apart from the halo nevus, epidermal melanocytes were still present, though shrunken and often vacuolated. Very small melanosomes were occasionally seen. The basal cells surrounding these atrophic melanocytes contained a small number of melanosomes. Similar findings have previously been described in vitiligo.[3]

COMMENT

For some time, it had been thought that nevi present at birth are huge and show the distribution of bathing trunks or other garments. Recently, it has been reported[4] that congenital nevi are almost always larger than 1.5 cm in greatest surface dimension, but are not always gigantic, whereas acquired nevi are usually smaller than 1.5 cm. Histologically, congenital nevi feature a distinctive pattern with nevus cells extending into the deep reticular dermis and even into the subcutaneous tissue. The nevocytes in congenital nevi may also involve, surround, and appear to invade the various adnexal structures of skin. The cells may be arranged in single file or in dense sheets, and at times show a neuroid configuration. Involvement of the deeper cutis is extremely unusual in acquired nevi. Congenital nevi have a higher incidence of associated malignant melanoma than the smaller acquired nevi; the melanoma may develop during childhood or later.[4] Prophylactic surgical removal has been advocated if feasible.

In our patient, a depigmented halo developed around a lesion that clinically, anamnestically, and histologically fulfilled the criteria for congenital nevus. It is well known that a halo can form around a variety of acquired melanocytic lesions,[1] including intradermal, compound, blue nevi, and benign juvenile melanoma (spindle and epithelioid cell nevus), as well as primary and metastatic melanoma, but very few cases of halo congenital nevus have been reported.[5,6] This is the first time, to our knowledge, the specific histopathologic picture of congenital nevus has been demonstrated in a halo nevus.

Halo nevi are often multiple, usually occur on the trunk, and appear most commonly in children and young adults. The condition is not inherited, nor does it show any sex predilection. In many patients, vitiligo develops at

distant and random sites.

Histologically,[1,2] the central lesion shows a dense, sharply demarcated infiltrate of lymphocytes and melanophages admixed with nevus cells that may be slightly atypical. When examined with the electron microscope,[7-10] the nevus cells have cytoplasmic vacuoles with evidence of autophagocytosis, and macrophages are found to contain phagocytosed portions of nevus cells. The epidermis over the pigmented lesion shows variable melanin pigmentation; the peripheral halo area progresses to complete absence of melanin. Clear epidermal cells in the halo are found to be Langerhans' cells on electron microscopic examination; melanocytes are not present.

Although early reports of halo nevi[11] mentioned nonregressing central pigmented lesions and central nevi without inflammation, most recent stud-

ies[1,2] emphasize the progression to total destruction of the central nevus cells, with clinical disappearance of the pigmented lesion and of the histologic inflammatory infiltrate and, at times, repigmentation of the skin. This seems likely in one of the reported cases of congenital halo nevus.[6] It is clear, however, that some halo nevi do not follow this course, nor do they have the characteristic dense inflammation. The nevus in our patient showed no evidence of regression clinically and no signs of inflammation histologically after one year. The depigmented halo thus can not simply be attributed to an inflammatory process that destroys the central nevus. In one study,[11] half of 18 halo nevi did not spontaneously disappear. Biopsy specimens of five of 14 lesions showed intradermal nevi. In a previously reported case of halo congenital nevus,[3] the patient was followed up for 20 years with no involution of the lesions and no inflammation on biopsy. The fact that a halo nevus can remain unchanged clinically and have no inflammation histologically deserves emphasis. In at least some instances, there is a correlation between inflammation and involution.

The mechanism of halo nevus formation is still obscure. It was previously thought[12] that the halo represented the fortuitous appearance of vitiligo around a pigmented nevus. Recently, circulating antibodies (IgG) against the cytoplasm of melanoma cells have been demonstrated in patients with primary malignant melanoma and in resolving halo nevi.[13] It has also been shown[14] that lymphocytes from patients with halo nevi exhibit increased cytotoxicity against melanoma cells in vitro. There has even been speculation[13] that halo nevus represents rejection of a mole developing malignant changes, though this seems unlikely.[15] An alternative hypothesis to immune mechanisms is that depigmentation is related to a disturbance of the melanocyte-nerve relationships. Recently, it has been suggested that such mechanisms operate in other noninflammatory depigmentary disorders, including vitiligo, incontinentia pigmenti achromians, and the Vogt-Koyanagi syndrome.[3]

Atypical Multicentric Reticulohistiocytosis With Paraproteinemia

Jonathan R. S. Rendall, MRCP; Robert I. Vanhegan, BM, DPhil; Alastair H. T. Robb-Smith, MD, FRCP; Robert E. Bowers, MD, FRCP; Terence J. Ryan, FRCP; Henry R. Vickers, MD, FRCP

• Two women had multiple subcutaneous nodules that showed features of multicentric reticulohistiocytosis (MR). Neither had joint symptoms. Both had a raised erythrocyte sedimentation rate, an immunoglobulin G paraproteinemia, and raised levels of nonhepatic serum alkaline phosphatase. The skin lesions have been followed up, using light and electron microscopy, immunoperoxidase, and histochemical methods. The material in the giant cells stained positively for γ heavy chain determinants: the light chain type in each case was that of the paraprotein. An attempt to reproduce the skin lesions in one patient by intradermal injection of her paraprotein failed.

(*Arch Dermatol* 113:1576-1582, 1977)

The narrative defining multicentric reticulohistiocytosis (MR) has been confusing. In the differentiation from rheumatoid arthritis, lipid disorders, histiocytosis X, and other granulomatous disorders, the condition has been described under 14 titles. The first case has been attributed to Weber and Freudenthal.[1] Goltz and Laymon[2] introduced the term "multicentric reticulohistiocytosis." Davis and Wood[3] emphasized the separation of MR from the single reticulohistiocytoma of Zak.[4] More recently, Barrow and Holubar[5] fully reviewed the literature, history, and clinical criteria. They suggested the definition:

MR is a systemic disease of unknown cause manifested by the gradual development of nodules in the skin, mucosa, subcutaneous tissues, synovia, and, at times, periosteum and bone resulting in destructive arthritis and disfigurement of the facies. On biopsy of a nodule, whether from skin, mucosa or synovia, multi-nucleated giant cells and histiocytes with a ground glass appearance of the cytoplasm secondary to lipid inclusions are invariably seen.

Mihm et al,[6] in their survey of the histiocytic infiltrates of the skin, describe the distinctions between the histiocytosis X group, juvenile xanthogranuloma, giant cell reticulohistiocytosis, and MR. Flam et al,[7] and later Ehrlich et al,[8] used electron microscopy in their examination of the lesions. Characteristically, numerous small membrane-bound, electron-dense particles are seen within the giant cells.

Two female patients with many of the characteristics of MR, in addition to paraproteins demonstrable in serum and within their skin lesions, have been studied.

Accepted for publication Sept 3, 1976.

REPORT OF CASES

The two patients have been shown individually to the section of dermatology of the Royal Society of Medicine.[9,10]

CASE 1.—A 65-year-old woman first noticed a painless lump beneath her right eye one year before an initial examination. Subsequently, two others developed on her face, another on the left side of the neck, and several more on the upper part of the trunk. During this year, she experienced nasal irritation, occasionally associated with mucoid, sometimes blood-stained discharge. For ten years, she had recurrent episodes of episcleritis affecting both eyes.

Twelve mobile, nontender subcutaneous lumps were palpable. The skin over each was normal save for the lesion below the right eye that showed a yellow discoloration. The majority of the lumps were distributed over the face, neck, and upper part of the trunk. None were found below the level of the umbilicus. She had bilateral episcleritis and crystals were seen in the cornea by slit-lamp examination. The nasal mucosa was atrophic in appearance. For the last nine months, she has developed a typical parkinsonian tremor and gait.

CASE 2.—A 55-year-old woman first noticed a lump beneath the left eye 18 months before initial examination. Subsequently, she developed further lesions around each orbit that coalesced into indurated yellow plaques (Fig 1). The eyelids themselves were spared. At the same time, similar lesions evolved on each breast and at the site of an appendectomy. The lesion below the left eye became slightly ulcerated for a period, then healed. Nasal irrita-

Fig 1.—Periorbital lesions in case 2. Indurated yellow-colored plaques surround both eyes; eyelids themselves are spared.

Fig 2.—Subcutaneous nodule in skin in upper back of subject 2 showing deep dermal infiltration with unaffected upper dermis (hematoxylin-eosin, original magnification ×15).

tion with discharge has become a feature.

In addition to the lumps, the spleen was palpable and bilateral conjunctival plaques near the inner canthus were seen. Most recently, thin red plaques have developed over the dorsal surfaces of several fingers, particularly at the joints.

LABORATORY DATA

The results of laboratory tests from these two patients are compared (Table 1). In addition, the following were found to be negative: Mantoux test (1 in 100 old tuberculin), Wassermann reaction, Reiter protein complement fixation test, routine plasma reagin tests, rheumatoid factor (latex screening test), antinuclear factor, and lupus erythematosus cell preparation. Patient 1 received an intradermal injection of 0.1 ml Kveim antigen; no nodule appeared at this site, and biopsy was refused. Patient 2 had a negative result after Kveim biopsy. Sternal marrow aspirates were obtained from both and were within normal limits. No excess of plasmacytoid cells was detected nor was any abnormality detected in the monocytic series. Patient 2 received an intradermal injection of her paraprotein in parallel with normal saline as a control. Erythema was detected at the site at 48 hours but not at the control site. A biopsy done on the test site at six weeks revealed no abnormality.

Table 1.—Laboratory Data

Test	Case 1	Case 2	Normal Range
Hemoglobin, complete blood cell count, platelets, ESR (Westergren)	Normal, 40-60 mm/hr	Normal, 41 mm/hr	
Sequential multichannel analysis (Ca, Pi, urea, uric acid, cholesterol)	Normal	Normal

HISTOPATHOLOGICAL FINDINGS

The biopsy specimens received for histopathological diagnosis were fixed either in formol-saline or Bouin's fixative. Nodules were seen to arise in the lower dermis at the border of the subcutaneous fat and were moderately well circumscribed although not encapsulated (Fig 2). A narrow free zone of normal dermis between epidermis and nodule was evident. Mast

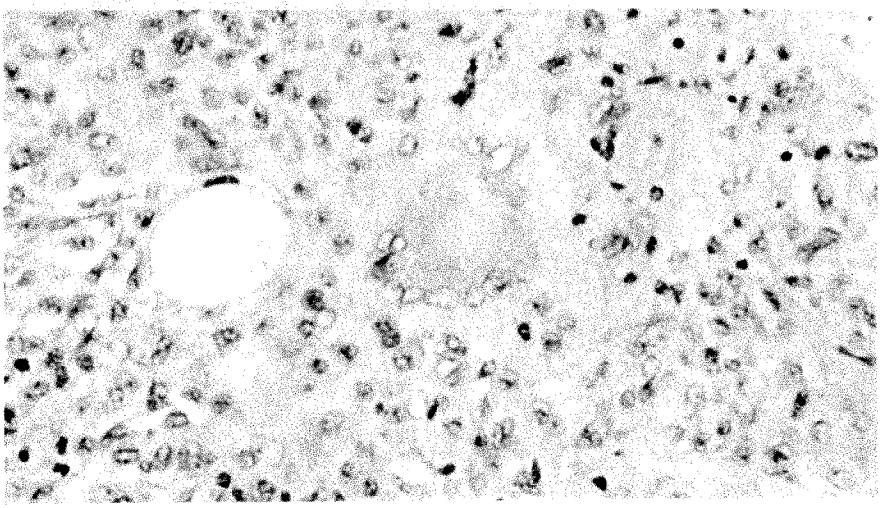

Fig 3.—Case 1. An area of subcutaneous adipose tissue infiltrated and replaced by monomorphic cells and multinucleate giant cells. Mature fat cell remains (clear space) with typical multinucleate giant cell near by (Diastase, PAS, and hematoxylin-eosin, original magnification ×500).

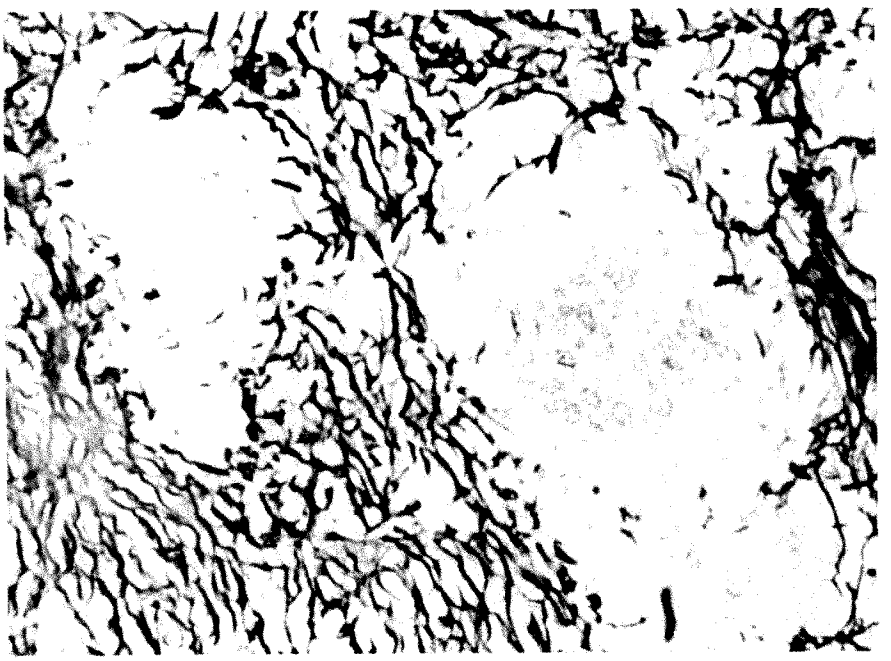

Fig 4.—Case 1. Reticulin around individual cells in infiltrate. Adipose tissue, collagen, and striated muscle have been replaced by newly formed reticulin around infiltrating cells and two giant cells shown (silver impregnation, original magnification ×500).

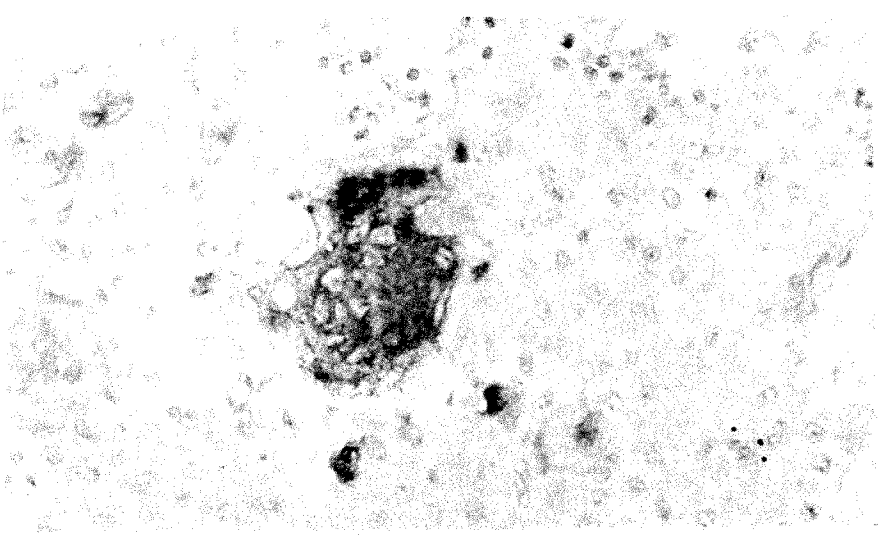

Fig 5.—Case 2. Immunoperoxidase staining for λ light chain determinants. Central giant cell is strongly positive as are five mononuclear cells in vicinity. Staining for κ determinants negative in this case (hematoxylin counter stain, original magnification ×500).

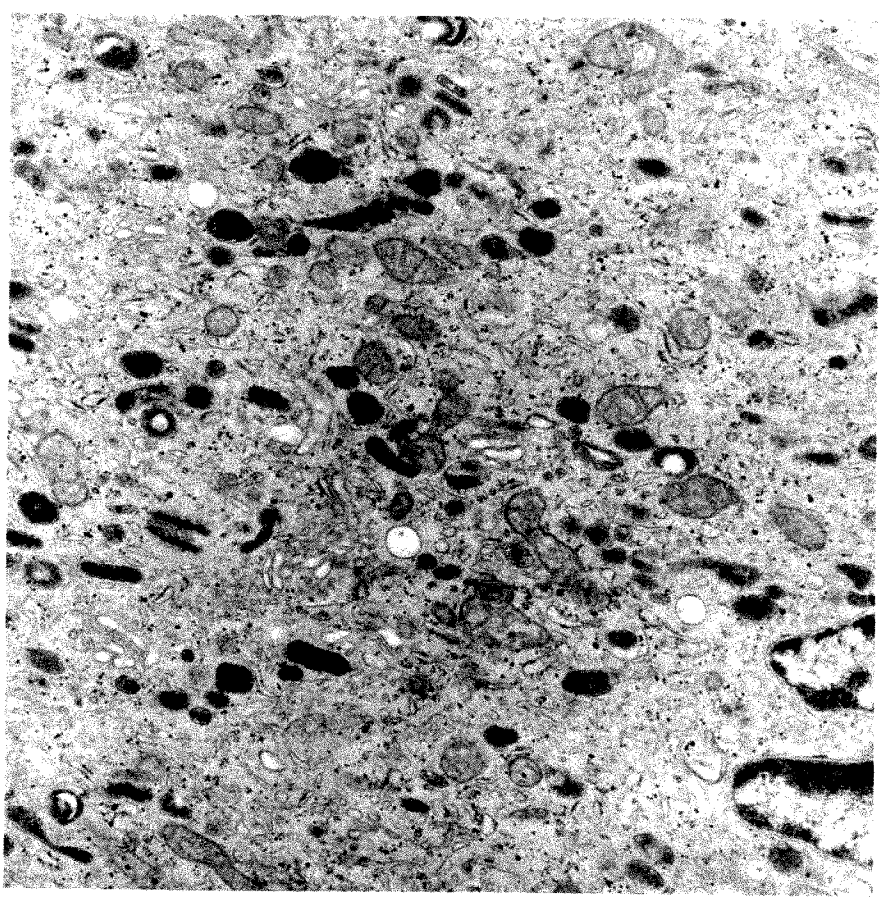
Table 2.—Multicentric Reticulohistiocytosis: Histiochemistry of Lesions

Technique	Single Cells	Multinucleate Cells
Diastase digestion followed by PAS for nonglycogen—CH (OH). CH (OH)—groups	Granular	Granular staining central to rim of nuclei
Oil red O for lipids on formalin fixed frozen sections	Small droplets	Larger droplets arranged peripherally, external to ring of nuclei
Alkaline phosphatase	Variable; slight to moderate activity	Very faint to negative in some cells
Acid phosphatase	Moderate activity	Heavy reaction product in peripheral lipid containing areas
Muramidase (by immunoperoxidase staining of antigen)	Negative	Negative
Paraprotein specific for each case (by immunoperoxidase)	Positive in only a few cells near multinucleate cells	Positive (Fig 4)
Amyloid (methyl violet, thioflavine T, Congo red and electron microscopy	None detected	
Reticulin (silver impregnation)	Normal dermal tissue (fat, collagen, and muscle) infiltrated and replaced by reticulin around single cells and multinucleate cells (Fig 7)	

Fig 6.—Case 2. Portion of cytoplasm of multinucleate cell. Numerous membrane bound electron dense granules are present in addition to mitochondria, smooth endoplasmic reticulum, and glycogen. Portion of one nucleus is visible at one corner (original magnification, ×25,200).



cells, when present, appeared "caught up" in the lesion, were granulated, and showed a normal morphological condition down to the electron microscopic level. Acute inflammatory cells, fibrinoid necrosis, and eosinophils were absent (Fig 3).

The nodules frequently abutted on normal collagen at the lateral margin. Sometimes the junction region was quite sharp, the collagen bundles giving way rapidly to split and swollen fibrillar forms that failed to stain altogether. The reticulin stain, however, was positive for fine fibers around individual cells and clumps of cells within the nodule (Fig 4). In the deeper aspect, the infiltrate was spreading between mature adipose cells. While the younger histiocytes showed an open nucleus and eosinophilic cytoplasm, clumps of older cells with condensed nuclei and foamy cytoplasm were often found in relation to adipose tissue.

A prominent feature in all the biopsy specimens was the presence of a considerable number of large multinucleated giant cells. These were both of the Touton type with a peripheral rim of foamy cytoplasm, an intermediate ring of nuclei, and a central island of eosinophilic cytoplasm, and also of the foreign-body type. The cytoplasm was eosinophilic, finely granular, and ground glass-like in appearance. These features form the hallmark of MR. No caseation or acid-fast bacilli were demonstrable.

The histochemical techniques were applied to Bouin's fixed, paraffin-embedded material when possible, and fresh-frozen sections where necessary. The histochemical reactions of the histiocytes were paralleled by both types of giant cells and are summarized in Table 2.

The immunoperoxidase studies followed the schedule of Burns.[11] Endogenous peroxidase activity in RBCs and leukocytes was destroyed by incubation in hydrogen peroxide in methyl alcohol after the sections were dewaxed: background staining was reduced by prior incubation of the sections in nonimmune swine serum. The location of bound rabbit antihuman antibody was demonstrated by using swine antirabbit serum to link it to a soluble complex of peroxidase/rabbit antiperoxidase. The specific peroxidase activity was demonstrated using diaminobenzidine and hydrogen peroxide. Antigens present in the dewaxed histological sections were then demonstrated by the binding of specific rabbit antihuman antibody (κ, λ, α, γ, μ determinants).

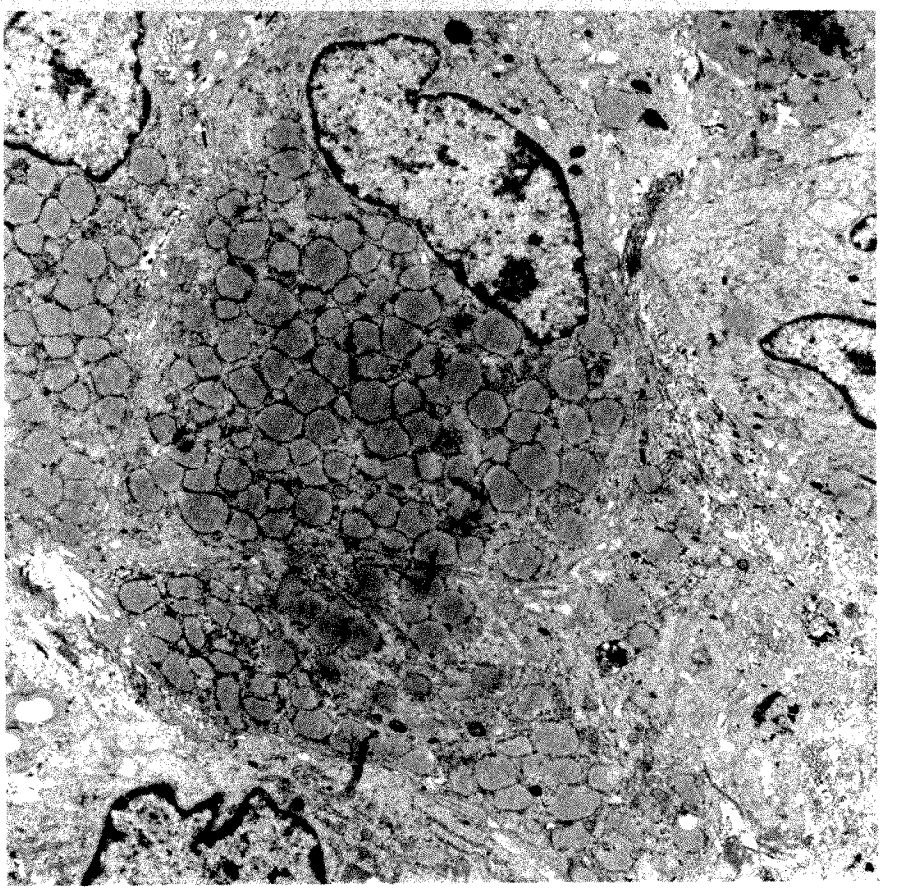


Fig 7.—Case 2. Mononuclear infiltrating cell showing cisternae bound by rough endoplasmic reticulum. Secretory protein has not been identified. Few such cells are found characteristically in the vicinity of the giant cells (original magnification, ×6,000).

The brown diaminobenzidine reaction product was well-localized and readily visualized in the light microscope. Sections may subsequently be stained with hematoxylin or the PAS techniques. The procedure has the advantage over immunofluorescence in that nuclear, cytoplasmic, and morphological detail may be visualized permanently in addition to the specific antigen.

No intracytoplasmic staining was observed, using antisera to the heavy chain determinants μ or α. The multinucleated giant cells and a number of surrounding mononuclears stained positively with the anti γ serum, indicating the presence of IgG. Those cells staining positively for γ heavy chains also stained positively for κ light chains in patient 1 and λ light chains in patient 2 (Fig 5). This corresponded to the paraprotein IgG, and no staining was seen with use of sera to the alternative light chain in either case.

The biopsy specimens intended for electron microscopy were immersed as rapidly as possible in phosphate-buffered 4% glutaraldehyde at pH 7.4. The tissues were immediately trimmed to approximately 1-mm cubes and fixed for six hours. They were then washed in two changes of cold phosphate buffer for two hours, after which they were postfixed in 1% osmium tetroxide in phosphate buffer at 4%. Dehydration was achieved with graduations of alcohol before passing the blocks into propylene oxide (1, 2 epoxypropane) and embedding in an epoxy resin. Sections were cut on an ultratome at 60 to 80 nm, mounted on bare copper grids, double-stained with 2% aqueous uranyl acetate and Reynolds lead citrate, and examined with an electron microscope.

The giant cell contained clear vacuoles, usually arranged around the periphery and corresponding in position with the oil red O positively in the fresh-frozen sections. In addition, they contained numerous small membrane-bound, electron-dense particles (Fig 6). A number of the single histiocytes showed cytoplasmic cisternae bound by a rough endoplasmic reticulum and contained uniform, moderately electron dense "secretion material for export" (Fig 7). Although this

Table 3.—Synopsis of Criteria for Diagnosis of MR

Criteria	Case 1	Case 2
1. Geographical distribution, most patients from United States or United Kingdom	+	+
2. Age of onset, mean 43 years	64	54
3. Sex, F to M ratio 3:1	F	F
4. Race, white 88%	+	+

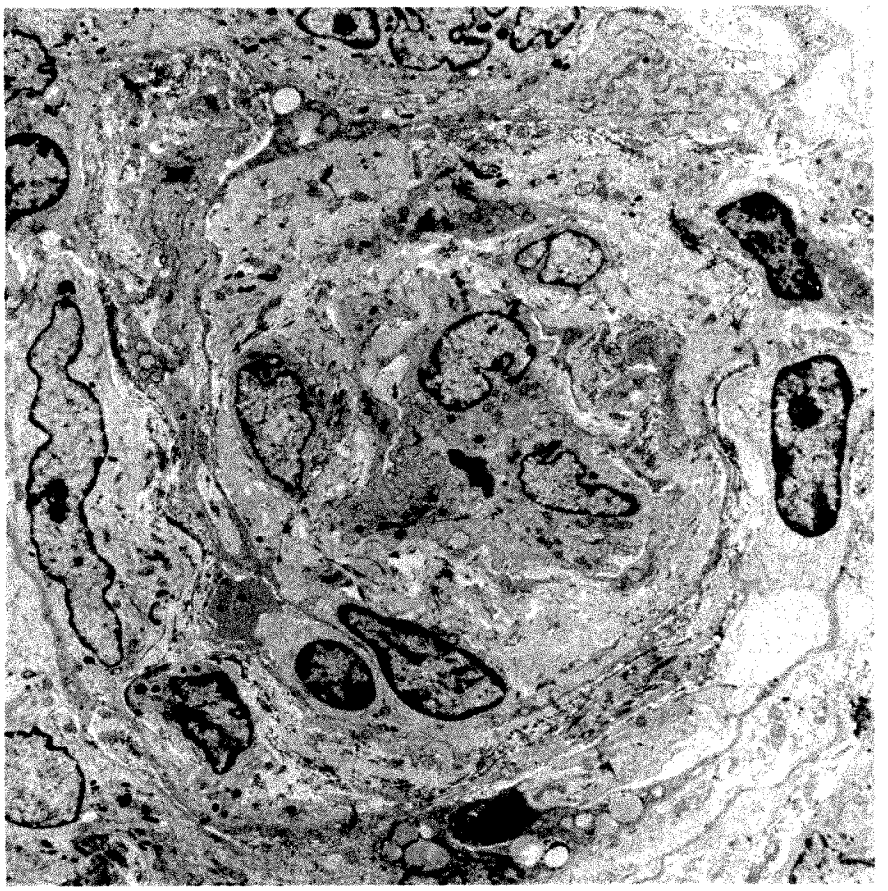

Fig 8.—Case 1. Capillary endothelial proliferation. Mononuclear cells in vessel lumen have cytological features similar to those in infiltrate (original magnification, ×4,320).

cytoplasmic appearance bore some resemblance to that of a plasma cell, the nuclear structure was more that of a histiocyte, and the Golgi apparatus did not figure so prominently. The material within the cisternae has not been characterized.

COMMENT

The criteria for the diagnosis of MR have been fully reviewed. The two cases described are compared with a synopsis of these criteria (Table 3). They conform well in showing most of the described features in so far as geographical distribution, age of onset, sex, race, clinical course, and pathological findings are concerned. However, there has been a striking absence of joint involvement, neither subject had ear nodules, and only one subject had slight changes over the back of the hands. Both patients may be in a relatively early stage of evolution of the process; alternatively, they may represent a rather benign variant of the disease. The differential diagnosis of MR has been exhaustively considered in the past.[7] A number of diseases are of special interest. Because the histological condition of the skin nodules in the two patients under discussion was reminiscent of that seen in a group of patients at the dermatology department with necrobiosis lipoidica, serum from six of these was investigated for the presence of a paraprotein. Three of the group had clinical diabetes, while three did not. In none was a paraprotein detected. Both the patients described in this report have normal glucose tolerance curves. Patient 2, however, has a cousin who suffered from maturity onset diabetes mellitus.

Capillary endothelial proliferation with narrowing of the lumen was occasionally seen (Fig 8) and bore a close resemblance to that described by Gray et al[12] in their histopathological study of diabetic and nondiabetic necrobiosis lipoidica. Such capillary changes are known to occur in the skin and other organs in patients with diabetes. Alteration in the composition of the serum proteins has been thought to play a role in the development of the vascular changes in this situation.

An immunoglobulin G λ serum paraprotein is invariably found in patients with papular mucinosis (lichen myxodermatosus). Five patients with the condition were reviewed by James et al.[13] In their series, the range for total immunoglobulin G was 610 to 1,220 mg/100 ml. In their cases and our own, the quantity of paraprotein was too small to give an increased total serum γ-globulin level. The clinical and histopathological appearances of papular mucinosis are, however, quite distinct from MR. The absence of osteolytic lesions and proteins in the urine, together with the normal bone marrow appearance, works against a diagnosis of multiple myeloma. It is possible that we have observed the coincidental occurrence of a benign monoclonal essential hypergammaglobulinemia and MR. The rarity of the latter makes this a very unlikely explanation.

The cause of MR is unknown. The two patients under discussion had three additional features, the significance of which is quite unknown, namely, a high serum alkaline phosphatase activity, a raised erythrocyte sedimentation rate (ESR), and paraproteinemia.

The "hepatic" 5-nucleotidase level in both was normal. Isoenzyme electrophoresis in agar showed the raised activity to be in a diffuse "bone" type distribution. The patients neither had symptoms nor radiological evidence of bone disease. There was no clinical evidence in either woman to suggest alternative sources of the enzyme such as the presence of placental tissue or a disorder of the gastrointestinal tract or kidney. An interpretation of the possible role of the enzyme in the disease will probably not be forthcoming until the heterogeneous enzymes contributing to serum alkaline phosphatase activity can be better defined. Reticulin is actively laid down around the cells in the dermal nodules, and it is conceivable that the enzyme from this process finds its way into the serum: the enzyme could be expected to display the same electrophoretic features as the mesodermal enzyme from bone.

The ESR is higher than would be predicted from the serum concentration of immunoglobulin. In case 2, the serum viscosity was measured and found to be raised at 2.29 centipoise (normal, 1.75 cp). The Coomb's test was negative in both patients, and immunoperoxidase staining on washed RBCs did not reveal surface binding of the paraprotein. Whatever causes the raised ESR may lead to sludging of RBCs and damage to small vessel walls favoring the deposition of

immune complexes. The side of the lesions may reflect differences in local blood flow or vascular reactivity.

By using sandwich immunofluorescence methods, it was not possible to demonstrate that the paraprotein from either patient would bind to uninvolved areas of their own skin or to skin biopsy specimens from patients with other conditions. Fluorescence was observed in the giant cells and a number of single cells, which, in so far as the technique permits, was in agreement with the immunoperoxidase results. Purified paraprotein from one patient injected intradermally into her own skin failed to elicit a nodule or cellular response.

The presence of the immunoglobulin within the older giant cells may be of significance. It appears to be specifically the paraprotein that is involved and not any of the other circulating immunoglobulins. Mature macrophages have receptors for the Fc portion of immunoglobulin G and can bind immune complexes. The impression gained from following up the two cases is that the earliest lesions consist of fairly large mononuclear cells around small vessels, and the fully developed dermal lesion, so well described in the literature, represents a late stage.

The hypothesis is advanced that the paraprotein might be an antibody produced following chronic exposure to an unidentified, possibly autologous antigen and that the proliferation of well differentiated histiocytes is a reactive process. The infiltrate may thus be viewed as having more in common with, for example, sarcoid than a neoplastic process in keeping with the fact that lesions show none of the features of malignancy. The improbability of a chance association of a paraprotein in two patients with MR suggests that an intensive search for an immunological basis could be rewarding in other cases.

Alfred J. Gunning, FRCS, referred case 1 for further study, and Anthony J. Bron, FRCS, gave an ophthalmological opinion in each case.

New Requirement for Authors

Congress recently passed *The Copyright Revision Act of 1976*, effective January 1, 1978, which impacts upon the American Medical Association's scientific publications procedure for acceptance of manuscripts submitted for publication.

In view of this new law, all transmittal letters to the editor accompanying manuscripts submitted for publication should contain the following language before manuscripts can be reviewed for possible publication: "In consideration of the AMA taking action in reviewing and editing my (our) submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to AMA in the event that such work is published by the AMA."

Ulcerative Systematized Porokeratosis (Mibelli)

Enthi M. Abdul Razack, MD, DD, Marthandam Natarajan, MD, ZDV, FDS

• **An unusual clinical variant of porokeratosis (Mibelli's disease) appeared in a patient soon after birth; the lesions were widely distributed mostly on the right half of the body. Spontaneous recurrent ulcerations occurred over certain sites. The right foot was grossly deformed as a result of atrophic scarring after ulcerations. Biopsy specimens of the classical lesion showed cornoid lamella. It is suggested that the term "ulcerative systematized porokeratosis" be used to describe this clinical variant of porokeratosis.**

(*Arch Dermatol* 113:1583-1584, 1977)

Porokeratosis (Mibelli), a rare disorder of keratinization, transmitted usually as autosomal dominant, affecting males twice as often as females, begins at birth, childhood, or later.[1,2] A second type of porokeratosis, disseminated superficial actinic porokeratosis (DSAP), was described by Chernosky and co-workers[3-6] as occurring in an older population and in sun-exposed parts of the body. The following clinical variants of porokeratosis have so far been described: the hyperkeratotic verrucous type, the hyperplastic type, Freund's forma minima[7] porokeratosis plantaris palmaris et disseminata,[2] Zosteriform porokeratosis of Mibelli[8] and linear porokeratosis of Mibelli.[9]

We recently had the opportunity of treating an adult man who had classical lesions of porokeratosis occurring with ulcerated ones that were confined mostly to the right half of the body and that did not conform to any one of the previously documented variants.

REPORT OF A CASE

A 52-year-old man was admitted to the Skin Ward, Government Stanley Hospital for foul-smelling ulcerative skin lesions that were all over the body. His parents had first noticed a coin-shaped "lesion" on the right groin soon after birth. Over the years, the patient noticed more of these lesions; many of them enlarged centrifugally and became rough and ulcerated, especially during the summer months.

In 1951 the patient, born of consanguinous parents, married his first cousin. His only son aged 20 years, his mother, and two younger brothers are doing well; his father died at the age of 72. There was no family history of similar eruption.

Examination of the skin revealed hundreds of pigmented, annular, and gyrate plaques limited by keratotic ridges and seen more on the right half of the chest, back, forearm, palm, right thigh, and leg. The lesions on the neck and groin were ulcerated, discharging a serosanguinous fluid that emitted a 'musty' odor. In about six weeks' time, the ulcerated lesions started healing, leaving atrophic areas (Fig 1 and 2). The eruptions on the forehead and back of the forearm were annular with central atrophy surrounded by keratotic walls. The right foot was deformed with hallux valgus and syndactyly of the lateral two toes (Fig 3). The foot was smaller in size than its normal counterpart and showed atrophic scarring on its outer half and a painful ulcerated lesion on its arch. All the modalities of sensations were intact, with the lateral popliteal nerve being normal in thickness. The maximum circumference of the right and left legs at corresponding points were 23 and 31 cm, respectively. There was no substantial regional adenopathy and the mucous membranes were spared. Systemic examination showed no abnormalities.

FINDINGS

The routine laboratory investigations were within normal limits. Erythrocyte sedimentation rate was 27 mm/hr for the first hour (Westergren). The VDRL tests of both blood and CSF were nonreactive. X-ray film of the chest was normal and that of the right foot showed demineralization of the metatarsal bones and pha-

Fig 3.—Deformed foot with atrophy and scarring.

Fig 4.—Section from keratotic wall showing typical parakeratotic tier (hematoxylin-eosin, original magnification ×120).

langes, with gross deformity of the bones.

Histologic examination of the classical lesion of porokeratosis revealed hyperkeratosis, acanthosis, and the typical cornoid lamella. There was pigment incontinence and a chronic inflammatory infiltrate in the dermis (Fig 4). Histologic section from the ulcerated area showed the following features. The surface was ulcerated, the margin of the ulcer showing epidermal downgrowths with no evidence of subjacent infiltrate penetrating the epidermis. The dermis showed pigment incontinence and an infiltrate mostly consisting of round cells with occasional plasma cells. Basophilic changes were noticed in the adjacent subepidermal collagen.

COMMENT

Porokeratosis is a familial disorder of the skin that is characterized by localized areas of faulty keratinization that result in the cornoid lamella that is the hallmark of the disease process.[10,11] The initial lesion is a crateriform horny papule that gradually enlarges in a centrifugal fashion to form a plaque of circinate or irregular contour.[1] Though Mibelli assumed that the peripheral extension of the lesion was effected by the progressive involvement of new sweat pores, there is not much convincing documentation to substantiate this view. Hence, the term porokeratosis is a definite, if not a total, misnomer. The disease may be related to the appearance of abnormal clones of cells in the epidermis.[10]

The appearance of the earliest lesion at birth, the preponderance of the eruption on the right half of the body, and the presence of classic lesions of porokeratosis over the forehead and the back of the forearm would classify the case as being one of the Mibelli types in a systematized form; yet, the ulcerations limited by keratotic ridges and recurring at summer months might well justify an addition to the list of erstwhile clinical variants. To our knowledge, such an occurrence has not been reported.

The extreme atrophy after the ulceration deserves special attention. Even though no malignant neoplasm was observed either clinically or histologically in the case being reported, a few cases in which squamous carcinoma and Bowen's disease developed in such lesions have been reported.[12-14] The atrophic scarring had caused the deformity of the right foot that resulted in the limp and the consequent dimunition in the circumference of the leg. Atrophy of the epidermis in combination with fibrosis of the dermis might give one the impression of a resolving granulomatous process or a localized scleroderma; yet, such possibilities have been ruled out clinically and histopathologically in this patient.

A. S. Thambiah, MB, FRCP, FAMS, DV, interpreted the histopathological sections.

Recurrent Pyoderma Gangrenosum and Agnogenic Myeloid Metaplasia

Jeffrey P. Callen, MD; Howard V. Dubin, MD; Charles F. Gehrke, MD

• Pyoderma gangrenosum has been associated with myelogenous leukemia and plasma cell dyscrasia. When associated with leukemia, pyoderma gangrenosum often has a distinctive clinical presentation with an advancing bullous margin. The pathogenesis of this disorder is unknown, although defective immune mechanisms may be operative. The occurrence of pyoderma gangrenosum and agnogenic myeloid metaplasia in the same patient has now been reported sufficiently to make it a recognized association.

(*Arch Dermatol* 113:1585-1586, 1977)

Pyoderma gangrenosum is an uncommon cutaneous condition often associated with internal diseases.[1] The diagnosis of pyoderma gangrenosum is a clinical one, made by exclusion of other entities. The typical appearance is that of an ulcerated lesion with violaceous necrotic borders. Often the lesion rapidly expands. Other causes of necrosis and ulceration must be ruled out prior to a diagnosis of pyoderma gangrenosum. The condition is most frequently associated with bowel disease (ulcerative colitis); however, it has also been associated with rheumatoid arthritis,[2] monoclonal gammopathy,[3-5] and leukemia.[1,6-10] We report a case of pyoderma gangrenosum in a woman with agnogenic myeloid metaplasia and review the literature of the association of pyoderma gangrenosum with myeloproliferative disorders and malignancies.

REPORT OF A CASE

A 62-year-old woman was in good health until June 1974 when she noticed a lump in her abdomen. In August 1974, an enlarged spleen was found. Her WBC count was 64,000/cu mm. Results of hemoglobin, platelet count, and blood volume studies were normal. Findings on a bone marrow biopsy were consistent with agnogenic myeloid metaplasia. Since that time, she has been treated with busulfan in varying dosages.

In October 1974, the patient noted development of a pustule on her right hand that spread and ulcerated and covered a large part of her hand. She had an associated lesion on her face (Fig 1). She was thought to have sporotrichosis and was therefore treated with potassium iodide. She developed a severe allergic reaction to the iodide, however, with fever, chills, abdominal pain, and was admitted to a hospital. The skin lesions spontaneously resolved after her iodides had been stopped. Cultures taken at that time from the skin lesions for atypical mycobacteria, fungi, and aerobic and anaerobic bacteria were all negative. She had no other skin diseases until October 1975, when she noted a pustule on her right hand that spread to cover the dorsum of her hand. No trauma was noted to her hand prior to the development of these lesions. In addition, within the week prior to admission, she noted the development of a small erythematous lesion on her face below her left eye. Cultures for atypical mycobacteria and deep and superficial fungi were negative. She was treated with dicloxacillin sodium monohydrate with no improvement. She was subsequently admitted to the University of Michigan Medical Center. Family history indicated one sister with leukemia (type unknown) and a daughter with ankylosing spondylitis. No similar skin problems, ulcerative colitis, or rheumatoid arthritis were noted in any family members. There has been no industrial exposure to halides or halogens. The patient denied fever, chills, or weight loss.

The physical examination revealed a blood pressure of 140/80 mm Hg, respirations of 16 per minute, pulse rate of 100 beats per minute, and a temperature of 36.6 C. She was a thin woman in no acute distress. Examination of her skin showed a tender ulcerated area with an advancing necrotic blue-gray margin that was approximately 7 × 6 cm on the dorsum of her right hand. The border was bullous. An erythematous plaque was present under her left eye. Examination of her neck revealed unremarkable cervical adenopathy. The liver span was 10 cm in the right midclavicular line. The spleen was palpated 7.5 cm below the left costal margin; it was firm and not tender. The width of the spleen was approximately 6 cm at its largest diameter. Other physical findings were normal.

Fig 1.—Facial ulcerated and crusted lesions of pyoderma gangrenosum.

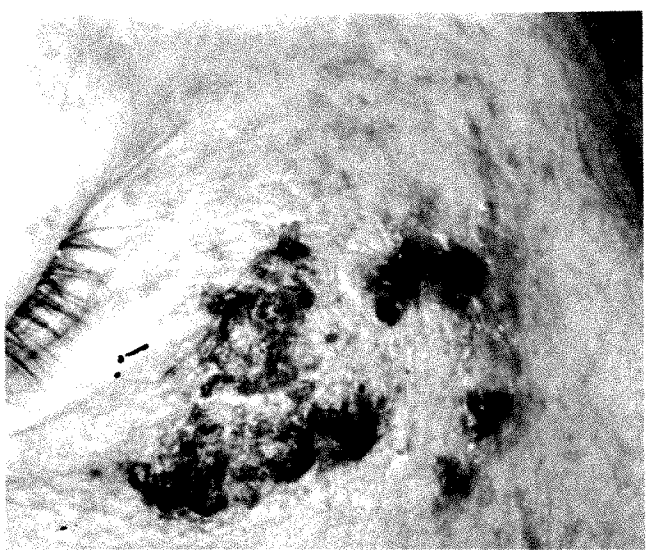

Fig 2.—Biopsy specimen of hand lesion demonstrating dense polymorphous inflammatory infiltrate with granulation tissue and purulent exudate (hematoxylin-eosin, × 40).

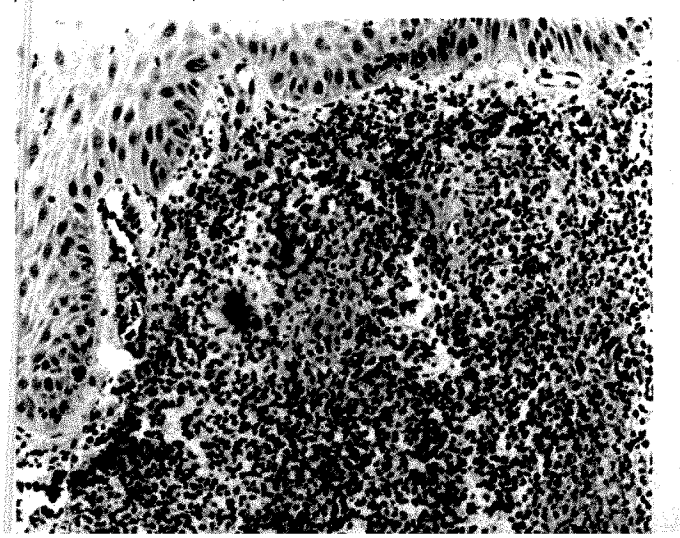

Laboratory findings included the following: WBC count of 45,000/cu mm, with a differential of 16 segmented polymorphonuclear cells, 48 band forms, seven lymphocytes, no mononuclear cells, 11 eosinophils, seven basophils, five metamyelocytes, five myelocytes, and five progranulocytes. Platelet count was 290,000/cu mm. Hemoglobin level was 16.6 gm/100 ml. Findings on a bone marrow biopsy were consistent with the diagnosis of agnogenic myeloid metaplasia. Cultures for fungi and acid-fast bacilli (AFB) were negative. The leukocyte alkaline phosphatase level was 294 units/100 ml (normal, 50 to 200 units/100 ml); complement fixation tests for fungi were negative; the lactic acid dehydrogenase (LDH) was 692 units/100 ml (normal < 205 units/100 ml); the alkaline phosphatase level was 290 units/100 ml (normal < 110 units/100 ml); the serum leucine aminopeptidase level was 180 units/100 ml (normal < 180 units/100 ml). The LDH isoenzyme pattern was normal. Protein electrophoresis and immunodiffusion were within normal limits. The VDRL test for syphilis was negative. X-ray films of chest, skull, and right hand and wrist, intravenous pyelogram, barium enema examination, and bone scan were normal. Cultures of her hand lesion and bone marrow were taken and were negative for fungi, AFB, and aerobic and anaerobic bacteria. A skin biopsy specimen of her hand lesion showed a hyperplastic epidermis that covered a dense polymorphous inflammatory infiltrate with granulation tissue and purulent exudate. No granulomatous inflammation was present (Fig 2). A biopsy specimen of the lesion on her face showed a circumscribed zone of necrosis with a purulent exudate in the reticular dermis. No organisms were seen on routine stains or special stains for fungi. The histologic findings in both lesions were compatible with the diagnosis of pyoderma gangrenosum. The patient was seen in consultation with hematologists, who agreed with our diagnosis of myeloid metaplasia. She was treated with soaks, wound debridement, and topically applied corticosteroid (fluocinonide gel). She was continued on busulfan (4 mg/day). Skin tests were done for dermatophytin, which was positive, and purified protein derivative, which was negative. She was started on a regimen of prednisone, 30 mg/day because of continued progression of the cutaneous ulceration. This therapy resulted in a marked improvement of her cutaneous disease.

COMMENT

Pyoderma gangrenosum is a clinically diagnosed condition that has no specific histologic or laboratory features. The clinical diagnosis depends on a typical clinical presentation and a careful evaluation to rule out other diseases, including bacterial pyoderma, fungal pyoderma, necrotizing vasculitis, bites, factitial ulceration, and iododerma. These were ruled out in our patient.

The cause of pyoderma gangrenosum is unknown. Reports of altered immunity have frequently appeared in the literature. Multiple case reports of the association of pyoderma gangrenosum with paraproteinemias have appeared.[3-5] To date, 16 cases of paraproteinemia and pyoderma gangrenosum have been reported (12 with IgA, five with IgG, and one with IgM).[3] Although some of these patients developed or had multiple myeloma, this was not always the case. It has been suggested that alteration of the serum immunoglobulins may in some way predispose to pyoderma gangrenosum.[4,5]

Association of pyoderma gangrenosum with rheumatoid arthritis has also suggested varying alterations in immunity. In a recent report, two patients with rheumatoid arthritis and pyoderma gangrenosum were studied.[2] The serum IgA was slightly elevated in each case. However, complement levels, lymphocyte counts, T rosettes, lymphocyte blastogenesis, and delayed type hypersensitivity in vivo were normal. Immunoglobulins could not be demonstrated by direct immunofluorescence of the skin. Their skin biopsies, however, were not noted to be taken from an early lesion, and therefore negative immunofluorescence was not meaningful. Positive immunofluorescence with immunoglobulins and complement has been demonstrated in a previous study of pyoderma gangrenosum in a lesion induced by injection of potassium iodide.[5] Although immunoglobulins have been found periodically in skin lesions of pyoderma gangernosum, serum complement has been normal or elevated,[11] and no circulating complexes have been demonstrated. It appears unlikely that pyoderma gangrenosum represents a Arthus reaction (type III hypersensitivity).

Alteration of cellular immunity has been discussed in the literature. Depressed phytohemagglutinin induced lymphocyte blastogenesis, and failure to sensitize to dinitrochlorobenzene has been noted.[12,13] Lazarus and his co-workers demonstrated dissociation of lymphocyte blastogenesis and macrophage inhibition factor production in vitro in pyoderma gangrenosum.[12]

Clinically, pyoderma gangrenosum associated with myeloproliferative disorders and leukemia has displayed characteristic features.[7] The ulcers are superficial, they spread concentrically with a blue-gray bullous margin, and they are associated with severe pain. These features were present in our patient's hand lesion during both of her episodes of pyoderma gangrenosum. However, the recent facial lesion was merely a superficial erythematous plaque. Two of the patients described by Perry and Winkelmann[7] were diagnosed as having agnogenic myeloid metaplasia. One case in the earlier review by Perry[1] and a subsequent case[10] suggest a specific association of pyoderma gangrenosum with agnogenic myeloid metaplasia. In addition, the cases of pyoderma gangrenosum associated with malignancy have been those associated with chronic myelogenous leukemia,[9] acute myelogenous leukemia,[7] and one case of acute lymphocytic leukemia.[8] The explanation for these associations and the lack of association with other lymphoproliferative disorders or solid tumors is unknown.

Cobb Syndrome

R. Thomas Jessen, MD; Stephen Thompson, MD; Edgar B. Smith, MD

• Cobb syndrome consists of a vascular skin nevus associated with an angioma in the spinal cord. We describe a young man with this condition. To our knowledge, this is the 28th case reported. Cobb syndrome must be differentiated from other syndromes characterized by vascular cutaneous lesions associated with central nervous system abnormalities, such as Sturge-Weber, Osler-Weber-Rendu, Fabry-Anderson, von Hippel-Lindau, and ataxia telangiectasia.

(*Arch Dermatol* 113:1587-1590, 1977)

Cobb syndrome, or cutaneomeningospinal angiomatosis, is the combination of a vascular skin nevus and an angioma in the spinal cord corresponding within a segment or two to the dermatome involved.[1] The first case was reported by Berenbruch in 1890.[2] The syndrome did not receive recognition until Cobb's description in 1915, however.[3] As of 1972, only 27 cases had been reported in the world literature, none in English language dermatologic periodicals.[2-24] We discuss the 28th case of cutaneomeningospinal angiomatosis.

REPORT OF A CASE

Our patient was 15 years old when he first came to Bernalillo County Medical Center in August 1972. Multiple hemangiomas over the right side of his trunk, buttocks, and right leg had been present since birth without evidence of involution. He sought care because of bleeding, superficial infection, and pain in the skin lesions that interfered with his activities. A hemangioma had been excised from the right knee in 1968. No other family members had similar lesions, and the patient was otherwise healthy. No neurologic abnormalities were detected on examination at that time. During that hospitalization, four ulcerated hemangiomas were excised from the right leg with the patient under general anesthesia. The histologic appearance of the tumors was that of a combined cavernous and capillary hemangioma with the cavernous pattern predominating.

At age 19 the patient returned to Bernalillo Country Medical Center requesting further excision of his cutaneous hemangiomas. He also complained of weakness of the right leg of two months' duration associated with a limp and difficulty emptying his bladder.

Physical examination showed no abnormalities except those relating to the dermatologic and neurologic findings on the right side of his trunk and lower right extremity. The right leg was noticeably smaller than the left, both in length and circumference. His gait was asymmetric and somewhat halting, with a shorter period of weight-bearing on the right leg than on the left and a tendency to advance the right leg with the knee extended. The right hip flexors and ankle dorsiflexors were weak. Knee and ankle jerks were brisk bilaterally with the right greater than the left, and Babinski's sign was present bilaterally. Sensitivity to pin, cotton, and vibration was diminished bilaterally from the upper level of the cutaneous lesions downward. Position sense was decreased bilaterally in the toes. Multiple skin tumors were present varying from 3 to 6 cm in diameter on the right side of the body (Fig 1). The lesions were vascular-looking and purple and had sharply demarcated irregular borders.

The surfaces of the lesions were rough, and many were crusted. These vascular lesions were present from the level of the umbilicus downward to the inguinal region and approximately followed the distribution of the fourth and fifth lumbar dermatomes on the right leg. The lesions were dense proximally and became sparse as they progressed distally down the leg.

Results of laboratory studies including hemogram, platelet count, urinalysis, and VDRL for syphilis were normal. The spinal fluid was clear and colorless with no increase in cells or protein, and no organisms were found on culture. Thoracic and lumbosacral spine x-ray films were unremarkable. A lumbar and thoracic myelogram showed partial obstruction at T-8 to T-9 by a fusiform widening of the spinal cord. Spinal angiography was performed by catheter in the right femoral artery with selective injection of the thoracic and lumbar spinal arteries. Angiograms failed to demonstrate any arteriovenous malformation. Biopsy of the skin lesions showed mild hyperkeratosis and thinning of the epidermis with focal acanthosis (Fig 2). Focal epidermal areas contained dilated and trapped vascular channels with single endothelial cell linings. These dilated vascular channels were also present in the papillary and deeper dermal layers (Fig 3). In the deeper dermis they interdigitated between glandular structures. There were scattered foci of extravasated erythrocytes and occasional perivascular inflammatory cells, mononuclear in type, in the upper dermis.

In August 1975, a thoracic laminectomy was performed. The spinal cord was found to be widened from the level of the eighth to the tenth thoracic vertebrae. The cord was nodular, and two bluish, mulberry-shaped hemangiomas were present on the right side. No attempt at surgical correction was made. Postoperatively the patient had a slow recovery with no change in his neurologic status. A cystometrogram performed after surgery showed a normal curve. Nine days postoperatively the patient was transferred to a special facility for rehabilitative therapy.

COMMENT

In 1915, Cobb described an 8-year-old boy who was suddenly stricken while playing ball with a sharp pain in his lower back that radiated to the lower abdomen. The first episode of pain resolved, but three days later a similar attack occurred, which, in 14 hours, progressed from numbness of the left leg to flaccid paraplegia

Fig 2.—Biopsy specimen of right leg lesion in 1972. Epidermis is mildly hyperkeratotic and thinned with focal acanthosis. Focal epidermal areas contain dilated entrapped vascular channels with single endothelial cell linings. These dilated vascular channels are also present in papillar and deeper dermal layers (hematoxylin-eosin, ×25).

accompanied by analgesia to about the ninth thoracic dermatome. On examination the patient was found to have a "birthmark of the 'port wine' variety on the left back" at the level of the upper limit of the analgesia. Over a period of 10½ weeks the paraplegia became spastic. Subsequently, "a swelling along the right side of the vertebral column from the 4th to the 8th dorsal vertabrae was noted. The patient was seen by Dr Cushing who ventured a diagnosis of congenital dermoid haemangioma." On laminectomy, the patient was found to have an "extraordinary tangle of large pulsating vessels" involving the spinal cord at the level of the sixth through the tenth thoracic vertebrae.[3]

Since Cobb's original discussion, only 25 additional cases have been reported. Seventeen of these were well reviewed by Kissel and Dureux in 1972.[4] These authors believed that Cobb syndrome may not be as rare as the small number of case reports implies. They suggested that improved radiographic techniques may increase the ease of diagnosis. Arteriography has been performed on nine of the reported cases of Cobb syndrome.[20-22,24] Despite the contention of Kissel and Dureux, this technique was not helpful in demonstrat-

	Cobb[2-24]	Sturge-Weber[1, 25, 27-30]
Synonym	Cutaneomeningospinal angiomatosis	Encephalotrigeminal angiomatosis
Inheritance	Not familial	Dominant partial trisomy or not familial
Sex distribution	More in males	Equal
Age of onset	Childhood or adolescence	Two thirds with hemangioma at birth
Skin lesion	Port wine stain or angiokeratomas in dermatomal distribution corresponding within segment or two of area of spinal cord involvement*	1. Ipsilateral capillary angioma or port wine stain in distribution of the superior and middle branches of the trigeminal nerve*; associated cavernous changes may occur 2. No consistent relationship between extent of skin lesion and degree of meningeal involvement
CNS findings	1. Arteriovenous or venous angioma of the spinal cord* 2. Neurologic signs of cord compression or anoxia	1. Angioma of meninges* 2. Intracranial gyriform calcifications 3. Mental retardation (60%)* 4. Epilepsy (usually focal)* 5. Hemiparesis contralateral to skin lesions* 6. Visual impairment (50% have one or more of variety of eye abnormalities)*
Associated findings	1. Angioma of vertebrae 2. Renal angioma 3. Kyphoscoliosis	1. Renal angioma 2. Coarctation of aorta 3. High arched palate 4. Abnormally developed ears
Diagnostic aids	1. Lateral spine x-ray 2. Myelography 3. Selective spinal angiography	1. EEG 2. Skull x-ray 3. Cerebral angiography
Treatment	Surgical removal of spinal cord angioma if possible	1. Anticonvulsants 2. Surgical removal of intracranial lesion if possible 3. Cosmetic procedures for skin lesions

* Major components of the syndrome.

Neurocutaneous Syndromes

Osler-Weber-Rendu[1, 28, 31]	Fabry-Anderson[1, 32]	Ataxia Telangiectasia[33-35]	Von Hippel-Lindau[1, 25, 36, 37]
Hereditary hemorrhagic telangiectasia	Angiokeratoma corporis diffusum	Cephalo-oculocutaneous-telangiectasia syndrome	Angiomatosis retinae et cerebelli syndrome
Autosomal dominant	Recessive trait (X chromosome)	Autosomal recessive	Autosomal dominant
Equal	Males tend to full syndrome: (1) angiokeratomas (2) extremity pain, (3) high blood pressure, (4) cardiomegaly, (5) albuminuria, (6) hypohidrosis	Equal	Equal
Childhood	Childhood	Childhood	Adult
Telangiectasia (skin and mucous membranes)*	1. Small clustered angiokeratomas (symmetric, mucosal, increased over bony prominences) 2. Palmar mottling	1. Telangiectasia (increased in sun-exposed areas)* 2. Inelasticity	1. Port wine stains in some; Most with no cutaneous lesions* 2. Café-au-lait spots
Angiomas in the brain or spinal cord with signs of localized tumor	1. Cerebral vascular accidents 2. Neuronal glycolipid deposition (peripheral neuritis)	1. Progressive cerebellar ataxia (voluntary movements)* 2. Ocular telangiectasia (spread from canthal fold)* 3. Peculiar eye movements (nystagmus, poor control)* 4. Retarded 5. Slow dysarthric speech 6. Decreased tendon reflexes	1. Cerebellar hemangioblastoma and cyst* 2. Spinal hemangioblastoma (rarely) 3. Retinal hemangiomas (tangle of vessels away from disk)*
1. Pulmonary arteriovenous anastomoses 2. Hemorrhage from lesions in the mouth, GI tract, GU tract, and associated anemia	1. Stooped posture 2. Slender limbs, thin, weak muscles 3. Dilated, tortuous conjunctival and retinal vessels 4. Varicose veins and stasis edema 5. Scant facial hair 6. Hypogonadism	1. Sinopulmonary infections* 2. Hypoplastic or absent thymus 3. Small spleen 4. Retarded growth 5. Malignancies (reticulum cell sarcoma, Hodgkin's disease, lymphosarcoma, gastric, carcinoma	1. Pheochromocytoma 2. Pancreatic cysts 3. Hepatic angiomas 4. Renal hypernephromas (20%) 5. Polycythema (erythropoietic substance from tumor)
None	1. Urinary glycolipids (ceramide trihexoside) 2. Slit lamp 3. Biopsy, renal or marrow (lipid deposits)	1. Diminished or absent IgA 2. Increased serum α-fetoprotein	1. Hemogram (polycythemia) 2. Urinalysis, excretory urograms 3. Skull x-ray, angiogram 4. Myelogram
Cautery of bleeding lesions	Symptomatic	1. Control infections 2. Plasma infusions (IgA) 3. Thymus transplant 4. Transfer factor	Supportive

ing the vascular malformation in our patient. Males slightly outnumber females in the cases reported. In most patients the neurologic problems occurred during childhood or adolescence. No inciting event except exercise has been reported. Although neurolgic problems in our patient did not begin suddenly after strenuous exercise, our patient was active in sports, and exercise may have played a role in the onset of his symptoms. Three modes of onset of the syndrome have been described: (1) a series of episodes of neurologic deficit separated by weeks or years, (2) the sudden onset of symptoms progressing to paralysis within hours, and (3) gradual onset of a progressive deficit such as occurred in our patient. The quiescent period is usually terminated by pain involving the area supplied by the involved segment of the spinal cord. Paraplegia and monoplegia are also frequent initial symptoms. Involvement of rectal and urethral sphincters is not common early, but it is usually present in the fully developed syndrome. The neurologic picture is that of an intraspinal tumor with a sharp sensory level, spastic paralysis, and decreased sensation to all stimuli. The results of a lumbar puncture are usually normal, but occasionally there will be evidence of spinal block, hemorrhage, and increased protein and cell counts. The vascular lesion is predominantly arteriovenous and intradural, with the alternate being a venous angioma. The skin lesions occur along the appropriate dermatome at the site of the spinal cord lesion and may be either flat lesions of the port wine stain type or papular and nodular angiomas. These angiomas do not tend to resolve spontaneously as do the usual capillary and cavernous hemangiomas of childhood. The angiomas are either asymptomatic or result in mechanical problems because of size or susceptibility to trauma. In those cases in which the vascular lesion is an arteriovenous malformation, limb hypertrophy may occur. Familial cases of Cobb syndrome have not been reported.[4]

The combination of cutaneous angiomas with neurologic disease results in a variety of unusual syndromes. Among these are the Sturge-Weber syndrome, Osler-Weber-Rendu disease, Fabry-Anderson disease, von Hippel-Lindau syndrome, and ataxia telangiectasia. The clinical features of these are summarized in the Table. Two additional rare neurocutaneous syndromes are the Bonnet-Dechaume-Blanc syndrome, characterized by a

telangiectatic facial nevus and retinal and intracranial angiomatosis predominantly around the thalamus and mesencephalon, and the Wyburn-Mason syndrome, consisting of an arteriovenous aneurysm of the midbrain, congenital anomalies of the retinal vessels of one side, and a telangiectatic nevus in the skin in the region of the affected eye.[2,25]

Cobb syndrome has much in common with Sturge-Weber syndrome. Kissel and Dureux point out, however, that the venous angioma of Sturge-Weber syndrome is characterized by a dense pial matting of small vessels and a peculiar calcification in the corresponding part of the brain. There is no counterpart in cutaneomeningospinal angiomatosis.[4] The pathogenesis of the neural deficit in Cobb syndrome is believed to be ischemia secondary to diversion of blood into the malformation. Intraspinal arteriovenous malformations without associated skin lesions are themselves somewhat rare. This lesion occurs in men four times as frequently as in women, and symptoms of spinal cord disease tend to appear in middle age or later. Inasmuch as there is no apparent difference between the spinal lesions in patients with or without associated skin nevi, it seems that these differences are more apparent than real. Too few cases of Cobb syndrome have been reported for accurate comparison.

Treatment as well as diagnosis may be aided by the selective spinal angiography.[4,24,26] Angiomas fed by the posterior spinal artery often are juxtamedullary and can be extirpated surgically without appreciable damage to the spinal cord. Those fed by the anterior spinal artery are often intramedullary. This artery supplies critical motor pathways and neurons, which makes its removal impossible with current techniques.

On reviewing the reported cases of Cobb syndrome, we found various cutaneous vascular tumors described, ranging from angiolipomas to cavernous hemangiomas. Many of the earlier reports do not describe the skin lesions well and most lack histologic confirmation. However, a majority of patients appear to have had lesions of the port wine type; some had associated angiokeratomas. A characteristic feature of all types of lesions was a dermatomal distribution on the trunk or the extremities. If a port wine stain or multiple angiomas are found in this distribution, the diagnosis of Cobb syndrome should be seriously considered. Unfortunately, laboratory aids are limited in predicting the development of neurologic problems. Lateral thoracic and lumbar spine radiograms may show early bony erosion by the angioma.[7] Arteriography at present has too many risks to be a useful predictive tool and should be used for confirmation of diagnosis and evaluation before treatment.

The combination of a cutaneous angioma in a dermatomal distribution and spinal cord angioma comprises a rare, potentially crippling or fatal syndrome. We describe this young man with Cobb syndrome in the hope that increased awareness will result in more frequent recognition by dermatologists and other physicians. Perhaps early diagnosis and counseling regarding the adverse affect of strenuous exercise might prevent or delay the tragic neurologic effects.

Diffuse Eosinophilic Fasciitis

A New Syndrome or Variant of Scleroderma?

Victor M. Torres, MD, William M. George, MD

• Recently, attention has been drawn to a scleroderma-like illness, characterized by transient eosinophilia, which is commonly antedated by unusual physical exertion, is apparently free from significant systemic changes, and in which the primary pathological alterations, consisting of intense inflammation and thickening with or without eosinophils, occur initially in the fascia, not the skin. These patients are said to respond well to oral corticosteroids and an occasional one may undergo spontaneous resolution. Clinicopathologic study of a patient with this syndrome, suggests an even deeper tissue genesis than that recently proposed for some of the cutaneoindurative disorders. Eosinophilic fasciitis probably represents an impressive, but perhaps relatively benign variant of diffuse scleroderma, according to reported cases.

(*Arch Dermatol* 113:1591-1593, 1977)

A middle-aged muscular man had a baffling indurative process and was presented at the March 1975 monthly conference of the Department of Dermatology, University of Miami School of Medicine. The clinical picture did not conform to the usual manifestations of cutaneous hardening, such as seen in scleroderma, scleredema, and other known connective tissue disorders. The histologic picture of the initial skin biopsy did not show notable pathologic changes in the dermis or subcutaneous tissue, but a fragment of fascia revealed inflammatory changes almost identical to those described by Shulman[1] in a strikingly similar disorder affecting two male patients. Other patients apparently suffering from the same condition have been reported by rheumatologists.[2,3] The distinctive clinicopathologic picture presented by this patient, which, though differing from diffuse scleroderma, shares with it certain important, probably basic, features, prompts this report.

REPORT OF A CASE

A 57-year-old man, who had always been in good general health and had not suffered antecedent trauma, saw his physician in March 1975, because of "hives" for one month, hardness of the skin, and "stiffening of his muscles," mostly those of the extremities, of six weeks' duration. The stiffness was fairly persistent but became more noticeable when playing tennis. Aside from this, there had not been any unaccustomed exertion. There was no suggestion of Raynaud's phenomenon, muscle weakness, or visceral symptomatological condition. His family history disclosed that one brother died at the age of 12 of diabetic complications. The patient was originally treated with small doses of prednisone daily for a few weeks, which made the hives disappear, but the stiffness and skin hardening persisted.

The examination on March 27, 1975, showed a muscular, dark-complexioned man with visible irregularities in skin contour, characterized by depressions and ridges most apparent on the anteromedial aspects of the arms and thighs (Fig 1). The integument in these areas, although smooth and unaccompanied by significant color changes, felt firm and irregularly nodular, and the tissues appeared tight and bound down. Tightness was also felt all around the arms and thighs, down to and including the knees, and almost throughout the trunk, but the latter presented a smooth, regular surface. The distal portion of the extremities was practically uninvolved, and the face appeared normal. There was limitation of motion of the shoulder girdles with notable wincing on abduction.

The laboratory tests revealed the following values: hemoglobin, 13.5 gm/100 ml; hematocrit, of 39.3%; RBC 4,620,000/cu mm; 2nd WBC, 8,400/cu mm, with a differential cell count of 63% neutrophils, 34% lymphocytes, 2% eosinophils, and 1% monocytes. Values for urinalysis, VDRL, tetratriiodothyronine, latex fixation, roentgenogram of the chest, ECG, and 12-factor automated blood chemical analysis were within normal limits or nonreactive, with a nonfasting glucose level of 55 mg/100 ml. The serum protein electrophoresis showed the following values in gm/100 ml: albumin, 3.4 (normal 3.5 to 5.0); α 1, 0.5 (normal 0.1 to 0.4); α 2, 1.0 (normal 0.5 to 1.1); β, 1.3 (normal 0.6 to 1.2); and γ globulin, 1.7 (normal 0.5 to 1.5); the sedimentation rate (Westergren) was 48 mm/hr (normal 15 to 20); and fluorescent antinuclear factor was positive 1:16 (homogeneous pattern).

HISTOPATHOLOGICAL FINDINGS

The following is a composite picture of two biopsies done on the left biceps area. In the hematoxylin-eosin stained sections, the epidermis showed no significant changes aside from slight effacement of the rete

ridges. The pilosebaceous structures, sweat glands, and dermal connective tissue appeared normal. Minimal collections of lymphocytes with an admixture of histiocytes were seen around occasional deep dermal vessels. The adipose tissue did not show appreciable changes but a fibrous septum separating deeply located fat lobules was thicker and appeared paler staining and more homogeneous and "hyaline" than the dermal connective tissue (Fig 2). Its collagen showed practically no birefringence in polarized light as compared to that of the dermis. The alcian blue stain revealed an increase in positive-staining mucopolysaccharide material and the elastic stain (Verhoeff-van Gieson) diminished, thin, delicately wavy and curled elastic fibrils (Fig 3) in this hyalinized area, both stains showing normal changes in the dermis. The stain for elastic also showed some delicate wavy fibrils and finely fragmented, almost granular, clumped material in the deeper fascial region. A scattering of small mononuclear cells and a few histiocytes and fibroblasts were present in the less compact stroma of the deep hypodermis and around one or two neighboring vessels, but inflammatory cells became more abundant in the loose connective tissue stroma of the fascia among markedly thickened collagen bundles. Lymphocytes and eosinophils were predominant, accompanied by lesser numbers of histiocytes and rare neutrophils. In some areas, the infiltrate was almost exclusively lymphocytic, but in most, eosinophils were found (Fig 4). This became more apparent with the Giemsa-Wright stain. The cellular collections were not dense and showed no tendency to form lymphoid follicular aggregates. A fragment of muscle included in the biopsy appeared normal. The vessels did not show any significant changes. Masson's trichrome, PAS, and reticulum (Gordon and Sweet) stains did not depict any appreciable abnormalities.

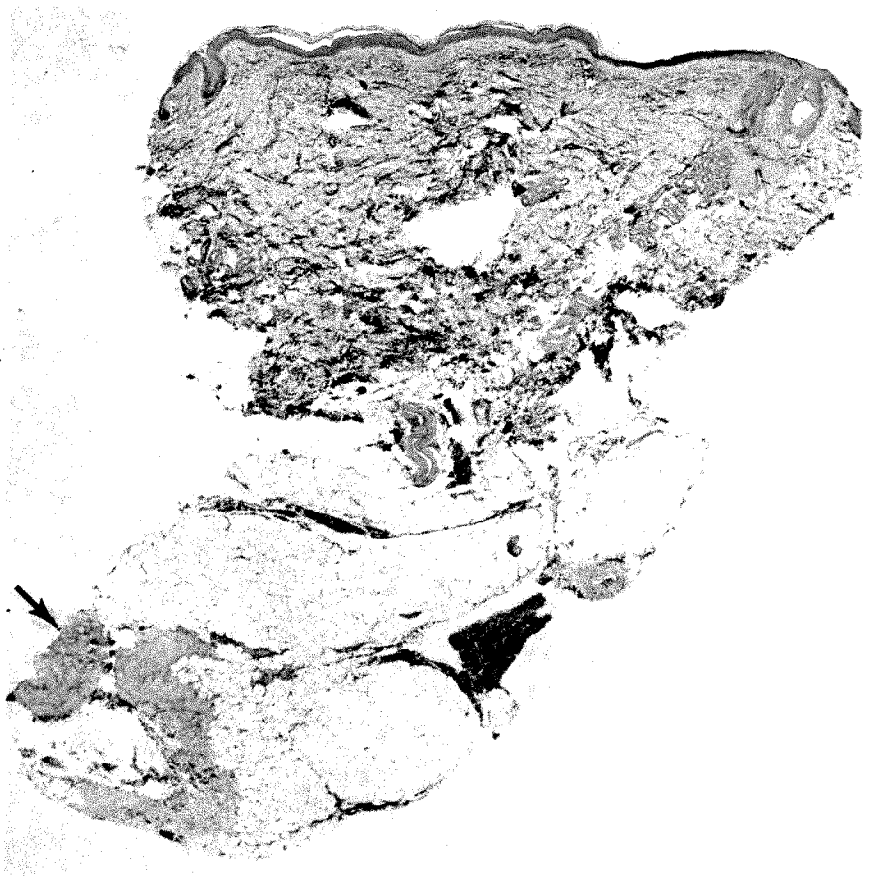

Fig 2.—Skin biopsy specimen, left arm. Thick, pale-staining, deep hyalinized interlobular septum (arrow); relatively normal skin otherwise (hematoxylin-eosin, original magnification ×11).

COURSE

The patient was treated with prednisone, 10 mg twice daily, and after nearly five months (last seen on Aug 28, 1975), he felt considerably happier and could move his arms with hardly any difficulty, but the objective findings of his skin had not undergone notable change.

COMMENT

When observed originally, it was

Fig 3.—Elastic fibers in deep hyalinized septum are diminished, thin, delicately wavy, and curled (Verhoeff-van Gieson, original magnification ×290).

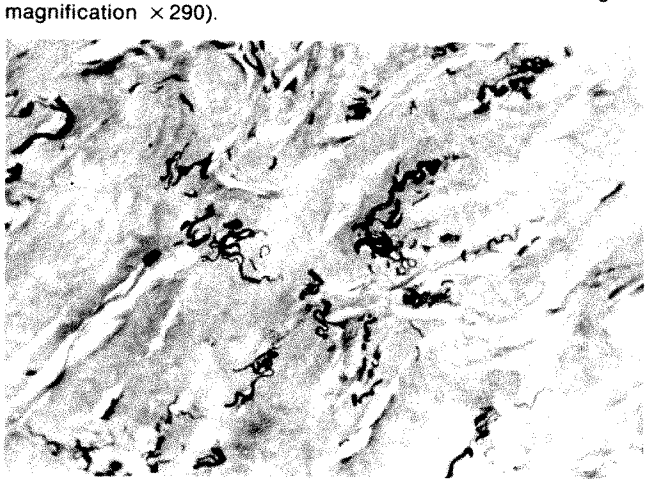

Fig 4.—Cellular infiltrate in loose stroma of fascia. Lymphocytes predominate, but eosinophils are also present (hematoxylin-eosin, original magnification ×267).

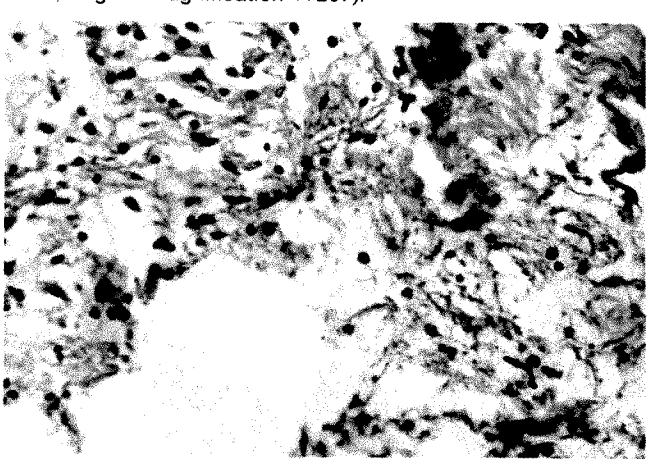

apparent that this patient's clinical manifestations did not conform to any of the known connective tissue disorders, mucinoses, or panniculitides. The symmetrical, irregular, firm nodularities of the proximal aspect of the extremities and the lack of involvement of the face, hands, and feet in an otherwise relatively asymptomatic patient did not resemble any of the usual expressions of generalized morphea, acrosclerosis, or progressive systemic sclerosis.[4-8] The superficially smooth but hard and bound down skin of the trunk suggested scleredema, but this, as well as scleromyxedema, which on clinical grounds was not strongly entertained, was eliminated by the normal acid mucopolysaccharide content of the dermis.[4] A faint clinical resemblance to an involuting, but surely atypical panniculitis was discarded by the paucity of findings in the patient's adipose tissue. The deep septal thickening, vaguely reminiscent of an erythema nodosum-like resolving septitis, could certainly not support that diagnosis in view of the bizarre clinical picture. The hyalinized septum, however, was the clue to the problem. The patient's changes, surmised clinically, pointed to diffuse involvement of the connective tissue that bound the skin and panniculus adiposus to the underlying muscles, ie, the fascia. This was confirmed by the study of the deeper tissues obtained during the first biopsy: the fascia showed a definite inflammatory process and thickening.

Shulman[1] recently described two male patients, one 53, another 19 years old, without myositis or the visceral manifestations of systemic sclerosis, who had "a diffuse scleroderma-like illness with firm, taut skin bound down to the underlying structures (sparing the face in both patients and hands and feet in one) the onset of which was antedated by unusual physical exertion." These patients had flexion contractures of elbows and knees and limitation of abduction at the shoulders, blood eosinophilia, elevated sedimentation rate, and hypergammaglobulinemia. The bone marrow showed plasmacytosis and eosinophilia, and the biopsies revealed striking thickening of the fascia between the subcutis and muscle, with intense infiltration with plasma cells and lymphocytes, but eosinophils were absent. There was no histologic evidence of scleroderma or myositis. One of the patients underwent a full remission after prednisone therapy for 15 months, but in the other, more severely involved, the clinical improvement had been minimal, even though reversal of laboratory abnormalities had occurred. Shulman's name for the condition was "diffuse fasciitis with hypergammaglobulinemia and eosinophilia" but this has already been simplified to "diffuse eosinophilic fasciitis."[3] It has also been stated that other patients have responded well to prednisone, and one who received no medication recovered spontaneously.[3]

Our patient fulfills the criteria for Shulman's concepts. The minor deviations, also noted in subsequent reports,[2,3] fall within the variations expected in a complex process, and rather than clouding it, probably serve to place it in its proper perspective. This patient, for example, showed tissue rather than blood eosinophilia and a slight instead of a marked increased in γ-globulins, suggesting a different, perhaps earlier, transitory stage of development.

There is no doubt that inflammation of subhypodermal connective tissue is fundamental in Shulman's and similar cases. Therefore, the distinctive pathologic alterations in a portion of interlobular connective tissue in the hypodermis of our case acquires great significance in understanding the pathogenesis of the process. This hyalinized tissue exhibits almost identically, the changes found by Fleischmajer et al[7,8] in the subcutaneous areas in cases of systemic scleroderma and generalized morphea, viz, hyalinized, pale-staining connective tissue with diminished, newly synthesized elastic fibrils. Since their studies indicated that dermal connective tissue was initially relatively unaffected, these authors conclude that the replacement of the panniculus by connective tissue is most likely the primary factor responsible for the skin induration in scleroderma and that it is likely that panniculitis may be a prominent feature during the early stages of this disease. This patient (and possibly Shulman's and other similar ones) indicates that, indeed, an even deeper inflammatory reaction, ie, a fasciitis, could be the earliest observable event in at least some members of the group of cutaneoindurative disorders.

Immunoglobulin abnormalities and antinuclear antibodies, whether significant or not, as well as possibly latent diabetes and hyperinsulinism, all seen in this patient to a minor degree, have also been reported in systemic scleroderma.[6,9,10,11]

Rodnan has been quoted as saying, "Although newly recognized, the condition is not new... patients with eosinophilic fasciitis have probably been thought to have scleroderma, or scleredema, in the past" (*Skin and Allergy News*, Aug 1975). Perhaps, eosinophilic fasciitis is a relatively benign, albeit impressive, variant of diffuse sclerosis. It has been emphasized that the condition does not progress to systemic sclerosis and that the patients' outlook for recovery is very good. This alone, added to the realization that deep biopsy specimens are essential, marks Shulman's contribution as a significant advance in our understanding and evaluation of these processes. Our patient's euphoric response when told that he was not suffering from progressive scleroderma reminded the senior author of another patient seen almost 20 years ago, a similarly labelled 31-year-old woman, who was "born again" when told that her diagnosis was, instead, atrophoderma of Pasini and Pierini, an entirely benign process.[12]

Stop at our place

before you go to more expensive topical steroids

Aristocort®

Triamcinolone Acetonide

Effective initial therapy in a wide range of steroid-responsive dermatoses.

Clinical efficacy proven again and again over almost 20 years of clinical use—a standard among fluorinated topicals.

One of the most *economical* topical steroids available—in forms, strengths and sizes for every susceptible steroid-responsive problem (large-size tubes and jars lower treatment costs even more for patients with chronic or widespread conditions...free trial samples available, too).

The *first* triamcinolone preparation to remove common sensitizers—contains no parabens, phenol preservatives, lanolin.

Indications: For relief of inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications: Viral skin diseases, such as varicella and vaccinia; hypersensitivity to any component (not for ophthalmic use); when circulation is markedly impaired.

Warnings: Safety of use in pregnancy has not been absolutely established. Do not use extensively, in large amounts, or for prolonged periods of time in pregnant patients.

Precautions: If irritation develops, discontinue use and institute appropriate therapy. In infections, use appropriate antifungal or antibacterial agents; if a favorable response does not occur promptly, discontinue the corticosteroid until the infection is adequately controlled. If extensive areas are treated or the occlusive technique is used, increased systemic absorption of the corticosteroid may occur; take suitable precautions.

Adverse Reactions: (local) Burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.

Supplied: Cream 0.5%—Per Gm.: triamcinolone acetonide 5 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; *Cream 0.1%*—Per Gm.: triamcinolone acetonide 1 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; *Cream 0.25%*—Per Gm.: triamcinolone acetonide 0.25 mg., sorbic acid 0.1% and potassium sorbate 0.1% as preservatives; all potencies are in a water base of mono and diglycerides, squalane, polysorbate 80 USP, polysorbate 60, cetyl esters wax NF, stearyl alcohol USP, Tenox II, and sorbitol solution USP. *Ointment 0.5%*—Per Gm.: triamcinolone acetonide 5 mg.; inactive ingredient: white petrolatum; *Ointment 0.1%*—Per Gm.: triamcinolone acetonide 1 mg.; inactive ingredient: white petrolatum. *ARISTOGEL® Gel 0.1%*—Per Gm.: triamcinolone acetonide 1 mg., 1.8% benzyl alcohol as preservative, inactive ingredients in a water base: polysorbate 80 USP, polyoxyethylene (20) cetyl ether, glycerin USP, and citric acid USP. 004-7

Obviously, efficacy is foremost in your mind when you recommend a therapeutic shampoo. And efficacy, coupled with cosmetic acceptability, usually guarantees a successful therapeutic course.

That's why Head & Shoulders is so highly regarded in the treatment of dandruff.

Clinically effective

For years, Head & Shoulders has proved effective in the treatment of dandruff—whether for initial therapy or long-term control. And now, research shows that Head & Shoulders is effective in the treatment of seborrheic dermatitis.*

Cosmetically pleasing

Head & Shoulders lathers well, has a pleasant odor and appearance, and need not be left on the scalp for an extended period of time. Also, it leaves hair clean, manageable, and attractive.

Head & Shoulders®

You'll like it for its therapeutic benefits. Your patients will like it for its cosmetic appeal.

Benign Mucous Membrane Pemphigoid

Response to Therapy With Cyclophosphamide

Harold J. Brody, MD, Donald J. Pirozzi, MD

Benign mucous membrane pemphigoid, also called cicatricial pemphigoid, is a chronic vesiculobullous disease of the mucosa and skin that results in permanent scarring of the affected areas, often causing blindness. Reports of treatment for this disorder have been scanty and quite variable in presentation. To our knowledge, this is the first case report of an initially recalcitrant patient treated successfully with cyclophosphamide.

Report of a Case

A 49-year-old man was in good health until June 1975 when he noted injection of the right conjunctiva accompanied by photophobia. The diagnosis was staphylococcal keratoconjunctivitis, and he was treated accordingly with antibiotics and topical steroid combinations with minimal response and progression to the left eye in September of 1975. Several months later an ulcer developed involving the right buccal mucosa. His vision was 20/20 in both eyes with correction, and examination OD revealed hyperemia of the lid margins and collarette formation. There was almost a pseudomembrane involving the inferior and superior tarsal conjunctiva with subepithelial cicatricial band formation inferiorly. Biopsy of a fleshy pedunculated vascularized mass at the limbus had been done in the past and pyogenic granuloma was the diagnosis. Examination OS showed similar conjunctival changes with early symblepharon (Fig 1). The patient was treated intensively with corticosteroid mixture (Predneferin) and gentamicin sulfate ophthalmic drops, his condition was diagnosed as probable benign mucous membrane pemphigoid, and he was admitted to the Dermatology Service of Emory (Atlanta) University Hospital.

On admission in January 1976, the patient was complaining of difficulty with swallowing secondary to ulcerations in his mouth. He noted increased photophobia and blurring of vision with considerably increased lacrimation. He denied anorexia, weight loss, or complaints relating to systemic illness. Physical examination revealed a well-nourished and anxious afebrile man in no acute distress. Scattered 2- to 3-mm ulcerations were present in the mouth, nasopharynx, hypopharynx, pharynx, larynx, and nose (Fig 2). Eye examination was unchanged. Results from the remainder of the physical examination were within normal limits.

Esophagoscopy revealed the entire upper half of the esophagus to be studded with small ulcerations. Proctoscopy to 22 cm revealed no mucosal disease. Findings for chest roentgenogram, complete blood cell count, urinalysis, anti-nuclear antibody, ECG, VDRL, SGOT, lactic dehydrogenase, bilirubin, cholesterol, uric acid, total protein, albumin, calcium, and phosphorus were all within normal limits. A slightly elevated alkaline phosphatase level of 114 mU/ml (normal, 20 to 85 mU/ml) was present.

Conjunctival biopsy was performed that revealed hyperemic tissue with superficial nonspecific inflammation and almost total erosion of the surface epithelium. A biopsy specimen of buccal mucosal ulceration was consistent with mucosal pemphigoid. Cultures of the conjunctiva and lid margin grew *Staphylococcus aureus* and *epidermidis*. Serum was negative for circulating antibodies to the skin by indirect immunofluorescence, and a conjunctiva specimen was negative for direct immunofluorescence.

The patient was begun on a regimen of triamcinolone acetonide 60 mg daily, with marginal improvement in visual blurring after one week. Therapy was changed to prednisone 80 mg daily and he was discharged. One month later, his eyes seemed to be worse, with persistent oral lesions; azathioprine 100 mg daily was added to his treatment plan and triamcinolone in orobase was used symptomatically for oral ulcerations. The following month, betamethazone 7.2 mg daily was substituted for prednisone without success. The patient now had a 9-kg weight gain, was noticeably cushingoid, was still incurring new oral ulcerations, and was bilaterally losing his vision. His azathioprine therapy was discontinued and he was begun on a regimen of cyclophosphamide 50 mg twice daily. This dosage was gradually raised to 200 mg daily during the next month, with healing of oral ulcerations and improvement in visual acuity. His corticosteroid therapy was changed again to prednisone and tapered to a dose of 20 mg every other day over the next six months with considerable resolution of his disease. Eight months after the onset of therapy with cyclophosphamide, the patient was largely clear of lesions and corticosteroid therapy was tapered off, with a maintenance

Fig 1.—Initial presentation showing severe bilateral conjunctivitis.

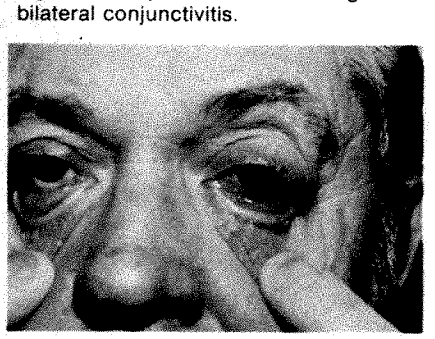

Fig 2.—Initial presentation of oral mucosa showing 2- to 3-mm ulcerations.

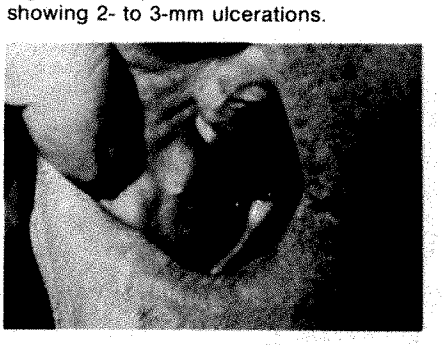

Fig 3.—Improvement of both eyes after treatment.

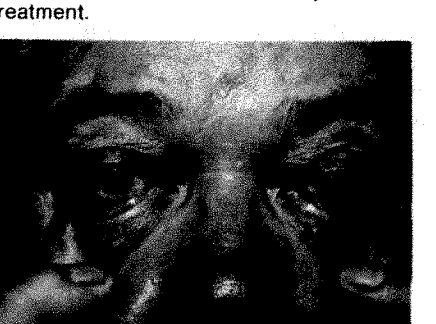

therapy of only 200 mg of cyclophosphamide daily (Fig 3).

COMMENT

Therapy in mucosal pemphigoid has been erratic in the past from the standpoint of consistency in improvement. Unfortunately, the steroids that are often helpful in bullous pemphigoid of the skin are not necessarily the drug of choice in cicatricial pemphigoid. Hardy et al[1] found that the equivalent of 40 mg of prednisone per day was necessary to retard or arrest the disease, triamcinolone being the most effective drug. The fluorinated corticosteroids are known to have a more rapid anti-inflammatory effect and also are associated with a greater degree of adrenal suppression. In the 81 patients in their series, 21 became blind, 17 in both eyes, and one patient died from the side effects of corticosteroid therapy. Though triamcinolone was more effective in this series, there were only five patients in the series treated with this steroid, and the impression of superiority was derived from improvement in four of these five patients. Herron[2] encountered success in his study using 80 mg of triamcinolone daily and tapering to 40 mg every other day during a two-month interval. It seems generally accepted that topical steroids do little to prevent shrinkage and symblepharon formation.

Immunosuppressive therapy in the form of azathioprine has been successful, especially in combination with prednisone.[3] Greatest benefit is reported with doses of 100 to 200 mg/day of azathioprine with steroids in a series of four patients. Visual impairment was arrested and oral ulceration minimized, thus improving the prognosis.

Cyclophosphamide[4] is a synthetic drug related to the nitrogen mustards that has been used chiefly for its immunosuppressive action by interfering with the cross-linking of DNA. Presumably metabolized in the liver, it may be associated with alopecia, mucosal loss, hemorrhagic cystitis, and myelosuppression. Used in much higher doses for lymphoma, multiple myeloma, leukemia, mycosis fungoides, and certain solid malignant neoplasms, WBC counts and serum hemoglobins are indicated on a regular basis during therapy with the drug.

To our knowledge, this is the first report of a successful trial of cyclophosphamide in controlling benign mucous membrane pemphigoid. Since its action is immunosuppressive and not anti-inflammatory, it supports an autoimmune etiology of the disease. Our patient did not have autoantibodies on immunofluorescence, although they have been reported inconsistently in the past.[5,6] It is significant that the addition of this agent enabled tapering of the corticosteroid dosage and elimination of the side effects of hypercortisolism.

Schering Pharmaceuticals provided funds for color reproductions.

Serratia marcescens Cellulitis

Dean E. Brenner, MD, Donald P. Lookingbill, MD

During the last decade, *Serratia marcescens* has become an important bacterial pathogen in the debilitated patient. This organism has been shown to cause infections in most organ systems.[1] It has not, to our knowledge, been found as a cause of cellulitis in unbroken skin. We report a unique case of cellulitis developing in areas of unbroken skin in a patient with *S marcescens* bacteremia.

Report of a Case

A 51-year-old nondiabetic man was admitted for the third time to the Hershey (Penn) Medical Center with increasing dyspnea. He was admitted initially in 1970 with dyspnea, and in 1972 after cardiac catheterization, idiopathic cardiomyopathy was diagnosed. He was readmitted in July 1975 for increasingly severe congestive heart failure. Two days after heart catheterization a deep vein thrombophlebitis of the left calf developed. Following treatment with continuous infusion heparin sodium, continuous warm soaks, and leg elevation, the calf improved but purulent drainage from the left arm intravenous catheter site was noted. Initial blood and urine cultures proved negative.

Four days after catheterization, the patient became lethargic. At that time, a warm, indurated, erythematous, extremely tender lesion was noted to be advancing rapidly on the left lateral thigh at a rate of 6 mm/hr. The skin of the thigh was intact. A 4-mm punch biopsy specimen of the skin lesion was taken and then was homogenized, Gram stained, and cultured. No organisms were seen on Gram stain. Gram stain of the drainage from catheter sites revealed scattered Gram-negative rods that were interpreted as contaminants. Treatment with intravenous nafcillin sodium was begun; however, because of spiking temperatures, and a rising WBC count, gentamicin sulfate was added to the treatment regimen later the same night.

A gentamicin-sensitive, non-pigmented strain of *S marcescens* grew from cultures of the skin biopsy specimen, catheter site drainage, and blood. Despite vigorous, high-dose antibiotic treatment, the hip cellulitis slowly progressed to cover the entire leg, buttock, thigh, and scrotum. The patient became increasingly lethargic, hepatic and renal failure developed and he died on the ninth postcatheterization day. Permission for autopsy was denied.

Comment

This report presents a case of *Serratia* cellulitis arising in unbroken skin, at a site that is remote from the presumed portal of entry. In this case, the appearance of the cellulitis also served as the initial manifestation of an underlying *Serratia* bacteremia. We surmise that the infection, originating at the left arm catheter site, was blood borne to an ecchymosis in the left thigh of this anticoagulated patient. The infection then spread by continguity in the neighboring skin and subcutaneous tissues.

Patients with chronic congestive heart failure may be predisposed to having Gram-negative cellulitis devel-

From the Division of Dermatology, Department of Medicine, the Milton S. Hershey Medical Center of the Pennsylvania State University, Hershey.

Reprints not available.

op as a result of the chronic edema present in their skin and subcutaneous tissues.[3] Once infection is established, endotoxin produced from the Gram-negative bacilli causes thrombosis of the nutrient small vessels, with resultant ischemia and edema. This environment enhances bacterial pathogenicity and the spread of the cellulitis.[2,3]

Diagnosis of Gram-negative cellulitis may be difficult and it requires a high index of suspicion. Initially, it may occur as a relatively benign lesion of warmth, induration, and discoloration. The border is usually poorly defined and there may be minimal erythema. The cellulitis then spreads rapidly and can be associated with local erythema, induration, necrosis, and sometimes crepitance.[3] Systemically, initial elevation of the WBC count and indolent fever may be the only clues of the process. Later, signs and symptoms of septicemia can be expected to supervene.

To identify the causative organism, culture material is required. Blood cultures, of course, should always be drawn, but diagnosis from the skin is often a difficult task. Although bacteria have, in some instances, been recovered with saline injection and needle aspiration,[4] in our hands this procedure is often unrewarding. Tronca et al[5] showed that for septic gonococcemia pustules, homogenized skin punch biopsy material yielded positive cultures more often than did aspirated material. Likewise, culture of a skin biopsy specimen in suspected cellulitis infection, as was successfully done in this case, may prove to be a productive diagnostic maneuver.

Tinea Capitis Due to *Trichophyton soudanense*

Donald R. Cox, MD, Fritz Blank, DSc Nat†

Trichophyton soudanense (Joyeux,[1] 1912) is a frequent cause of tinea capitis in certain regions of Africa. Infections of skin and nails are less frequent.[2] To our knowledge, this is the first published report of a scalp infection by this dermatophyte in the United States; however, two reports of tinea corporis have been published.[2,3]

Report of a Case

A 6-year-old, American girl who had never left the Philadelphia area developed four pruritic, round areas of alopecia in the occipital area of her scalp. The plaques were slightly elevated, scaly, dull red, and 1- to 4-cm in diameter. The follicles contained black dots that were broken hairs containing spores 6 to 7 μ in diameter. There were enlarged lymph nodes in the posterior cervical and postauricular areas. Inoculation of broken hairs on Sabouraud's glucose agar yielded a folded, yellow to dried apricot colony surrounded by submerged mycelium. Results of microscopical examination of this growth showed septate hyphae with reflexive branching and chains of arthrospores. The culture was therefore identified as *T soudanense.*

From the Skin and Cancer Hospital, Temple University Health Sciences Center, Philadelphia.

Reprint requests to 416 Balboa Ave, Stuart, FL 33494 (Dr Cox).

†Deceased.

The patient was treated with 250 mg of griseofulvin (Fulvicin U/F), microsize, twice daily with meals. The lesions were treated topically with clotrimazole (Lotrimin) cream (1%) twice daily. Her mother was asked to shampoo the scalp daily. After two months of therapy, inoculation of epidermal scalp scrapings yielded no growth on Sabouraud's glucose agar. Inflammation and scaling regressed, and there was a gradual regrowth of hair during the next nine months.

The patient's mother had two scaly red patches on her back. Epidermal scrapings from these lesions did not show any hyphae when examined microscopically, and there was no growth after inoculation of Sabouraud's glucose agar.

The patient had a friend born in Africa who had lived in the United States for four years. Unfortunately, permission was not granted to examine the friend and her family.

Comment

Travel has been responsible for the spread of *T soudanense* infections to countries outside of Africa. Cases have been reported in Europe.[4] Additional unreported cases have been found in the New York area. A Jamaican girl who had been living in New York for 4½ years had two lesions on the left thigh that had been present several months (personal communication with M. Silva-Hutner). Unpublished cases of scalp infections include a 4-year-old child born in New York (personal communication with I. Waitzman) and two American children who most probably had contact with African children (personal communication with S. A. Rosenthal).

The number of African visitors to the United States has doubled between 1967 and 1974.[5] It may be surprising that more infections have not been discovered since the last reported isolation by Johnson and Rosenthal in 1968.[3] The sometimes chronic and nearly asymptomatic clinical manifestations of *T soudanense* infection,[4] which can easily be confused with other dermatologic diseases, and the lack of proper facilities for identification of this dermatophyte[6] may explain the relatively small number of infections reported.

When either Benzoyl Peroxide or Retinoic Acid can't solve the puzzle of pustular acne...

Sulfacet-R®

(10% sodium sulfacetamide,
5% microsize sulfur)

PENETRATES into the skin to exert its antibacterial activity.

CONTROLS pustular stages of acne and seborrhea quickly, safely... without unsightly desquamation.

SAFETY RECORD..."in thousands of patients during the past two decades, not a single instance of sensitivity has been observed."*

PROVIDES instant **"Social Confidence"** with the exclusive Dermik Color Blender,™ customized tinting to match individual patient skin tones.

Dermik

Dermik Laboratories, Inc.
Fort Washington, Pa., U.S.A. 19034

SULFACET-R® LOTION

DESCRIPTION—Sulfacet-R® Acne Lotion contains (as dispensed) sodium sulfacetamide 10% and microsize sulfur 5% in a flesh-tinted lotion of purified water, alkyl aryl sulfonic acid salts, hydroxyethylcellulose, propylene glycol, xanthan gum, lauric myristic diethanolamide, polyoxyethylene laurate, cyclohexanediamine tetraacetic acid, butylparaben, methylparaben, silicone emulsion, talc, zinc oxide, titanium dioxide, attapulgite, iron oxides, pH buffers and 2-bromo-2-nitropropane-1, 3-diol.

ACTIONS—Provides keratolytic, peeling, drying and antiseborrheic action.

INDICATIONS—An aid in the treatment of acne vulgaris, acne rosacea and seborrheic dermatitis.

CONTRAINDICATIONS—This product is contraindicated for use by patients having known hypersensitivity to sulfonamides, sulfur or any other component of this preparation. Not to be used by patients with kidney disease.

PRECAUTIONS—For external use only. Keep away from eyes. If irritation develops, discontinue use and consult physician. Sensitivity to sodium sulfacetamide may occur. Therefore, caution and careful supervision should be observed when prescribing this drug for patients who may be prone to hypersensitivity to topical sulfonamides. Particular caution should be employed if areas of denuded or abraded skin are involved. Patients should be carefully observed for possible local irritation or sensitization during long term therapy. Occasionally, certain individuals may be sensitive to one or more components of this preparation. The object of this therapy is to achieve desquamation without irritation, but sodium sulfacetamide and sulfur can cause reddening and scaling of the epidermis. These side effects are not unusual in the treatment of acne vulgaris, but patients should be cautioned about the possibility. Keep out of the reach of children.

ADVERSE REACTIONS—Previous toxic reactions such as agranulocytosis, acute hemolytic anemia, purpura hemorrhagica, drug fever, jaundice and contact dermatitis indicates hypersensitivity to sulfonamides.

DIRECTIONS—Shake well before using. Apply a thin film 1 to 3 times daily with light massaging to blend in each application in accordance with the physician's directions. Each package contains a "Dermik Color Blender" which enables the patient to alter the basic shade of the lotion so that it matches the skin color exactly.

[Important to the Pharmacist—At the time of dispensing, add contents of vial* to the bottle. Shake well and/or stir with a glass rod to insure a uniform dispersion. Place expiration date of four (4) months on bottle label.]

*"Sulfa-Pak" vial contains 2.4 grams of sodium sulfacetamide.

HOW SUPPLIED—Bottle, 1 oz.

CAUTION—Federal law prohibits dispensing without prescription.

Added versatility in dermatology

new Lidex®-E (fluocinonide) 0.05%

The established potency of fluocinonide, in a soothing emollient base.

Less drying than a cream, with the lubricating qualities of an ointment–cosmetically acceptable to patients.

Especially useful wherever a soothing topical steroid is indicated, as in atopic dermatitis.

Available in 15g and 60g tubes.

SYNTEX

Please see following page for summary of prescribing information

new
Lide® E
(fluocinonide)
Cream 0.05%

Prescribing Information

Description LIDEX-E cream 0.05% contains the active compound fluocinonide. Fluocinonide, which is the 21-acetate ester of fluocinolone acetonide, has the chemical formula 6α, 9-difluoro-11β, 16α, 17, 21-tetrahydroxypregna-1, 4-diene-3, 20-dione, cyclic 16, 17-acetal with acetone, 21-acetate.

The cream contains fluocinonide 0.5 mg./g. in a water-washable aqueous emollient base of stearyl alcohol, cetyl alcohol, mineral oil, propylene glycol, sorbitan monostearate, polysorbate 60, citric acid and purified water.

Actions Topical steroids are primarily effective because of their anti-inflammatory, antipruritic and vasoconstrictive actions.

Indications For relief of the inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications Topical steroids are contraindicated in vaccinia and varicella.

Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions If irritation develops, the cream should be discontinued and appropriate therapy instituted.

In the presence of an infection, the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid cream should be discontinued until the infection has been adequately controlled.

If extensive areas are treated, the possibility exists of increased systemic absorption and suitable precautions should be taken.

Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not absolutely been established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

This product is not for ophthalmic use.

Adverse reactions The following local adverse reactions have been reported with topical corticosteroids: burning sensations, itching, irritation, dryness, secondary infection, folliculitis, acneform eruptions, hypopigmentation, striae, skin atrophy.

Dosage and Administration A small amount should be gently massaged into the affected area three or four times daily, as needed.

How Supplied LIDEX®-E (fluocinonide) cream 0.05% — 15g. and 60g. tubes.

Books

Psoriasis: Proceedings of the Second International Symposium, edited by Eugene M. Farber, MD, and Alvin J. Cox, MD, 487 pp. 225 + illus, $35, New York, Yorke Medical Books, 1977.

The proceedings of the Second International Symposium on Psoriasis, which was held at Stanford University from July 12 through 15, 1976, have been published in a handsome volume that is a great improvement over that of the 1971 symposium. The type is clear and can be read easily, and the many graphs and photographs consistently are reproduced well. There are few errors, and the editors are to be congratulated.

The opening remarks of the symposium by Dr G. Donald Whedon, director of the National Institute of Arthritis, Metabolism, and Digestive Diseases, are of particular interest. In essence, Dr Whedon acknowledged the effects of lobbying by institutions and individuals to obtain money for research on psoriasis. Of particular note was the urging of the National Institute for Arthritis, Metabolism, and Digestive Diseases by the Senate Appropriations Subcommittee for Health, Education, and Welfare to increase its efforts in funding research on psoriasis; the Institute was directed also to analyze the needs and priorities for dermatologic research. It is this kind of direct plotting that will be needed to obtain more funds for dermatologic research.

The papers are presented uniformly. Some of the chapters are especially outstanding, such as the chapter by Van Scott and Yu, "Pharmacobiologic Leads in Psoriasis," and the chapter by Stoughton, "A Perspective of Topical Corticosteroid Therapy." The bibliographic references were carefully selected and up-to-date and will add to the reference value of this volume.

My only criticism of the book is the absence of an index—an addition that would make the book more useful.

This book will bring the reader reasonably up-to-date with the old and the new ideas in the treatment and research in psoriasis. It would be an excellent addition to the library of every dermatologist, as well as research workers in the field, and certainly should be available to all residents in dermatology.

SIGFRID A. MULLER, MD

Atlas of the Face in Genetic Disorders, ed 2, by Richard M. Goodman, MD, and Robert J. Gorlin, DDS, MS, 586 pp, 1,181 illus, $57.50, St Louis, CV Mosby Co, 1977.

The purpose of this atlas is to aid the clinician in making a diagnosis of a genetic disorder on the basis of certain distinguishing facial features. The number of syndromes recorded in the second edition is almost triple that in the first edition. A tremendous amount of information is presented to assist the reader in the quest for a specific diagnosis.

An introductory section on genetic inheritance and counseling details the importance of the family history, the modes of genetic transmission, and, most importantly, an integral part of the treatment both to the patient and to his family—genetic counseling. The embryology of the face and precise methods of head and facial measurements are presented briefly. Guidelines and definitions on the classification, nomenclature, and naming of morphologic defects are proposed.

Genetic disorders of the face are recorded either alphabetically or by an increasing chromosomal number and according to the various modes of inheritance—autosomal dominant, autosomal recessive, X-linked, chromosomal, or uncertain genetics. Abundant clinical photographs and radiographs of excellent quality illustrate the distinguishing features of each genetic disorder presented. In addition, a large summary table, an appendix with extensive tables, and medical and genetic glossaries are included to further aid in pursuit of a diagnosis.

The authors acknowledge that some genetic syndromes with unusual facial features are omitted; however, these omissions do not detract from the value of the text. This atlas effectively achieves the goal of assisting the clinician in making a diagnosis of a genetic disorder. This outstanding contribution should be of interest to medical personnel of all disciplines, particularly those working in human genetics, dermatology, oral pathology, otolaryngology, ophthalmology, and plastic and reconstructive surgery. Since receiving this atlas, I have referred to it on numerous occasions and value it immensely in my reference library.

News and Notes

Postgraduate Course and Workshop in Dermatomycology.—The course in dermatomycology will be offered from Aug 25-27, 1978, for dermatologists, clinical pathologists, medical mycologists, and other persons interested in the current status of medical mycology. This program will be limited and is acceptable for category I credit toward the American Medical Association Physician's Recognition Award and the Certificate in Continuing Education of the California Medical Association. For further information please contact Extended Programs in Medical Education, University of California, Room 569-U, San Francisco, CA 94143, or call (415) 666-4251.

Pediatric Dermatology Seminar.—A three-day pediatric dermatology seminar will begin Thursday evening, Feb 23, 1978, at the Konover Hotel on the ocean front of Miami Beach. The program will conclude on Sunday afternoon, Feb 26, to be followed by a one-week postseminar flight and cruise to the Caribbean and South America. Dr R. Winkelmann, of the Mayo Clinic (Rochester, Minn), will conduct daily lectures and discussions at Curacao, Caracas, Grenada, Guadeloupe, St Thomas, and San Juan.

The course is designed to review the most recent advances about skin diseases of children. The format will be two 45-minute lectures followed by a 30-minute question and discussion period in which the audience can quiz an internationally renowned faculty. Continuing medical education credit will be awarded.

The faculty and their subjects include as follows: Albert Kligman, "Contact and Irritancy Dermatitis, Myths About Acne and Diaper Rashes;" Richard Winkelmann, "Bullous Diseases of Children, Review of Pediatrics Dermatological Literature;" Gerald Weissman, "Inflammation and Infection—New Views and Therapy;" Heinz Eichenwald, "Neonatal Skin Abnormalities and Infectious Diseases of Children's Skin;" Loren Golitz, "Difficult and Practical Diagnostic Problems of Pediatric Dermatology Reviewed and Updated;" William Awad, "Internal Abnormalities of Children With Skin Disease;" Guinter Kahn, "New Thoughts, Types and Therapies—Hemangiomas."

The tuition is $150 for physicians and $100 for physicians in training. For further details write to Guinter Kahn, MD, 16800 NW Second Ave, Suite 401, N Miami Beach, FL 33169.

Seminar.—A postgraduate seminar in dermatology will be held March 3-5, 1978 at the Carillon Hotel, Miami Beach. Registration fee is $180. For further information, contact William Eaglstein, MD, 3900 NW 79th Ave, Suite 469, Miami FL 33166, or call (305) 592-9298.

American Society for Dermatologic Surgery.—The Fifth Annual Clinical and Scientific Meeting, will be held March 28 to April 1, 1979, at the Princess Hotel, Grand Bahama Island. For information contact Daniel E. Gormley, MD, Society Secretary, 210 S Grand Ave, Suite 307, Glendora, CA 91740.

University of Cambridge School of Clinical Medicine.—The fifth five-year course "Progress in Biological Sciences in Relation to Dermatology" will be held in Cambridge, England, Sept 25-29, 1978.

Details may be obtained in due course from the Secretary, Cambridge University School of Clinical Medicine, Addenbrooke's Hospital, Hills Road, Cambridge CB2.2QQ, England.

"Your Consultant Speaks".—The Stanford University Department of Dermatology will offer the postgraduate symposium, "Your Consultant Speaks," on Feb 7-10, 1978, at Del Webb's Sahara Tahoe Hotel and Casino, Lake Tahoe, Nev. This multidisciplinary course is designed for the dermatologist. Objectives are to encourage dermatologist-consultant cooperation in diagnosing and treating skin diseases, and to update and broaden the dermatologist's knowledge of chemotherapy, DNA, endocrinology, hematology, immunology, infectious diseases, internal medicine, and psychiatry. Sessions will be held at Lake Tahoe from 7:00 to 9:00 AM and from 5:00 to 7:00 PM. This is an American Medical Association accredited postgraduate seminar. For information contact Paul H. Jacobs, MD, Department of Dermatology, Stanford University Medical Center, Stanford, CA 94305; (415) 497-6101.

University of California, San Francisco-Cleveland Clinic—Northwestern University Dermatology Seminar in Hawaii.—This seminar sponsored by the University of California Medical Center, San Francisco, Cleveland Clinic, and Northwestern University, will be held at the Hotel Inter-Continental, Maui, Hawaii, from Jan 20-25, 1978. In addition to the faculty of these three institutions, guest speakers include Drs John Strauss and Harry Arnold.

Registration is limited in number. For a program, please write the Department of Dermatology at the University of California Medical Center, San Francisco, CA 94143 or the Department of Dermatology, Northwestern University Medical School, Chicago, IL 60611.

Dermatopathology Club Meeting.—The Dermatopathology Club will meet with the International Academy of Pathology in Atlanta on March 5, 1978 at 1:30 PM in the Hilton Hotel. The program will include clinicopathologic correlations, basic research, and experimental pathology. Any person interested in diseases of skin is encouraged to attend. Submit proposed titles of material to Richard J. Reed, MD, 234 Loyola Ave, suite 603, New Orleans, LA 70112, or to David L. Page, MD, Department of Pathology, Vanderbilt University Hospital, Nashville, TN 37232. The last hour of this afternoon session is jointly sponsored by the American Society of Dermatopathology and the Dermatopathology Club.

Advanced Dermatology Course.—The Institute of Dermatology, St John's Hospital for Diseases of the Skin, as an organization accredited for 30 hours in category I of the American Academy of Dermatology of their continuing medical education award, and of the PRA of the American Medical Association, is holding an advanced dermatology course in London, Sept 11-15, 1978, assuming a minimum of 100 participants. The speakers will be authorities in their field from different British Centers. The course consists of clinicopathological conferences, color slide presentations, and lectures and laboratory demonstrations, and is suitable for hospital and office dermatologists and for residents in training. For further information please write to Dr A. Kobza Black, Institute of Dermatology, St John's Hospital for Diseases of the Skin, Lisle St, London WC2H 7BN, England.

b.i.d. Diprosone®

brand of

betamethasone dipropionate Cream 0.05%

(Potency expressed as betamethasone)

Twice a day for prompt relief of corticosteroid-responsive dermatoses

In contact dermatitis

90% **of patients showed marked or moderate improvement in seven days***

34 of 38 contact dermatitis patients responded to therapy.

In atopic dermatitis

86% **of patients showed marked or moderate improvement in seven days***

133 of 155 atopic dermatitis patients responded to therapy.

In psoriasis

62% **of patients showed marked or moderate improvement in only seven days***

116 of 188 psoriasis patients responded to therapy.

Additional benefits:

- Rapid onset of response.
- Economy and convenience of b.i.d. dosage.
- Occlusive dressings infrequently needed.
- Sensitivity is rare.
- Choice of convenient package sizes—in 15 Gm. and moneysaving 45 Gm. tubes.

Diprosone® brand of betamethasone dipropionate

Cream 0.05%/Ointment 0.05%

Clinical Considerations:

DESCRIPTION DIPROSONE is betamethasone dipropionate (9-fluoro-11β, 17,21-trihydroxy-16β-methylpregna-1,4-diene-3,20-dione 17,21-dipropionate). Each gram of DIPROSONE **Cream** 0.05% contains 0.64 mg. betamethasone dipropionate (equivalent to 0.5 mg. betamethasone) in a hydrophilic, emollient cream consisting of purified water, mineral oil, white petrolatum, polyethylene glycol 1000 monocetyl ether, cetostearyl alcohol, phosphoric acid, and monobasic sodium phosphate with 4-chloro-*m*-cresol as preservative. Each gram of DIPROSONE **Ointment** 0.05% contains 0.64 mg. betamethasone dipropionate (equivalent to 0.5 mg. betamethasone) in an ointment base of mineral oil and white petrolatum. **CONTRAINDICATIONS** DIPROSONE **Cream** and **Ointment** are contraindicated in vaccinia and varicella. Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of such preparations. **PRECAUTIONS** If irritation develops with the use of DIPROSONE **Cream** or **Ointment,** treatment should be discontinued and appropriate therapy instituted. In the presence of an infection, the use of an appropriate antifungal or antibacterial agent should be instituted. If a favorable response does not occur promptly, the corticosteroid should be discontinued until the infection has been adequately controlled. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use in pregnant females has not been absolutely established. Therefore, they should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time. DIPROSONE **Cream** and **Ointment** are not for ophthalmic use. **ADVERSE REACTIONS** The following local adverse reactions have been reported with topical corticosteroids: burning; itching; irritation; dryness; folliculitis; hypertrichosis; acneiform eruptions; hypopigmentation. The following may occur more frequently with occlusive dressings than without such therapy: maceration of the skin; secondary infection; skin atrophy; striae; miliaria. **DOSAGE AND ADMINISTRATION** Apply a thin film of DIPROSONE **Cream** to the affected skin areas twice daily, in the morning and at night. Clinical studies of DIPROSONE have indicated that applications twice a day are generally adequate. Apply a small quantity of DIPROSONE **Ointment** to the affected skin areas twice daily, in the morning and at night.

Letters to the Editor

Percutaneous Penetration Following Use of Hair Dyes

To the Editor.—Maibach et al[1] reported in the ARCHIVES that thin-layer chromatography (TLC) of urine samples from four of eight subjects, which were taken one to four days after they had dyed their hair with one of two commercially distributed, semipermanent hair dyes, disclosed a purple spot. The spot, which was unidentified, was the same with both dye preparations and was neither detected in control TLC of urine samples from the subjects nor in TLC of either hair dye. The authors concluded that "It is likely that these hair dyes not uncommonly penetrate the skin," and that the purple spot was most likely a metabolite.

We found the same purple spot in urine specimens from 13 of 14 subjects who had been treated according to the procedure of Maibach et al, ie, ether extraction of concentrates that were adjusted to pH 1, followed by ether extraction of the concentrates adjusted to pH 11; the extracts were then subjected to TLC on silica gel in either of Maibach's solvent systems C or D. Eight of the urine specimens were obtained from persons who had used a black shade of hair color lotion. Since the purple spot was detected in the urine specimens from this group either before or after the application of the dye to their hair, as well as in urine from nonusers, we suspected that the purple urinary metabolite was an artifact produced from a normal urinary constituent by the conditions used for the extraction.

An artifact was confirmed by the following:

1. The spot was detected only when the extraction at pH 11 followed the extraction at pH 1. The spot was not detected when the sequence was reversed.

2. The spot was detected in the pH 11 extract when the residue from the extraction at pH 1 was heated for one hour on a steam bath. When the residue from the extraction at pH 1 was adjusted immediately to pH 11 without heating, the spot was not detected.

3. The spot was detected in the extracts at pH 11 when the residue from the extraction at pH 1 was held at room temperature for six to 24 hours prior to the extraction. When the residue was held for one hour or less following the extractions at pH 1, the spot was not detected. The intensity of the colored spot at 24 hours indicated a higher concentration of the purple substance than at six hours.

Consequently, we believe that we have demonstrated that the purple metabolite reported by Maibach et al is an artifact produced by the extraction procedure used. The reason Maibach et al did not detect the spot in extracts of all the urine specimens that were examined might be because the specimens stood at pH 1 for varying lengths of time before being extracted at pH 11, and/or the amount of artifact present in various urine specimens was not sufficient to be visible on all of the TLC plates.

ROBERT S. YARE, PHD
MARIO GARCIA, PHD
Stamford, Conn

1. Maibach HI, Leaffer MA, Skinner WA: Percutaneous penetration following use of hair dyes. *Arch Dermatol* 111:1444-1445, 1975.

In Reply.—We observed in our laboratories and in others that when urine is heated at 100 C for periods of one to two hours at pH 1 and is extracted by ethyl acetate or other solvents at pH 11 and is followed by TLC, a variety of colored spots can be observed owing to hydrolysis of conjugated blood pigments. When this procedure is followed without heating at pH 1, no colored spots are observed on TLC.

In our previous study, we were careful to avoid heating the urine at pH 1 or allowing the urine to stand longer than two to three hours at 20 C before extraction. In our control urine samples, taken from persons prior to hair dyeing, we never observed colored spots on TLC (eight subjects). Furthermore, a total of thirty-seven 24-hour urine samples that were taken from the subjects after they had dyed their hair were processed in the same manner and yielded no evidence of coloration on TLC.

In view of the recent publication by Ames et al,[1] wherein hair coloring dye components have been shown to be mutagenic in his microbial systems, evaluation of whether dye components contained mutagens, in the urine of persons who have been treated with the dyes, is desirable.

In Reply.—Urine specimens from the eight individuals included in our study, who had used color lotion (natural black), were evaluated for mutagens by using the liver microsome activation method described by Durston and Ames.[1] Urine specimens that were collected prior to the use of the hair colorant were tested also. Neither the control nor the experimental urine showed mutagenic activity. In addition, urine specimens from 75 regular users of hair-coloring products have been evaluated by the same technique. All evaluations were negative.

Rifampin in Leishmaniasis

To the Editor.—I was very interested in the letter by Griffiths and Sodeify (*Arch Dermatol* 112:1791, 1976) in which rifampin is mentioned as a valuable drug for the treatment of cutaneous leishmaniasis.

I would like to report the case of a 19-year-old woman who had a 4 × 4-cm ulcer of eight months' duration on the right forearm. On October 1976, a Giemsa stain revealed Leishman-Donovan bodies on a smear obtained from the base of the ulcer. The patient was started on a pentavalent antimonial compound, methylglucamine antimoniate (Glucantime [France]; no comparable US product); she received two courses, (ten injections of 1.5 gm each) during a period of four weeks, without any signs of improvement. After reading the above-mentioned letter, I decided to start her on a regimen of rifampin, 600 mg twice a day for ten days; complete healing of the lesion with this treatment was observed. If further experiences show efficacy in the treatment of leishmaniasis with Rifampin, we will have a safe, easily obtainable and easy to manage drug, for this kind of problem.

Like Griffiths and Sodeify, I have not had good results with the use of metronidazole (Flagyl) in previous cases.

F. ROLANDO VÁSQUEZ, MD
Guatemala City

Photosensitivity Owing to Thiourea

To the Editor.—In two of our patients who were suffering from photosensitivity, thiourea could be identified as the sensitizer.

Report of Cases.—CASE 1.—A 51-year-old white man developed photosensitivity three weeks after having started work with a photocopying machine. Fiery redness and swelling developed on the skin that was exposed to light, accompanied by burning sensations; even indoor light caused complaints.

In light tests, the skin showed an increased sensitivity mainly to ultraviolet-A light (UV-A). Photopatch tests showed that the photocopy paper that was used by the patient in his work made his skin strongly reactive to light. The manufacturer of the paper kindly supplied us with data on the chemical composition of the paper and with samples of the 12 compounds involved. In photopatch tests with the separate compounds, thiourea turned out to be the cause of the severe reactions of the skin to light. Thiourea is used in almost all kinds of photocopy paper as an antioxidant, serving to prevent yellow discoloration of the paper.

After the patient's contact with the photocopying process was ended, the photosensitivity persisted for several years. However, at this writing three years have elapsed, and the patient's problem has become noticeably less severe.

CASE 2.—A 40-year-old black man was recently admitted to our clinic with an itching dermatosis. The areas most affected were the hands, including the palms and nailbeds, and the face. The patient complained of reactions of his skin to sunlight. Light tests showed that the skin reacted abnormally to ultraviolet-B light (UV-B); swelling could be produced anywhere on the skin with UV-B in doses corresponding to less than one minimal erythema dose (MED) for white skin. Repeated irradiation caused papules and vesicles on the patient's skin. A blister was elicited in the palm of the hand with UV-B administered in a dose insufficient to cause any visible reaction on the corresponding site in a white normal person. Patch tests showed strongly positive reactions to thiourea, even without intentional exposure to light. Such reactions could be avoided by decreasing the concentration of the aqueous thiourea solution used in the test to 0.0001 N; the total amount of thiourea applied per square centimeter of skin in this way was estimated to be only 0.01% of that present in 1 sq cm of a typical photocopy paper. Even then, papular reactions could be elicited in the contact area with either UV-B or UV-A.

Since avoiding any contact with photocopy paper was not compatible with the patient's job as an architect, we looked for a combination of photocopy paper and developer that did not contain thiourea or related compounds; we found such a combination in paper and developer that is marketed by a company in Great Britain.

Comment.—Contact sensitivity to photocopy paper has been described before,[1,2] but in these reports there is no indication that either thiourea or light were involved. Thiourea is toxic; amounts that penetrate through the skin may cause symptoms of poisoning.[3] The use of this agent as an antithyroid drug was discontinued because of the severe reactions it caused.[4] Thiourea is not only used in photocopying processes but also, for instance, as a rubber additive.

Photosensitivity owing to thiourea is rare, judging from the lack of reports to this effect, and especially considering that the compound is so widely used. Nevertheless, other investigators and physicians should be alerted to this possibility, now that two cases were found in one center in just a few years' time.

Dr H. G. J. de Boer of GAF-Nederland, Delft, and Dr H. Mustacchi of GAF-Great Britain, Colnbrook, gave us information on the composition of photocopy papers; they also supplied the paper and developer that did not contain thiourea.

Transient Acantholytic Dermatosis

To the Editor.—We are concerned about the report of a so-called variant of transient acantholytic dermatosis (TAD) by Waisman et al.[1] Their three patients all exhibit the clinical, histologic, and therapeutic picture of bullous impetigo (BI), but test data to exclude this more common entity, eg, skin lesion culture and Gram's stain, coagulase and phage typing, and injection of organisms into neonatal mice,[2] were not presented.

Clinically, the crusted, bullous lesions (some of which became purulent) with a + Nikolsky's sign, which originate periorificially, are typical of BI. Therapeutically, the partial response or nonresponse to penicillinase-sensitive or bacteriostatic antibiotics is consistent with BI. Incidentally, the observation of new bullae possibly precipitated by sunlight or suction trauma is interesting but may be coincident since BI prefers exposed surfaces too.

Histologically, the appearance of acantholysis[3] with negative immunofluorescence, and, particularly, a high cleavage plane (sub- or intragranular layer) is almost pathognomonic in these three patients of the so-called localized variant[4] (BI) of scalded skin syndrome. The more typical findings of TAD, ie, suprabasilar clefts, dyskeratotic cells, corps ronds, and grains,[5] were not described in any of these patients.

Perhaps the reason TAD was considered was because of (unstated) negative skin cultures. We would suggest that in the setting described, BI (missed by technical error) would still be a more appropriate diagnosis than TAD and that appropriate antibiotic therapy should have been administered. Perhaps the protracted course and the risks of potent topical corticosteroids and corticosteroid therapy that produces systemic effects, which were administered, could thus have been avoided.

3. Steigleder GK: Zur Differentialdiagnose des pemphigus vulgaris aus dem Blasengrundausstrich. *Arch Klin Exp Dermatol* 202:1-9, 1955.

4. Elias PM, Levy SW: Bullous impetigo: Occurrence of localized scalded skin syndrome in an adult. *Arch Dermatol* 112:856-858, 1976.

5. Grover RW: Transient acantholytic dermatosis. *Arch Dermatol* 101:426-434, 1970.

In Reply.—Drs Lockwood and Elias strive mightily to establish a case for bullous impetigo. They minimize the evidence that points to transient acantholytic dermatosis and deprecate the credibility of two experienced clinicians (my coauthors) who observed the cases reported. In rebuttal, let me point out that the degree of acantholysis was far in excess of that in impetigo and simulated pemphigus foliaceus, and no microorganisms were present in the many histologic sections. Incidentally, Ralph W. Grover, MD (ARCHIVES 101:426-434, 1970) reviewed our material prior to

submission for publication and concurred in the diagnosis.

Practicing dermatologists do not usually perform the extensive and costly laboratory work demanded by Drs Lockwood and Elias for bullous impetigo. In the office in which we practiced, there were no neonatal mice that we were aware of.

Houston

Ocular Involvement in Pyoderma Gangrenosum

To the Editor.—Pyoderma gangrenosum (PG) is an inflammatory disease of unknown origin that may be associated with ulcerative colitis and polyarthritis.[1-3] Ocular involvement, however, has not been reported to our knowledge. We observed a patient with PG of the left temporal region and ipsilateral ulcerative scleritis.

Report of a Case.—A 64-year-old man had had seronegative asymmetrical arthritis of the distal finger joints, the knees, and the sacroiliacal joints for many years. There was no evidence of rheumatic nodules, bowel disease, or a hematological disorder. In 1971, several inflammatory papules appeared on his left temple. Ulceration of these lesions resulted in a 6 × 10-cm defect with a highly inflamed margin (Fig 1). Simultaneously, severe scleral conjunctivitis of the left eye occurred and was followed by a scleral ulcer, anterior uveitis, and corneal opacity (Fig 2). Histological examination of biopsy specimens from both ocular and cutaneous lesions revealed a nonspecific inflammation. Laboratory test results were normal, with the exception of an increased ESR.

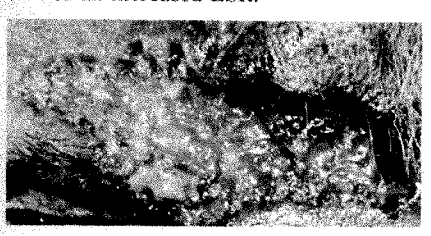

Fig 1.—Pyoderma gangrenosum of four months' duration.

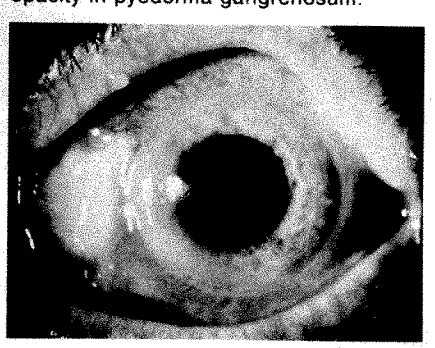
Fig 2.—Ulcerative scleritis with corneal opacity in pyoderma gangrenosum.



Local and systemic treatment with antibiotics was without effect. Cryotherapy of the scleral ulcer and treatment with cortisone for systemic effects (12 mg/day) was followed by improvement of the ocular lesions. The skin ulcer, however, persisted. Therefore, a combined therapy with prednisone and azathioprine was initiated, and prompt improvement was achieved. Reductions of the dosage led to recurrences on repeated occasions. With 50 mg of azathioprine and 5 mg of prednisone twice a week, the patient has been free of symptoms for three years.

Comment.—In PG, ocular manifestations have not been reported. Our patient's ipsilateral involvement and clinical course may indicate that both ocular and cutaneous lesions are owing to a common pathogenetic trait. Ulcerative scleritis may be an extracutaneous manifestation of PG. On the other hand, the ulcerative scleritis of our patient may be merely incidental. To make this point clear, all patients with PG should be examined for ocular involvement.

Macular Anetoderma in an Appendectomy Site

To the Editor.—The macular anetodermas are idiopathic atrophies of the skin characterized by multiple, discrete, oval lesions of loose, wrinkled, skin that may be depressed or bulge loosely. I report a particular case, in which a classical eruption was associated with the very elective occurrence of several lesions of anetoderma in an appendectomy site.

Report of a Case.—A 12-year-old girl had an eruption of macular anetoderma that appeared at the age of 8 years and developed gradually. When the patient was first seen, lesions were in the atrophic stage and had the characteristic bulging appearance. Pressure with the tip of the finger readily depressed the bulge, and a defect in the dermis was felt. The bulge reappeared when the finger was released, much like an umbilical hernia. The lesions were distributed over the shoulders, interscapular area, upper arms, and trunk. Subjective symptoms were absent. About 40 typical lesions were irregularly scattered over the body. A string of four typical macules of anetoderma was present in a small, appendectomy scar (Figure). The patient had undergone a classical appendectomy at the age of 5 years. According to her mother, the scar remained unchanged until the age of 10 years, when it became looser, bulging, and atrophic because of the development of lesions of anetoderma in this site. Histopathologic study showed the destruction and loss of elastic fibers, without perivascular infiltration.

Anetoderma in appendectomy site.

Comment.—The two following types of macular anetoderma are classically distinguished[1-4]: (1) secondary macular anetodermas that arise directly from inflammatory lesions (syphilids, tuberculids, urticarial lesions, purpuric lesions) and (2) primary macular anetodermas that arise from apparently normal skin. The case herein reported undoubtedly falls under the group of primary macular anetodermas. In this group, the localization of the eruption in old scars is exceptional, since in the literature, I have found only a case reported by Degos and Larregue,[2] in which some lesions had developed electively in chickenpox scars.

Therefore, it is possible to distinguish a new type of primary macular anetoderma, in which lesions electively occur in old scars. These findings might be compared with a recent report of lichen sclerosus et atrophicans in vaccination scars.[1]

Toxic Epidermal Necrolysis in Patients Who Are Allergic to Penicillin

To the Editor.—I congratulate Dr Elias and his associates for the excel-

lent review of staphylococcal scalded skin syndrome.[1] However, on page 212, in the "Treatment" section, the authors state that they are not aware of any study documenting the effectiveness of alternate drugs in treating patients with toxic epidermal necrolysis (TEN), who are allergic to penicillin. I would like to invite their attention to a report by Rudolph et al[2] (reference 84 cited in the article by Elias et al), where a 2-year-old boy (patient 9) who was suffering from *Staphylococcus aureus*-induced TEN and allergic to penicillin, was treated with erythromycin (150 mg/day) orally for eight days. His lesions cleared with desquamation in six days. This case clearly supports Dr Elias and colleagues' presumptive choice of using erythromycin as one of the alternates in treating patients with TEN, who are allergic to penicillin.

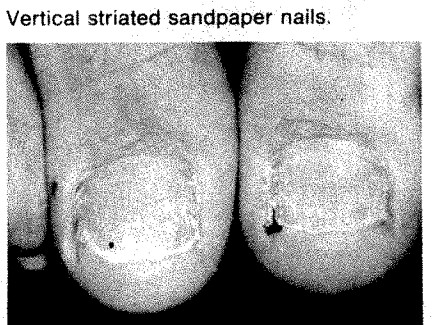
Vertical Striated Sandpaper Nails

To the Editor.—In a general sense, 25 years ago Alkiewicz[1] and, recently, Achten and Wanet-Rouard[2] described rough nails under the title "Trachyonychie."

In a study soon to be published in the *Annales de Dermatologie et Syphiligraphie*, we report on a number of cases of rough nails that are suggestive of an expression of alopecia areata and bear a clinical similarity to the cases reported by Drs Hazelrigg, Duncan, and Jarratt in their article "Twenty-Nail Dystrophy of Childhood" (ARCHIVES 113:73-75, 1977). The descriptive term *l'ongle grésé peladique* (vertical striated sandpaper nails) is offered (Figure). This entity, observed in both children and adults, may involve all 20 nails.

Vertical striated sandpaper nails.



When the vertical striated sandpaper effect is not uniformly distributed over the full expanse of the nail plates, the disorder may be caused by lichen planus or even psoriasis. Historical evidence of keratolytic degeneration supports this thesis.

Paraneoplastic Acrokeratosis of Bazex

To the Editor.—The entity paraneoplastic acrokeratosis of Bazex[1,2] has to be regarded as a true paraneoplastic syndrome affecting middle-aged men. The sudden clinical dermatological manifestations are related to the existence of a cancer; they may disappear if the malignant growth is removed, but appear again if there is a recurrence of tumor.[3] The cutaneous changes must alert the physician to search the upper respiratory and digestive tract for a malignant tumor, always a carcinoma, before it begins to produce it's own signs and symptoms.

The lesions are symmetrically located on the extremities, involving hands, feet, ears, and, rarely, the nose (Figure). Ungual involvement is constant and also the earliest manifestation. The nails are deformed by subungal hyperkeratosis that lifts their free edge. Their surface is irregular, flaky, and whitish. When the lesions are severe, their appearance is similar to a major psoriatic onychopathy, including even total nail loss.[4]

In some instances there is total or nearly total onychopathy, mostly of the toenails. The nail bed is replaced by a smooth, soft epidermis, and debris (remnants of the nail plate) are adherent to this epidermis by means of irregular, horny, ridged, and fissured formations. When ungual involvement is mild, only soft, thinned, crumbling, and cracking nails are seen.

Sometimes, both degrees of severity corresponding to two stages of the affection are shown in some observations in which the proximal third of the nail is atrophic, while in contrast the distal two thirds are hypertrophic.[5]

The dorsal aspects of the distal portions of toes and fingers are more or less sheathed by erythematous and

Foot showing symmetrical lesions of paraneoplastic acrokeratosis of Bazex. Nails are deformed, surface irregular, flaky, and whitish.

scaly patches. Perionyxis with intermittent suppuration is frequently seen. The tips of fingers and toes are covered with rough, fissured, and keratotic patches.

The pathological changes described by Bazex are not always present. There is allergic vasculitis in the dermis and the epidermal cells show a cytoplasm rapidly becoming eosinophilic and then disappearing and leading to vacuolated cells.

Bullous Erythema Multiforme

To the Editor.—In the December 1976 issue of the ARCHIVES (112:1757-1760), Drs Robinson and Samorodin presented a case report entitled "Thiabendazole-Induced Toxic Epidermal Necrolysis." The clinical presentation began initially with typical bullous erythema multiforme. This progressed to the picture of toxic epidermal necrolysis. The authors raised the issue of this conjunction. Moreover, they raised the interesting point that the immunologically changed lymphocyte may release a pharmacologically active agent that damages the epidermis.

Years ago at the US Naval Hospital, Chelsea, Mass, we saw a similar patient whose bullous erythema multiforme was initially treated with penicillin ointment followed by penicillin, given for systemic effects, that was administered on shipboard when the original, allergic nature of his disease was not appreciated by his paramedical attendants. His disease progressed to a point where he shed broad areas of skin. The mucous membrane involvement, high fever, and systemic deterioration continued as he received intramuscular penicillin for ten days.

Although he was desperately ill when seen at Chelsea, Mass, and he was thought to have smallpox, he recovered with massive amounts of intravenous adrenocorticotropic hormone that was available at that time.

I pondered with astonishment over the fact that he endured what we would call "delayed hypersensitivity" albeit severe, rather than go on to an acute anaphylactic course in the presence of continued antigen administration systemically. The development of modern immunologic theory has begun to clarify such issues.

However, I do not think that we have sufficient information to separate the drug type of toxic epidermal necrolysis from erythema multiforme until we have isolated the agent responsible for the epidermal necrosis, as is seemingly the case with the staphylococcal variety.

Chronic Bullous Dermatosis of Childhood

To the Editor.—Contrary to the comments of Esterly et al (ARCHIVES 113:42-46, 1977), linear deposition of IgA at the dermoepidermal junction may be found in 12% of cases of dermatitis herpetiformis (*Br J Dermatol* 92:157-166, 1975), as well as in "chronic bullous dermatosis of childhood."

Although this pattern appears to be more frequent in "chronic bullous dermatosis of childhood," than in dermatitis herpetiformis, it cannot be used as a reliable criterion for differentiating these two entities.

DAVID A. VORON, MD
Arcadia, Calif

In Reply.—We did not intend to imply that the finding of linear IgA at the dermoepidermal junction on direct immunofluorescence is diagnostic of chronic bullous dermatosis of childhood. In bullous pemphigoid, IgA can be found in a similar pattern, but IgG is the predominant immunoglobulin present, and the morphologic characteristic of the band is distinctive. In dermatitis herpetiformis, IgA can also be found along the dermoepidermal junction but is uncommon; such a patient was described recently by Yaoita et al.[1] The characteristic immunofluorescent finding in dermatitis herpetiformis is deposition of IgA in the dermal papillae and/or discrete granular deposits at the dermoepidermal junction, especially prominent in the dermal papillae.

It is becoming apparent that children who have a chronic eruption of large blisters with rosette formation and figurate erythematous plaques can have deposition of IgA along the dermoepidermal junction. All of the cases with positive immunofluorescent findings reported to date[2-5] have had this finding, including an additional case reported recently.[6]

Whether one calls this entity the large blistering type of juvenile dermatitis herpetiformis, mixed bullous pemphigoid-dermatitis herpetiformis, juvenile pemphigoid, or the "chronic bullous dermatosis of childhood,"[7] the disorder is a distinct clinical entity with characteristic immunologic abnormalities.

Nail Polish Remover Sensitization

To the Editor.—While one of my patients was using topical tretinoin on her face, she noticed that her nail polish came off. I hurriedly confirmed that tretinoin indeed removes nail polish (the liquid and swabs work much better than the cream or the gel), and I would consider this property worthy of note for patients who have become sensitized to nail polish remover.

Contaminated Fungal Cultures Owing to *Tyrophagus putrescentiae*

To the Editor.—Acarodermatitis is an occupational disorder caused by the stored-food mites of the families Tyroglyphidae and Pyemotidae. These normally nonpathogenic mites do occasionally cause skin irritations (cheese mite dermatitis, fig mite dermatitis, copra itch, grain itch, grocer's itch), which may become extremely severe, but are self-limited and never transmitted from person to person.[1-4]

Recently, one of these mites, *Tyrophagus putrescentiae*, was identified as the cause of our continuing failure to successfully culture dermatophytes from several of our private patients. Fungal cultures that originally appeared normal, rapidly and at an early stage, changed their appearance to that of gross bacterial contamination. Microscopic examination of these contaminated specimens demonstrated myriads of mites, which were subsequently identified as *T putrescentiae*. All existing cultures within our offices and all old cultures within the clinical laboratory's teaching collection were discarded. Working areas were decontaminated with gamma-benzene hexachloride spray. Lindane crystals were added to the stock teaching collection, and subcultures of this collection were made on Sabouraud's agar slants to which two drops of concentrated lindane in 95% alcohol were added. The lindane was added after autoclaving but before agar cooling (B. Russel, personal communication, 1977). Other, but equally successful, approaches to the control of these mites have been suggested.

These mites live not only on stored foods, such as cheeses and cereals, but also in molds and pathogenic fungii. Therefore, they should be suspected and looked for in those cultures whose early appearance is that of gross bacterial contamination.

Clarification of Lichen Planus Actinicus

To the Editor.—In the recent article by Dilaimy in the ARCHIVES (112:1251-1253, 1976), the author describes an annular lichen planus that is unique and clinically distinct in the Middle East countries and that he has named "lichen planus subtropicus."

However, I wish to refer to an article by Katzenellenbogen[1] in which the author describes similar features, ie, pigmented patches, with a slightly elevated border, on sun-exposed areas of the skin that are worsened by sun exposure and that occur in a younger age-group of persons than that in cases of classical lichen planus. In addition, this author describes a dyschromic and granular annulare variety of lichen planus in these patients.

Dilaimy does not mention these varieties dyschromic granuloma annulare) in his patients, but the similarity of the pigmented, annular, actinic lichen planus in these two articles should warrant the retention of the original name, lichen planus actinicus, rather than the renaming of the disease.

SYLVIA MARTIN, MD
Vancouver, British Columbia, Canada

1. Katzenellenbogen I: Lichen planus actinicus (lichen planus in subtropical countries). *Dermatologica* 124:10-20, 1962.

In Reply.—When we call a lesion "actinic," as in actinic keratotis, we imply that the lesion is caused by the sun. If the sun was one of many factors that caused a condition, we cannot call that condition actinic.

In lichen planus subtropicus, there are other factors that play a role in its origin besides the sun. These factors include heat, nutritional deficiencies, and genetic predisposition. Lichen planus actinicus is an existing clinical variety of lichen planus that usually follows a sunburn and is considered as a Koebner's reaction; the name "lichen planus actinicus" should be restricted to this variety of the disorder only.

MOUTA DILAIMY, MD

An Unusual Variant of Darier's Disease: A Therapeutic Suggestion

To the Editor.—In the March 1977 issue of the ARCHIVES (113:374), Dr Dolezal describes a severe case of the cornifying variant of Darier's disease that was widespread distribution, with painful, malodorous, and secondarily infected vegetations on the lower legs and feet. The article is illustrated with four color photographs that emphasize the patient's tragic plight. The patient was lost to follow-up for 11 years, but when seen again, the patient's condition had not changed. There was no mention of therapy on either occasion, except that the secondary infection had been cleared up with "tetracycline and acetic acid compresses" during his initial visits. When seen 11 years later, the malodorous infection was again present.

We reported the successful control of keratosis follicularis (Darier's disease) with the use of a combination of vitamins A and E (*Arch Dermatol* 106:909-910, 1972). Our patient was a 26-year-old man who had had a severe, widespread eruption of classical Darier's disease with notable photosensitivity for 13 years. He had failed to respond to vitamin A in a dosage of 200,000 IU daily, during a five-year period, but he became much worse if the dose was reduced.

A synergism between vitamin A and vitamin E was demonstrated by Ames,[1] who showed that the serum vitamin A level of rats that are on a vitamin E-deficient diet remained low, no matter how much vitamin A was given, either by mouth or by injection; however, the serum vitamin A level returned to normal when vitamin E was added to the diet.

On the basis of these experiments, our patient was instructed to continue a regimen of 200,000 IU vitamin A daily. This course was later reduced to 150,000 IU of vitamin A, and vitamin E was also given in the form of *d*-α-tocopheryl acetate, 1,200 IU daily. The patient was also instructed to avoid ingesting inorganic iron, either as a dietary supplement or in white bread or cereals that are reinforced with iron, since inorganic iron combines with and inactivates vitamin E. During the ensuing 15 months of observation, the eruption almost completely cleared.

We have observed two additional patients with Darier's disease, in a milder form, whose conditions cleared completely, and we are aware of 11 additional cases of Darier's disease or of pityriasis rubra pilaris that were successfully controlled with a combination of vitamins A and E. The fact that large doses of vitamin E appear to be the key to treatment of this condition does not necessarily mean that there was a deficiency in vitamin E intake, although a relative deficiency that is due to an abnormally high requirement from congenital or acquired causes, or a defect in absorption or utilization of the vitamin may be indicated.

In any event, we would strongly recommend a therapeutic trial of the combined vitamins for treatment of this spectacular occurrence of cornifying Darier's disease.

Griseofulvin Therapy in Molluscum Contagiosum

To the Editor.—Griseofulvin has recently been found useful in the treatment of viral warts (unpublished data) and molluscum contagiosum.[1] Keeping this in mind, we treated five cases of extensive molluscum contagiosum with griseofulvin fine particles, giving dosages of 500 mg a day, orally, for patients above 14 years of age, and half this dosage for younger patients. The treatment was continued for four to six weeks. The patients ranged in age from 4 to 17 years and had had lesions for 15 to 30 days. In each patient, the lesions started to regress within two weeks after treatment was begun, and the lesions completely disappeared in four to six weeks. There had been no recurrence of the condition in any of these patients after six to eight months of follow-up.

Although further studies are required to attribute antiviral activity to griseofulvin, disappearance of the lesions in every case within a few weeks of therapy is notable. Without treatment, the lesions are known to persist for six to nine months, or even as long as three to four years.[2]

Treatment of Atopic Dermatitis With the Scholtz Regimen

To the Editor.—Atopic dermatitis continues to present a challenge to the dermatologist, in spite of much research on the theoretical aspects of the immunological process. We would like to call attention again to an important contribution by Dr Jud R. Scholtz in two papers on the management of atopic dermatitis that were published in 1964 and 1965.[1,2] We have designated Scholtz's technique as the "Scholtz regimen," and we have used this method during the ensuing 14 years for the successful control of this recalcitrant disease.

We feel that the dramatic response of atopic dermatitis to the Scholtz regimen is comparable to the advancement in the therapy of infections by the introduction of antibiotics, and of inflammatory diseases by corticosteroids; the Scholtz regimen has not received the attention that it merits.

Our introduction to this new technic for the management of atopic dermatitis occurred at the October 1963 meeting of the Los Angeles Dermatological Society, when Scholtz reported on two lifelong victims of this harassing disease. Both individuals, in their middle years, appeared to have perfectly normal skin with no trace of inflammation. Only after reading the protocols and examining pretreatment color transparencies, did one become aware of the fact that this treatment had transformed these two sufferers from chronic dermatologic invalids into normal and happy members of society. As might be expected, several highly critical skeptics expressed their disbelief.

The rationale of the Scholtz regimen is based on the concept of an impaired functioning of the skin with especial reference to a defective sweating mechanism, associated with dryness, as reported by Sulzberger and his colleagues.[3,4] Food sensitivities, emotional disturbances, and contact irritants may be important secondary factors, but without correction of the long overlooked primary defect of skin function, treatment will be unsatisfactory.

The Scholtz regimen is divided in two main categories: things to avoid, and things to do; the factors in these categories must be scrupulously observed indefinitely if satisfactory results are to be achieved. We have made several minor modifications in Scholtz's original program that we feel have improved patient cooperation.[5] The regimen is summarized following:

Prohibitions.—No soap on affected areas; no contact with water except for brief, one-minute showers; no topical applications containing oil or grease, which might occlude sweat ducts; no heavy exercise (such as tennis), which would tend to promote perspiration; no wool, rough, or occlusive clothing; no exposure to occupational or household irritants; no oral steroids.

Topical Therapy.—Cetaphil lotion, a nonlipid, softening and cleansing lotion, followed immediately by .01% fluocinolone acetonide lotion (Synalar solution) twice daily, or oftener as needed. If secondary infection is present, .5% Neomycin sulfate with .025% fluocinolone acetonide (Neo-Synalar cream) may be used temporarily.

Systemic Therapy.—Scholtz recommended small doses of thyroid, once or twice daily if there is evidence of hypothyroidism or if the pulse is slow; and vitamin A, 10,000 IU to 100,000 IU daily (depending on age) if the skin is excessively dry. Oral antibiotics may be given for a short time if there is pronounced secondary infection. Foods that have been observed to aggravate the condition should be avoided.

We have treated all of our atopic dermatitis patients with this regimen since Scholtz first reported it in 1963. During these 14 years, we have had uniformly excellent results, sometimes with a 75% or 80% improvement within two or three weeks. There have been a few instances of relapse, but usually these occurred when the patient had gotten "off the beam," and had resumed frequent and prolonged bathing or other prohibited activities. We have seldom found it necessary to restrict the patient's diet or to administer thyroid, vitamin A, or antibiotics.[5,6]

The effectiveness of the regimen was dramatically emphasized in the case of a 26-year-old man who was seen in our office within the past month. The patient had suffered from atopic dermatitis at intervals since infancy, and he had suffered continuously during the past year and severely during the preceding three weeks. At the time of his second visit, two weeks after beginning the Scholtz regimen, the patient's eruption was 90% clear.

Dapsone-Induced Hepatic Changes

To the Editor.—Dapsone is a sulfone commonly used in the treatment of dermatological diseases, eg, leprosy and dermatitis herpetiformis and, on occasion, in the treatment of acne conglobata, erythema elevatum diutinum, relapsing polychondritis, and actinomycetoma. The side effects of dapsone, including hemolytic anemia and methemoglobinemia, agranulocytosis, diverse dermatoses, neuropathy, and upper gastrointestinal disturbances are generally well appreciated. Recently, I noted three patients who were on dapsone regimens (one patient for Hailey-Hailey disease, and two patients for dermatitis herpetiformis) who developed abnormalities in the results of their liver function tests.

Report of Cases.—All three patients were healthy aside from their dermatological conditions; they had normal glucose-6-phosphate dehydrogenase levels, had regularly screened normal blood counts and methemoglobin levels, and normal BUN, serum phosphorus, calcium, glucose, cholesterol, total protein, albumin, and alkaline phosphatase levels. Abnormal levels of lactic dehydrogenase, SGOT, and total bilirubin were observed consistently (Table).

Patient 1 began taking dapsone, 600 mg daily because of a pharmacy error. This error was discovered, and the medication was discontinued four days later after the patient had complained of malaise, fatigue, weakness, and gastrointestinal upset. Three weeks later, a regimen of dapsone was started at a dosage of 150 mg/day. In late April 1976, dapsone was discontinued because of recurring malaise and gastrointestinal problems and because of persistently abnormal results of liver function studies. Results of liver function studies returned to normal in May 1976, and remained normal until July 1976. In February 1977, the patient resumed the use of dapsone for treatment, at 150 mg daily, and again the results of his liver function studies became abnormal (Table); malaise, fatigue, and gastric symptoms prevailed and necessitated discontinuation of the use of dapsone. The results of liver function studies normalized within four weeks.

Patients 2 and 3 have been on continued regimens of dapsone (150 mg/day) and are

taking dapsone regularly despite the abnormalities of test results.

Patients 1 and 2 had gastroenterology consultations. Despite extensive workup, excluding liver biopsies, no reason for the abnormal results of liver function studies was uncovered. Dapsone was tentatively deemed the culpable agent.

Comment.—The purpose of this letter is threefold:

1. To alert colleagues to the potential of dapsone to cause abnormalities of hepatic function. Despite careful screening of several review articles on the side effects of dapsone, I have not found any mention of such hepatic changes. Neither have pharmacology texts been helpful on this subject.
2. To solicit confirmatory reports or literature references on this subject.
3. To stimulate investigations of the cause of these liver function changes and to determine the long-range effects of continued dapsone therapy.

Lymphomatoid Papulosis

To the Editor.—I wish to correct a misunderstanding introduced by the phrase, "lymphomatoid papulosis, or as he has named it, 'Rhythmic Paradoxical Eruptions,'" which refers to my use of nomenclature and appears in the first paragraph of Drs Thomsen and Schmidt's letter to the editor (ARCHIVES 113:232-233, 1977). The term "lymphomatoid papulosis" is not exactly synonymous with the term "rhythmic paradoxical eruption." Rather, lymphomatoid papulosis is one band in the spectrum of the rhythmic paradoxical eruptions.

In collecting data on lymphomatoid papulosis, it became apparent to me that there are a number of conditions, as yet unnamed and unclassified, that fit the description of "a continuing, self-healing eruption, clinically benign—histologically malignant."[1] Although they have many features in common, such as lesions coming and going for protracted periods of time, and they follow an apparent benign course while having histopathologic characteristics of a malignant lymphoma, these conditions differ in certain clinical features, histologic patterns, and prognosis. In short, there seems to exist a whole spectrum of continuing, self-healing eruptions that have the histopathologic characteristics of a malignant lymphoma of one type or another. To encompass this constellation of similar yet different disorders, I proposed the term "rhythmic paradoxical eruptions"[2] and assigned lymphomatoid papulosis as one band in this unusual spectrum of eruptions.

The foregoing concept is expounded in more detail with case histories and bibliographic review in a communication entitled "Lymphomatoid Papulosis and Some Other Rhythmic Paradoxical Eruptions," scheduled to appear in a forthcoming issue of the *International Journal of Dermatology.*

2. Macaulay WL: Lymphomatoid papulosis and rhythmic paradoxical eruptions. Read before the Clinicopathologic Conference of the American Academy of Dermatology, San Francisco, December 1975.

In Reply.—Firstly, I want to thank Dr Macaulay, the father of the term "lymphomatoid papulosis," for his remarks on nomenclature. Secondly, allow me to make use of the opportunity to report yet another case of lymphomatoid papulosis that coexisted with parapsoriasis en plaque.

Report of a Case.—A 64-year-old man was referred to us two months ago with parapsoriasis en plaque since 1974, which was clinically characteristic and without poikiloderma. Histologic findings did not show evidence of mycosis fungoides. The eruption was localized to the lower back, the buttocks, hips, and thighs. Since the summer of 1975, he also had a recurring eruption of 3- to 5-mm, dark red papules on the buttocks, thighs, and legs, which left small, depigmented scars. Histologic findings showed a dermal infiltrate of abnormal lymphoreticular cells, some of which resembled Reed-Sternberg's cells. Pautrier's abscesses were not seen. The rest of the results of physical examination were normal, with no enlargement of lymph nodes, liver, or spleen. Results of routine blood tests and a roentgenogram of the lungs were all normal.

A valuable guide to diagnostic and therapeutic procedures for the cancer patient

Current Concepts in Cancer

While national attention focuses on cancer through specialized cancer centers, physicians are aware that the majority of cancer patients are treated in office practices. For most practicing physicians, cancer treatment is not a research objective, but a very practical problem in patient management.

Current Concepts in Cancer, a compilation of articles originally published in the *Journal of the American Medical Association,* is designed to be a guide for the practitioner in the choice of diagnostic and therapeutic procedures for many types of malignancies. It presents an objective interdisciplinary view by MDs outstanding in their respective fields, emphasizing principles of diagnosis and surgical, radiotherapeutic, and chemotherapeutic treatment.

Selsun®

(SELENIUM SULFIDE LOTION, U.S.P.) ℞

Brief Summary

Contains:

Selenium sulfide, 2½%, w/v; bentonite; lauric diethanolamide; ethylene glycol monostearate; titanium dioxide; amphoteric—2; sodium lauryl sulfate; sodium phosphate (monobasic); glyceryl monoricinoleate; citric acid; captan; perfume; and water.

Indications:

For the treatment of dandruff and seborrheic dermatitis of the scalp.

Contraindications:

Should not be used by patients allergic to any of its components.

Warnings:

Safety for use on infants has not been established.

Precautions:

Cutaneous sensitization of the scalp or adjacent areas has been reported; if sensitivity reactions should occur, discontinue use. Chemical conjunctivitis may result if product enters the eyes. Do not use when acute inflammation or exudation is present as an increase in absorption may occur.

Adverse Reactions:

As with other shampoos, oiliness or dryness of the hair and scalp may occur following use; there have been occasional reports of an increase in the amount of normal hair loss. Hair discoloration may occur; can be avoided or minimized by thorough rinsing.

For Skin Without Water

Neutrogena® Dry Skin products are specially formulated to supplement surface fats and aid in the retention of moisture.

- Neutrogena® Dry-Skin Soap contains humectants, lubricants, and emollients to soften and moisturize, and is nonirritating to sensitive skin.
- Neutrogena® Rainbath® Dry Skin Bath Gel is lipid-free, cleanses with a rich lather without the drying effect of ordinary soap, and leaves skin soft and smooth. Available both scented and unscented.
- Neutrogena® Hand Cream is a heavy-duty formula containing a special blend of naturally occurring oils and glycerin, and is a useful adjunct in steroid-responsive hand dermatoses.[1]

LOS ANGELES DERMATOLOGICAL SOCIETY
May 11, 1977

Arnold W. Gurevitch, MD, Recorder

Atrophoderma (Type Unknown). Presented by ARNOLD W. GUREVITCH, MD, DORE J. GILBERT, MD.

This 20-year-old woman has had an asymptomatic eruption on her legs for 3½ years, with recent spread to her trunk and right upper arm. She also complains of tender, red areas on her buttocks that she believes are secondary to being bathed in chlorine bleach as a child.

Various topical creams have produced no beneficial results.

Multiple macular, erythematous lesions are seen on both thighs, within which are regions of circumscribed atrophy. The right upper arm, as well as the trunk, reveals small pink papules. The buttocks show extensive bilateral and symmetrical atrophic, tender, and very erythematous areas, with marked wrinkling of the skin.

Four punch biopsy specimens were taken from normal skin, a small erythematous papule, an atrophic macule, and from the atrophic buttock lesion. They were stained with hematoxylin-eosin and for elastic tissue.

Discussion

LEO INDIANER, MD: Histologically, the lesions show atrophy of the epidermis, basilar vacuolopathy, exocytosis of lymphocytes and monocytes, and a tremendous upper dermal inflammatory infiltrate of lymphocytes and histiocytes. Of interest is that the elastic tissue is greatly decreased. In some areas, it is almost completely lost. In other areas, the elastic fibers are thin, almost whittled down. This change is quite characteristic of what has been called "elastolytic," in which there is a tapering of the long ends of the elastic fibers, and the elastic fibers appear longer than usual. These changes alternate with areas in which the elastic fibers are fairly normal, or minimally altered. In this case, it represents an inflammatory process.

The question is: how should this lesion be classified? It could be classified as macular atrophy of Jadassohn, which is the inflammatory type of macular atrophy, except that those lesions are small, generally 0.5 to 1 cm in size. Most of the lesions of macular atrophy of the inflammatory type that I am accustomed to seeing are no larger than a thumbprint. However, the type of process we are seeing here has been described in the literature as "postinflammatory elastolysis." The lesions are characteristically 10 to 20 cm in size, and they have a tremendous inflammatory infiltrate and elastolysis. They occur in young individuals and particularly involve the buttocks, but they can involve other areas of the body. There may be smaller areas of the 1-cm size but more characteristic are the large lesions.

We have not been able to pinpoint the origin of this problem. Is it secondary to a collagen vascular disease? Is it a variant of poikiloderma vasculare atrophicans? Will it respond to penicillin, as some cases of elastolysis do? We cannot tell. May this be a precursor to mycosis fungoides, which will develop in lesions that show elastolysis, inflammation, and atrophy of the epidermis? The only thing we have been able to do, I believe, is to classify it as other than a simple macular atrophy. Its proper classification is postinflammatory elastolysis.

IRWIN LINDEN, MD: Were the biopsy specimens from the other lesions the same histologically as the biopsy specimen from the hip?

DR INDIANER: Three of the biopsy specimens show a tremendous inflammatory infiltrate. Two of the three show epidermal atrophy. All three did show foci of elastolysis, varying in degree from minimal to extensive, and the control, from normal skin, showed just some mild perivascular inflammatory infiltrate without elastic alteration.

LOUIS WINER, MD: I agree wholeheartedly with Dr Indianer's histologic description. Clinically, if this lesion were on the legs or arms, you would call it acrodermatitis chronica atrophicans. Histologically, it is just what was described: loss of elastic, elastolysis, an infiltrate hugging the epidermis, and atrophy of the epidermis. Clinically, there is a cigarette-paper wrinkling on the surface. Prior to the penicillin era, we used to see this eruption in Minneapolis, and even here I have seen cases of it. It has been shown that some cases respond to penicillin. I believe the clinician in this case should treat this patient with penicillin, and not do anything else, to see if the lesions respond.

DR GUREVITCH: I remain very puzzled as to what is going on in this woman. It is of interest that these lesions are progressing, and some of them are progressing rather rapidly. She has newly developing lesions on her abdomen. The new ones are small papules, whereas slightly older lesions, as on her arm, are small, macular areas of atrophy with a cigarette-paper type of wrinkling on the surface. Some of those individual lesions on her arm and on her leg look like the macular atrophy of Jadassohn's type. However, as Dr Indianer pointed out, there are just too many alterations, both clinically and histologically, for that diagnosis. And finally, the buttock eruption looks quite different. These changes on her buttocks have been there since infancy. Unfortunately, she was adopted by her aunt and uncle, and we do not have an adequate history of these lesions. She was told that she was dipped in chlorine bleach as an infant, and her current family blames the buttock eruption on that. Her buttocks are not only very soft and atrophic; they are also very tender. This combination is puzzling. We also considered acrodermatitis chronica atrophicans, but this is not only exceedingly rare in the United States, occurring mostly in people of European origin, but it also tends to begin distally, down around the ankles and feet, the lower legs, and may progress up to the thighs. Occasionally, it involves other areas but usually after progression from the legs. Many cases will, after several years, show evidence of fibrosis with banding. She has no evidence

of these fibrotic bands. So, she does not fit very well into that category either. I am not yet sure exactly how to categorize her unusual problem.

Feb 9, 1977

Arnold W. Gurevitch, MD, Recorder

Congenital Linear Porokeratosis. Presented by MORTON D. SCRIBNER, MD.

A 13-month-old girl was noted at birth to have an eruption on the left leg. The lesions have enlarged only in proportion to her growth, have not spread, and have not been pruritic. Family history is negative for similar skin disorders, consanguinity, diabetes, or psoriasis.

Physical examination reveals a healthy-appearing infant with numerous lesions that extend down the left thigh and leg in a band-like pattern. The patches are round and reddish-brown, and have sharp, slightly elevated margins.

A biopsy specimen was interpreted by Dr Bernard Gottlieb as follows:

"There is marked focal epidermal acanthosis associated with columns of parakeratotic material and loss of the stratum granulosum. There is benign dyskeratosis within the epidermis beneath the parakeratotic masses, but there is no mitotic activity or atypia and the change is not malignant in character. The marked parakeratosis and hypogranulosis virtually exclude simple ichthyosis and rule against ichthyosis hystrix of the usual type. Although the designation epithelial hamartoma is preferred, the pattern is that of linear porokeratosis. Although other types of linear epithelial nevi can be parakeratotic and psoriasiform in character, the sharp definition of the parakeratotic columns is somewhat against this possibility."

Flurandrenolide cream, applied four times daily for two months gave no improvement. One month ago, nightly application of tretinoin (retinoic acid; 0.05% Retin-A cream) was begun. Because of irritation, flurandrenolide cream is now being used two or three times during the day in addition to the tretinoin cream. There has been some improvement during the past few weeks.

Discussion

LEO INDIANER, MD: The histological features of this case bring up many points about porokeratosis. The biopsy specimen reveals thick columns of parakeratotic cells that alternate with areas of massive hyperkeratosis. Beneath the parakeratotic columns is a zone with absence of the granular layer and notable acanthosis, in which there are large dyskeratotic cells, proliferating smaller epithelial keratinocytes, and multiple small basaloid cells all intermingled. Also of interest, within the stratum corneum are large colonies of bacteria that are seen as basophilic granular material. In the differential diagnosis of linear lesions, the only diagnosis that would seem to fit in this case is porokeratosis. Lichen striatus, linear epidermal nevi of the usual type, linear psoriasis, and linear lichen planus do not fit in this histological pattern. However, in other entities, such as inflammatory linear verrucous epidermal nevus, there can be an inflammatory disorder occurring within the epidermis and resembling psoriasis. This inflammation may be associated with parakeratosis and even microabscesses within the stratum corneum. However, the parakeratosis is either spotty or diffuse, rather than in columns as occurred in the case presented.

Could this be an epithelial hamartoma? The linear hamartoma is of follicular origin, so that a tremendous amount of verrucous acanthosis with dyskeratotic cells, proliferating basaloid cells, and keratinocytes, resembling an inverted follicular keratosis, could be a part of the linear hamartoma syndrome. Yet, the parakeratotic columns seen in this case would be unusual for that entity. My own feeling is that much of the peculiar epidermal reaction in this case is due to the bacterial proliferation. I think a biopsy specimen from another lesion that had been treated with a topical antibiotic beforehand might give a purer picture of porokeratosis.

This case would have to be classified as a linear form of porokeratosis. The correlation between this form of porokeratosis and other variants is often discussed. Persons with linear lesions before the age of 5 years may develop the Chernosky type of disseminated superficial actinic porokeratosis later in life. In some patients with porokeratosis, squamous cell carcinoma has developed, even though the histopathology, aside from the presence of dyskeratotic cells, does not suggest cancer. I believe that this patient does have linear porokeratosis, but I think that biopsies of noninfected areas might reveal a clearer histology.

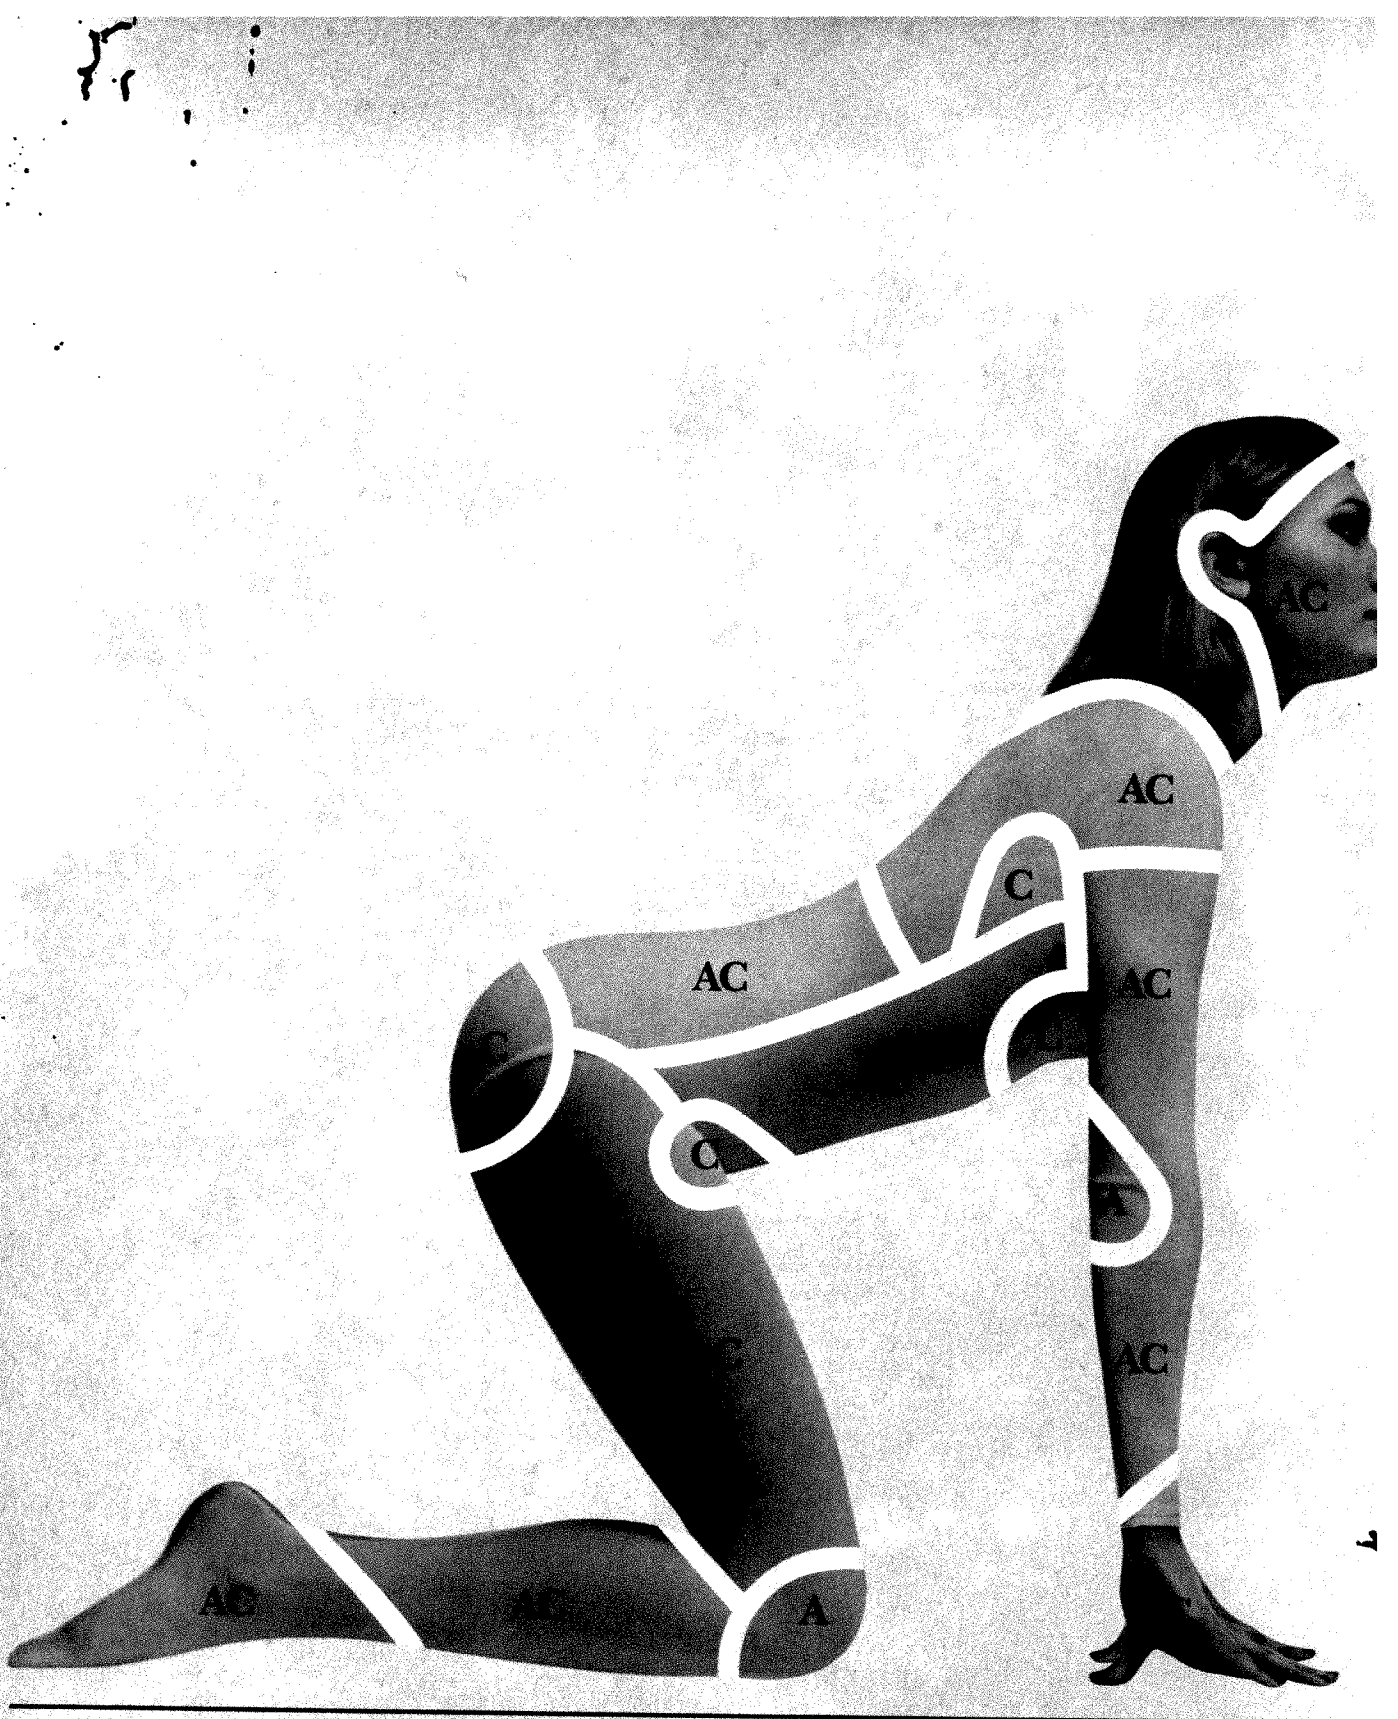
REID BINDER, MD: Is it the current feeling that porokeratosis is an accurate name?

DR INDIANER: The parakeratotic process in porokeratosis follows the periphery of the entire lesion. There is no way that we can postulate a sweat duct going all the way around a single lesion and enveloping it. The parakeratotic cornoid lamella involves epithelium in areas other than sweat pores and can also occur on buccal mucous membrane and on penile areas in which there are no duct openings. Therefore, porokeratosis is not an accurate term.

SAMUEL AYRES, JR, MD: We do not see cases of this condition very often. In the last case of porokeratosis of Mibelli that I had occasion to see, there were scattered lesions, some of which were linear and some patchy. My patient made good progress on a regimen of tretinoin, but this progress eventually came to a standstill. Ultimately, the patient achieved almost complete resolution after treatment with liquid nitrogen. The patient presented here, according to the mother, has made some progress with topical tretinoin. I would say that if this patient does not continue to respond to the tretinoin, I would certainly try liquid nitrogen in the hope of getting a complete response.

MORTON SCRIBNER, MD: In France, there has been one published report of clearing with 5% tretinoin. So far, this patient has had difficulty tolerating .05% tretinoin.

VICTOR NEWCOMER, MD: A similar case of porokeratosis at the UCLA School of Medicine exhibited striking improvement with tretinoin after a very brisk inflammatory response.



FOR THE

Clinical experience

A total of 984 psoriatic patients in US clinical studies were treated with either the Solution, the Creams, or the Ointment. After 2 weeks' therapy,* 151 (78%) of 194 patients improved with Halog Solution, 407 (92.5%) of 440 patients improved with full-strength (0.1%) Halog Cream, 132 (72%) of 184 patients improved with quarter-strength (0.025%) Halog Cream, and 145 (87%) of 166 patients improved with Halog Ointment.

In general, the preferred topical formulations for lesions in specific areas are: solutions for scalp lesions, creams for moist areas/lesions, and ointments for dry areas/lesions. The studies cited above, however, were not limited to lesions in these specific areas.

*Majority of patients evaluated after 2 weeks' therapy. Data on file at Squibb Institute for Medical Research.

See next page for brief summary.

HALOG®

HALCINONIDE

SQUIBB®

©1977 E.R. Squibb & Sons, Inc. 357-508

HALOG® (Halcinonide) Cream/Ointment/Solution

Halog Cream 0.025% (Halcinonide Cream 0.025%) and Halog Cream 0.1% (Halcinonide Cream 0.1%) contain 0.25 mg. and 1 mg. halcinonide per gram, respectively, in a specially formulated cream base. Halog Ointment (Halcinonide Ointment 0.1%) contains 1 mg. halcinonide (0.1%) per gram in Plastibase® (Plasticized Hydrocarbon Gel), a polyethylene and mineral oil gel base. Halog Solution (Halcinonide Solution 0.1%) contains 1 mg. halcinonide (0.1%) per ml.

CONTRAINDICATIONS: Topical steroids are contraindicated in vaccinia, varicella, and in those patients with a history of hypersensitivity to any of the components of the preparations. These preparations are not for ophthalmic use.

PRECAUTIONS: *General*—If local infection exists, suitable concomitant antimicrobial or antifungal therapy should be administered. If a favorable response does not occur promptly, application of the corticosteroid should be discontinued until the infection is adequately controlled. If extensive areas are treated or if the occlusive technique is used, the possibility exists of increased systemic absorption of the corticosteroid and suitable precautions should be taken. If irritation or sensitization develops, the preparation should be discontinued and appropriate therapy instituted. Although topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use during pregnancy has not been absolutely established; therefore, they should not be used extensively on pregnant patients, in large amounts, or for prolonged periods of time.

Occlusive Dressing Technique—The use of occlusive dressing increases the percutaneous absorption of corticosteroids; their extensive use increases the possibility of systemic effects. For patients with extensive lesions it may be preferable to use a sequential approach, occluding one portion of the body at a time. The patient should be kept under close observation if treated with the occlusive technique over large areas and over a considerable period of time. Occasionally, a patient who has been on prolonged therapy, especially occlusive therapy, may develop symptoms of steroid withdrawal when the medication is stopped. Thermal homeostasis may be impaired if large areas of the body are covered. Use of the occlusive dressing should be discontinued if elevation of the body temperature occurs. Occasionally, a patient may develop a sensitivity reaction to a particular occlusive dressing material or adhesive and a substitute material may be necessary. If infection develops, discontinue the use of the occlusive dressing and institute appropriate antimicrobial therapy.

ADVERSE REACTIONS: The following local adverse reactions have been reported with topical corticosteroids: burning, itching, irritation, striae, skin atrophy, secondary infection, dryness, folliculitis, hypertrichosis, acneform eruptions, and hypopigmentation. The following may occur more frequently with occlusive dressings: maceration of the skin, secondary infection, skin atrophy, striae, and miliaria. Contact sensitivity to a particular dressing material or adhesive may occur occasionally (see PRECAUTIONS).

For full prescribing information, consult package insert.

HOW SUPPLIED: The 0.025% and 0.1% Cream and the 0.1% Ointment are supplied in tubes of 15 g. and 60 g., and in jars of 240 g. (8 oz.). The 0.1% Solution is supplied in plastic squeeze bottles of 20 ml. and 60 ml.

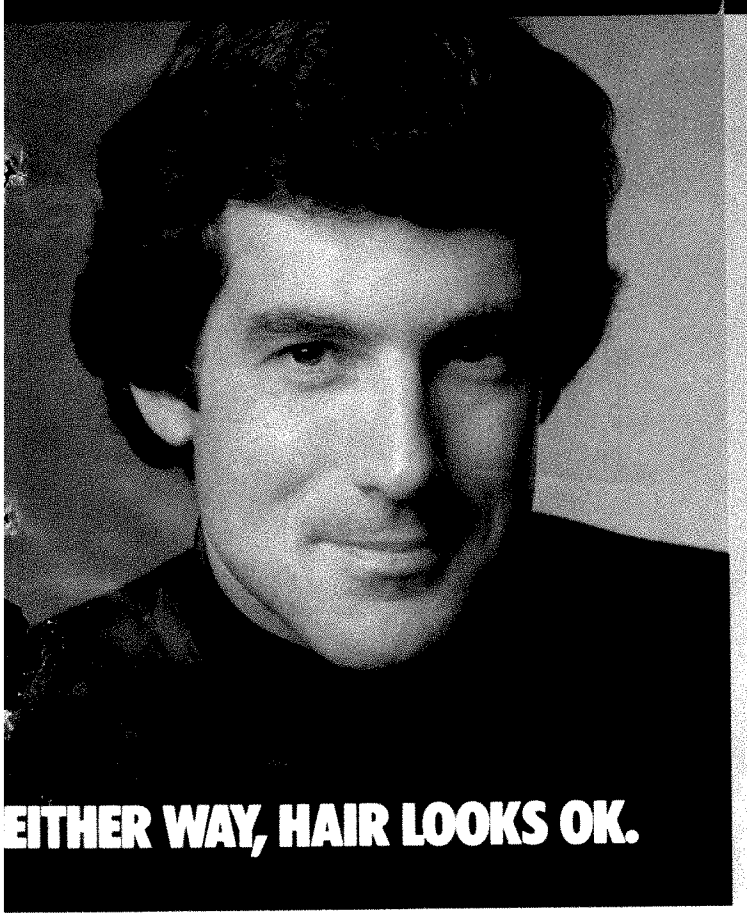
BARNES HIND OFFERS TWO Rx EXCLUSIVES FOR SEBORRHEIC DERMATITIS



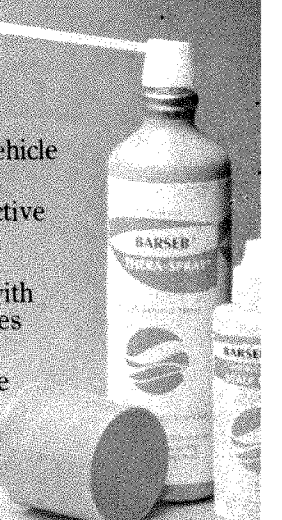
You can offer your seborrheic patients a choice of remedie that are effective yet cosmetically elegant—Barseb® Thera-Spray® and Barseb® HC Scalp Lotion.

Either way, you'll be prescribing Barnes Hind exclusive combinations of hydrocortisone and salicylic acid with their proven anti-inflammatory, antipruritic and keratolytic capabilities.

Without mussing the hair, the Thera-Spray snorkel directs the active ingredients onto the scalp in a vehicle that spreads and penetrates.

The Barseb HC base holds the active ingredients on the skin, not on the hair shafts. Barseb HC won't dry hair, or increase oiliness. And it's compatible with hair sprays, colorings, permanent waves and grooming agents.

Both Thera-Spray and Lotion are clear, non-staining, odorless.



BARSEB® THERA-SPRAY®
BARSEB® HC SCALP LOTION

(hydrocortisone and salicylic acid)

For complete prescribing information, please see package insert.

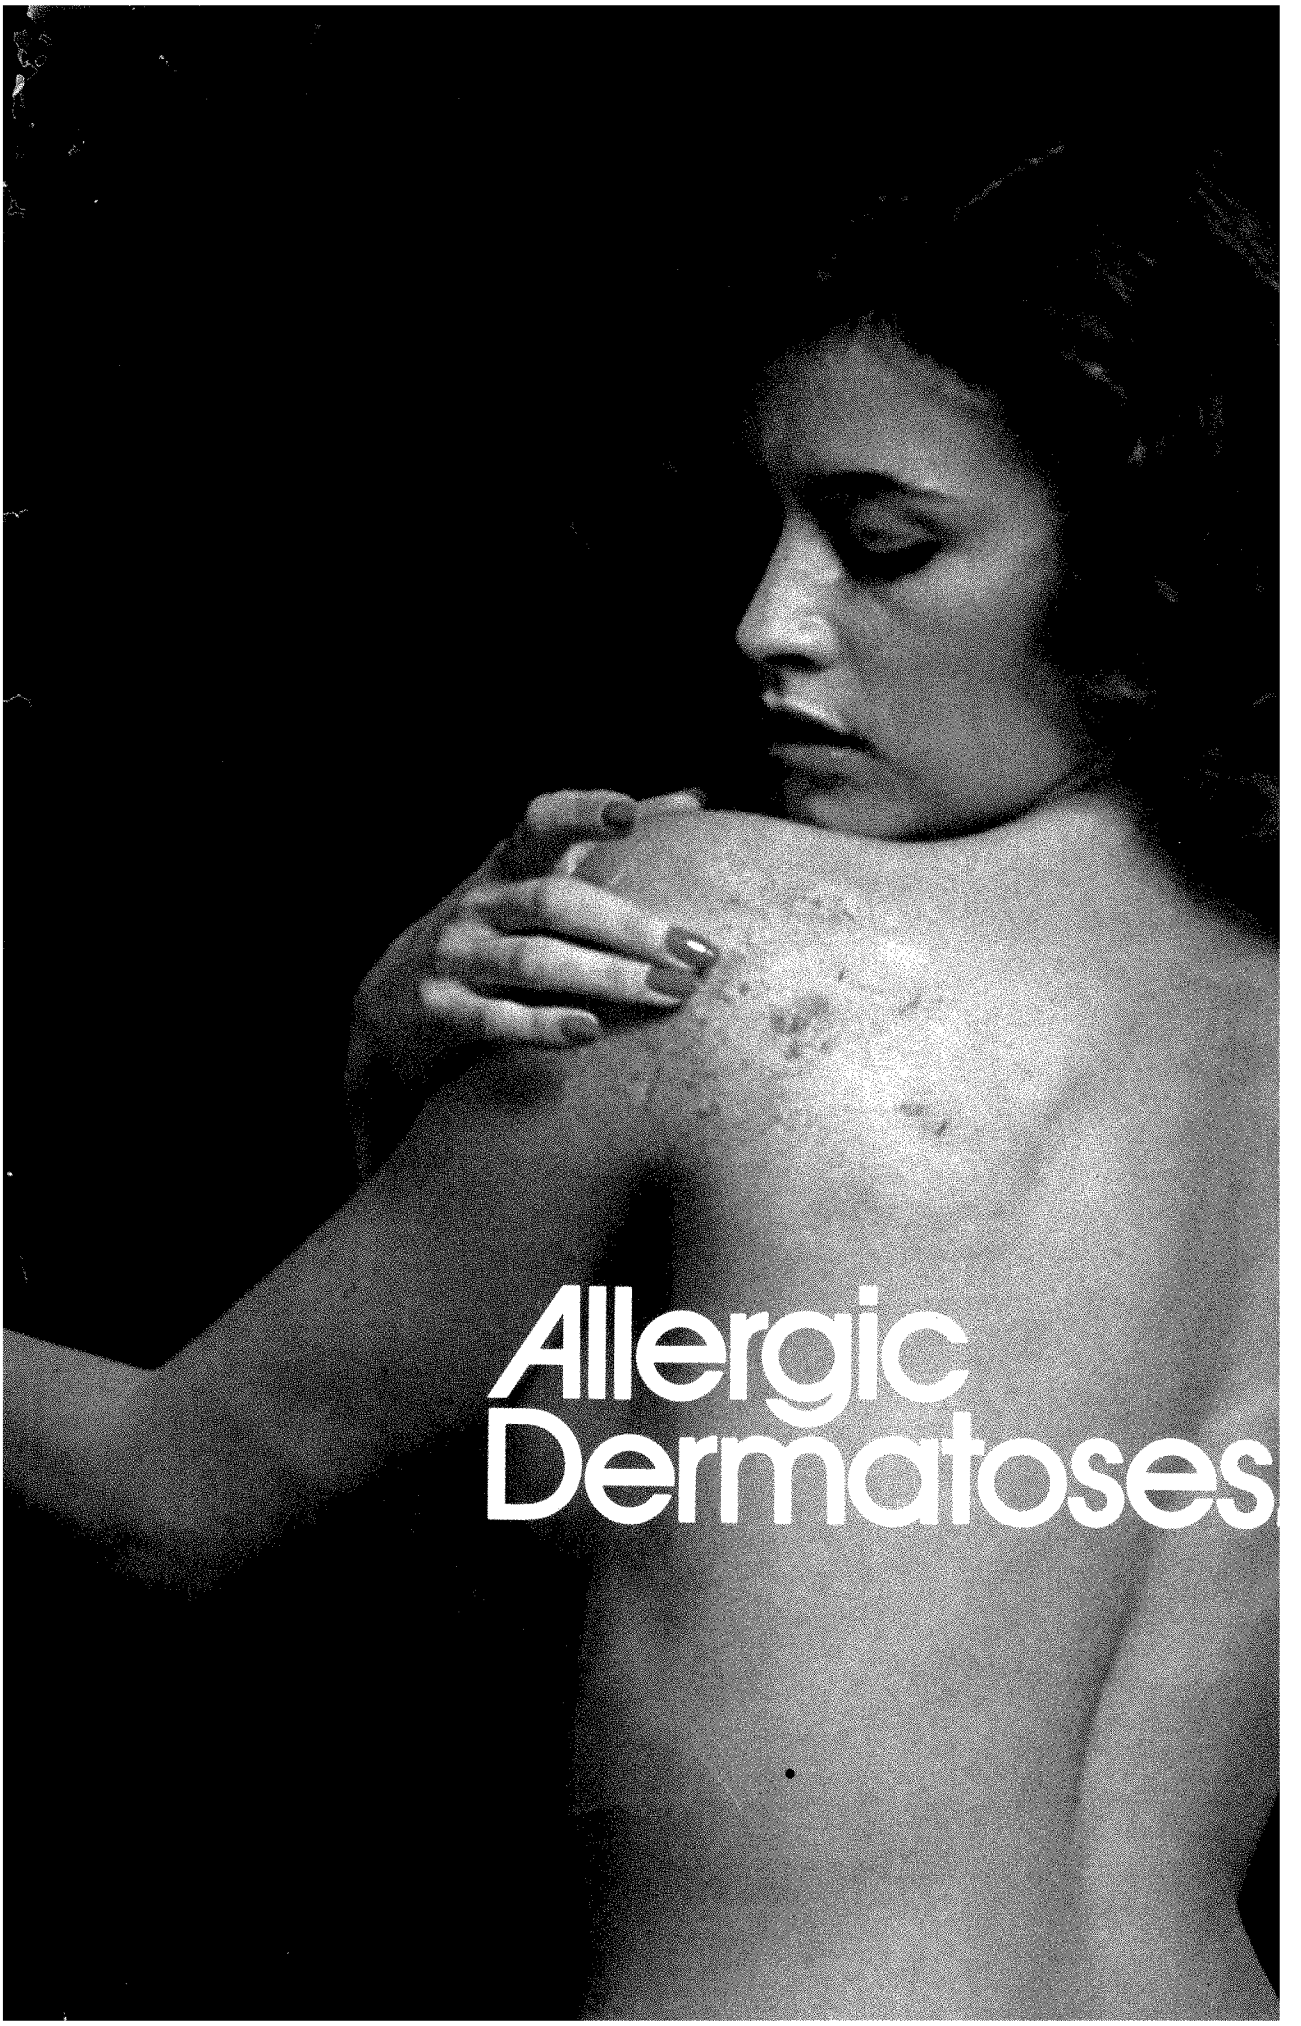
CONTRAINDICATIONS
Hydrocortisone is contraindicated in tuberculosis, fungal, and most viral infections of the skin (especially herpes simplex, vaccina and varicella, etc).

WARNING
While topical steroids have not been reported to have an adverse effect on pregnancy, the safety of their use has not been absolutely established. Therefore, they should not be used extensively on pregnant patients in large amounts nor for long periods of time.
Avoid inhalation, ingestion or contact with eyes or nose.
BARSEB® THERA-SPRAY
Contents under pressure. Do not puncture, burn or

PRECAUTIONS
Transient discomfort may occur when first applied to an inflamed scalp. This normally disappears with repeated use. Discontinue use if condition does not improve or if sensitivity reactions occur. The anti-inflammatory action of hydrocortisone may mask the presence of infection. If bacterial or fungal infection exists or supervenes, concomitant antimicrobial or antifungal therapy should be considered. When topical steroids are used on large areas of skin for long periods of time, there is the possibility of systemic absorption. Should adrenal suppression, electrolyte imbalance, metabolic changes, or other symptoms of systemic absorption occur, suitable counter measures should be taken. Precautions should be taken when hydrocortisone is used in the treatment of skin diseases associated with impaired circulation such as stasis dermatitis.
Avoid spray inhalation, ingestion, or contact with eyes or nose. If medication accidentally gets into eyes, immediately flush with copious amounts of water; if irritation persists, notify your physician.
Keep out of reach of children.

CAUTION
U. S. Federal law prohibits dispensing without prescription.

Barnes Hind Pharmaceuticals, Inc
895 Kifer Road
Sunnyvale, California 94086



Allergic
Dermatoses

Contraindications: Hypersensitivity to hydroxyzine. Hydroxyzine, when administered to the pregnant mouse, rat, and rabbit, induced fetal abnormalities in the rat at doses substantially above the human therapeutic range. Clinical data in human beings are inadequate to establish safety in early pregnancy. Until such data are available, hydroxyzine is contraindicated in early pregnancy.

Precautions: Hydroxyzine may potentiate the action of central nervous system depressants such as meperidine and barbiturates. In conjunctive use, dosage for these drugs should be reduced. Because drowsiness may occur, patients should be cautioned against driving a car or operating dangerous machinery.

Adverse Reactions: Drowsiness may occur; if so, it is usually transitory and may disappear in a few days of continued therapy or upon dosage reduction. Dryness of the mouth may occur with higher doses. Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with higher than recommended dosage.

Supply: Tablets, containing 10 mg, 25 mg, or 50 mg hydroxyzine hydrochloride, 100's and 500's; Tablets, containing 100 mg, 100's; Syrup, containing 10 mg per teaspoonful (5 ml) and ethyl alcohol 0.5% v/v, pint bottles.

Before prescribing or administering, see package circular.

Once-a-day dosage DD

Fulvicin® P/G*

brand of griseofulvin [ultramicrosize], USP

(specially processed) **125 mg. tablets**

*"P/G" means a new polyethylene glycol system for enhanced absorption –

A 250 mg. daily dose (two 125 mg. tablets) of new FULVICIN P/G can replace 500 mg. of griseofulvin (microsize), USP. This is made possible by a special process in which the ultramicrosize griseofulvin crystals are partly dissolved in polyethylene glycol and dispersed through the tablet matrix for enhanced absorption.

Patient convenience –

FULVICIN P/G can be prescribed as two 125 mg. tablets once a day. Compliance is further assured by the easy-to-swallow size of the tablets.

Patient savings –

FULVICIN P/G is up to 35 per cent less expensive per dose than all microsize griseofulvin formulations.**

Schering

Fulvicin P/G

griseofulvin [ultramicrosize], USP

(specially processed) **125 mg. tablets**

Clinical Considerations: INDICATIONS FULVICIN P/G Tablets are indicated for the treatment of ringworm infections of the skin, hair, and nails, namely: tinea corporis, tinea pedis, tinea cruris, tinea barbae, tinea capitis, tinea unguium (onychomycosis) when caused by one or more of the following genera of fungi: *Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes, Trichophyton interdigitalis, Trichophyton verrucosum, Trichophyton megnini, Trichophyton gallinae, Trichophyton crateriform, Trichophyton sulphureum, Trichophyton schoenleini, Microsporum audouini, Microsporum canis, Microsporum gypseum,* and *Epidermophyton floccosum.* Note: Prior to therapy, the type of fungi responsible for the infection should be identified. The use of this drug is not justified in minor or trivial infections which will respond to topical agents alone. Griseofulvin is not effective in the following: Bacterial infections, Candidiasis (Moniliasis), Histoplasmosis, Actinomycosis, Sporotrichosis, Chromoblastomycosis, Coccidioidomycosis, North American Blastomycosis, Cryptococcosis (Torulosis), Tinea versicolor, and Nocardiosis. **CONTRAINDICATIONS** This drug is contraindicated in patients with porphyria, hepatocellular failure, and in individuals with a history of hypersensitivity to griseofulvin. **WARNINGS** *Prophylactic Usage:* Safety and efficacy of griseofulvin for prophylaxis of fungal infections have not been established. *Animal Toxicology:* Chronic feeding of griseofulvin, at levels ranging from 0.5-2.5% of the diet, resulted in the development of liver tumors in several strains of mice, particularly in males. Smaller particle sizes result in an enhanced effect. Lower oral dosage levels have not been tested. Subcutaneous administration of relatively small doses of griseofulvin once a week during the first three weeks of life has also been reported to induce hepatomata in mice. Although studies in other animal species have not yielded evidence of tumorogenicity, these studies were not of adequate design to form a basis for conclusions in this regard. In subacute toxicity studies, orally administered griseofulvin produced hepatocellular necrosis in mice, but this has not been seen in other species. Disturbances in porphyrin metabolism have been reported in griseofulvin-treated laboratory animals. Griseofulvin has been reported to have a colchicine-like effect on mitosis and cocarcinogenicity with methylcholanthrene in cutaneous tumor induction in laboratory animals. *Usage in Pregnancy:* The safety of this drug during pregnancy has not been established. *Animal Reproduction Studies:* It has been reported in the literature that griseofulvin was found to be embryotoxic and teratogenic on oral administration to pregnant rats. Pups with abnormalities have been reported in the litters of a few bitches treated with griseofulvin. Additional animal reproduction studies are in progress. Suppression of spermatogenesis has been reported to occur in rats, but investigation in man failed to confirm this. **PRECAUTIONS** Patients on prolonged therapy with any potent medication should be under close observation. Periodic monitoring of organ system function, including renal, hepatic, and hematopoietic, should be done. Since griseofulvin is derived from species of penicillin, the possibility of cross sensitivity with penicillin exists; however, known penicillin-sensitive patients have been treated without difficulty. Since a photosensitivity reaction is occasionally associated with griseofulvin therapy, patients should be warned to avoid exposure to intense natural or artificial sunlight. Should a photosensitivity reaction occur, lupus erythematosus may be aggravated. Griseofulvin decreases the activity of warfarin-type anticoagulants so that patients receiving these drugs concomitantly may require dosage adjustment of the anticoagulant during and after griseofulvin therapy. Barbiturates usually depress griseofulvin activity, and concomitant administration may require a dosage adjustment of the antifungal agent. **ADVERSE REACTIONS** When adverse reactions occur, they are most commonly of the hypersensitivity type, such as skin rashes, urticaria, and rarely, angioneurotic edema, and may necessitate withdrawal of therapy and appropriate countermeasures. Paresthesias of the hands and feet have been reported rarely after extended therapy. Other side effects reported occasionally are oral thrush, nausea, vomiting, epigastric distress, diarrhea, headache, fatigue, dizziness, insomnia, mental confusion, and impairment of performance of routine activities. Proteinuria and leukopenia have been reported rarely. Administration of the drug should be discontinued if granulocytopenia occurs. When rare, serious reactions occur with griseofulvin, they are usually associated with high dosages, long periods of therapy, or both.

INDICATIONS: For relief of inflammatory manifestations of corticosteroid-responsive dermatoses.

CONTRAINDICATIONS: Viral skin diseases, such as varicella and vaccinia; hypersensitivity to any component (not for ophthalmic use); when circulation is markedly impaired.

WARNINGS: Safety of use in pregnancy has not been absolutely established. Do not use extensively, in large amounts, or for prolonged periods of time in pregnant patients.

PRECAUTIONS: If irritation develops, discontinue use and institute appropriate therapy. In infections, use appropriate antifungal or antibacterial agents; if a favorable response does not occur promptly, discontinue the corticosteroid until the infection is adequately controlled. If extensive areas are treated or the occlusive technique is used, increased systemic absorption of the corticosteroid may occur; take suitable precautions.

ADVERSE REACTIONS: (local) Burning sensations, itching, irritation, dryness, folliculitis, secondary infection, skin atrophy, striae, hypertrichosis, acneform eruption and hypopigmentation.

ARISTOCORT A CREAM: Each gram contains 5 mg. (0.5%) of the highly active steroid, Triamcinolone Acetonide (a derivative of triamcinolone) in AQUATAIN, a specially formulated base composed of emulsifying wax NF, isopropyl palmitate, glycerin USP, sorbitol solution USP, lactic acid, 2% benzyl alcohol and purified water. AQUATAIN is non-staining, water-washable, paraben-free, spermaceti-free and has a light texture and consistency.

ARISTOCORT A OINTMENT: Each gram contains 5 mg. (0.5%) of the highly active steroid, Triamcinolone Acetonide (a derivative of triamcinolone) in a specially formulated base composed of emulsifying wax NF, white petrolatum, and propylene glycol.
